Preface

Since the first edition of the *Handbook of Spectroscopy*, there have been many fantastic developments in instrumentation and great research progress in spectroscopy. In addition, many new applications have been published. This second version of the *Handbook* therefore covers new fields of spectroscopy, provides an update on the status in the various fields, and includes an enlarged applications section; two further volumes have been added to accommodate this new information. However, although this second version of the *Handbook of Spectroscopy* is intended to serve as an authoritative reference source for a broad audience involved in the research, teaching, learning, and practice of spectroscopic technologies, it also takes into account that spectroscopy is defined as a science that deals with interaction between electromagnetic radiation and matter. This field of research has experienced a continuous growth as a result of innovations in methodologies and instrumentation, which offer opportunities for new applications and novel methods of analysis to solve common analytical problems and to address new challenges. Accordingly, research scientists, analytical scientists, environmental investigators, and industrial engineers who are often confronted with the ever-increasing complexity of real-life sample analysis, need a readily accessible source of information and an authoritative guidance on how best to apply currently available spectroscopic techniques to their particular fields of interest and to their specific applications.

Like the first edition, this second edition of the *Handbook of Spectroscopy* is designed to provide a straightforward introduction to spectroscopy, what this field can do, and how an investigator can use it effectively. The Handbook also provides a clear, integrated, and objective account of the wealth of information that can be derived from spectra. The sequence of chapters covers the range of the electromagnetic spectrum and the physical mechanisms involved, from rotation processes in molecules to phenomena in the nucleus.

Following the success of the first edition, the second edition of the Handbook is also not designed to be just another treatise on the theory of spectroscopy, but rather a practical day-to-day laboratory guide. It is intended to help the newcomer in the various fields of spectroscopy, and the academic level is based on the standard level of a graduate student in the physical or life sciences.

The Handbook represents the work of over ***60*** leading scientists and engineers in their field of research. The Handbook contains ***56*** chapters, which are grouped into ***15*** sections.

Seven sections cover the state-of-the-art practices in major fields of spectroscopy. The treatment of each field of spectroscopy presents the most up-to-date developments in methodologies, techniques, instrumentation, and data treatment. These sections are:

(I) Sample Preparation and Sample Pretreatment
(II) Methods 1: Optical Spectroscopy
(III) Methods 2: Nuclear Magnetic Resonance Spectroscopy
(IV) Methods 3: Mass Spectrometry
(V) Methods 4: Elemental Analysis
(VI) Methods 5: Surface Analysis
(VII) Methods 6: Spectroscopy in Nano Dimensions

Section VII has been added to cover also the growing interest in using spectroscopy in the nanosciences.

To enlarge the essential part of applications, further applications have been added. This application part comprises the following sections:

(VIII) Applications 1: Bioanalysis
(IX) Applications 2: Polymer Analysis
(X) Applications 3: Environmental Analysis
(XI) Applications 4: Process control
(XII) Applications 5: Spectroscopy at Surfaces
(XIII) Applications 6: Nano-Optics

Section XIV: Hyphenated Techniques and Section XV General Data Treatment has been updated.

The goal of this Handbook is to provide a comprehensive forum that integrates interdisciplinary research and development of interest to scientists, engineers, manufacturers, teachers, and students. The Handbook is designed to present, in a single source, the most recent advances in instrumentation and methods. Light has become an important diagnostic tool; therefore, the range of applications has been enlarged, and it is our hope that this Handbook will be a valuable companion to the practicing spectroscopist and will stimulate a greater appreciation of the usefulness, efficiency, and potential of spectroscopy.

Section I
Sample Preparation and Sample Pretreatment

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

1

Preparation of Liquid and Solid Samples

Brian M. Cullum and Tuan Vo-Dinh

1.1

Introduction

Sampling and sample preparation of liquids and solids often present significant challenges for real-world quantitative analyses using spectrometric techniques (e.g., UV–vis and infrared absorption, luminescence and Raman spectroscopies). Very often, the native form of a sample is unsuitable for analysis. This could be due to (i) the complex nature of the object, which could provide false measurements due to interferences or masking agents; (ii) the size of the object being too large to analyze in its entirety (e.g., laboratory sample of contaminated soil); or (iii) the awkward shape of the object, preventing it from fitting within the instrument in which the measurement is to be made. To overcome these problems, some sort of sample preparation must be performed. In many cases, sample preparation is required before any quantitative analysis, and both can have dramatic impacts on the measured results and their accuracy.

The previous chapter presented the main criteria to be followed for solid and liquid sample collection. This chapter presents a general overview of various methods for sample preparation. This general topic has been described extensively in a variety of research papers and review chapters in the literature [1–6], with specific variations for particular applications often being necessary. This chapter deals with the sample preparation required to provide a material suitable for spectrometric analysis.

1.2

Preparation of Samples for Analysis

1.2.1

Measurement Process

Samples collected for spectral analysis can generally be classified into three categories based on their state: (i) solids, (ii) liquids, and (iii) gases. Samples

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

are typically classified on the basis of their state as a method of providing an initial means of handling/treating them. A general flow diagram depicting the measurement process for various samples is shown in Figure 1.1.

1.2.2
Preparation of Samples for Analysis

Once a representative sample has been obtained from the object of interest, the next step is to prepare the sample for analysis. Since sample preparation depends upon both the analyte (e.g., iron in water, polycyclic aromatic compounds in benzene, etc.) and the instrumentation used to perform the spectroscopic measurement (e.g., UV–vis or IR absorption, luminescence, Raman, HPLC-fluorescence, GC–MS, etc.), details of the preparation process will vary from analysis to analysis. Many general procedures have been developed over the years for the preparation of various types of samples prior to analysis. Most of these procedures can be classified depending upon the type of samples that are to be analyzed, either solid or liquid. Within each of these categories exist several subcategories based upon the type of analyte to be measured.

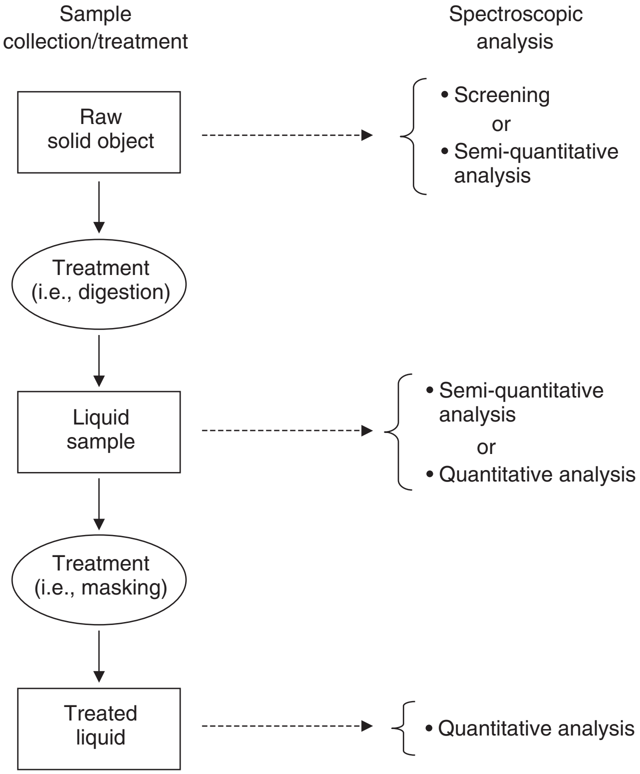

Figure 1.1 Schematic diagram depicting generalized sample preparation and analysis steps.

1.2.3
Solid Samples

The first of the two categories that we will discuss is solid samples. The various types of solid samples that are most often encountered have been discussed elsewhere in the sampling section of this chapter (i.e., powders, chunks, or cores). In the case of the latter two sample types (chunks and cores), the first preparation step involves grinding the larger pieces into a powder, which is much easier to deal with, and introduce it into the measuring instrument. The most common method for obtaining powders from these samples involves grinding a solid sample into a powder using either a mortar and pestle or a ball mill. Mortars typically come in two different types: the agate version (or ceramic) for relatively soft solid materials (e.g., large crystalline substances) that must be ground into a fine powder; or steel mortars, which are used for crushing much harder materials. In agate mortars, the material to be ground is placed in the depression of the mortar and then the sample is pressed down with the pestle in a rotating movement. When using agate or ceramic mortars and pestles, it is important to clean them thoroughly to avoid sample contamination. Less expensive mortars are typically softer and hence can be scratched more easily than more expensive ones. This is especially the case for ceramic mortars. Once scratched, they are much more difficult to clean, and may require the use of an abrasive or even a strong HCl solution. Steel mortars, also known as *percussion mortars*, have a hardened steel sleeve and pestle that fit snuggly into the mortar, and a hammer is then used to strike the pestle and subsequently crush the sample.

Another grinding tool that is often used to grind solid samples is the ball mill. A ball mill is a ceramic drum within which are placed the sample and many small balls made of hard ceramic. To grind the sample, the drum is rotated, producing a very fine powder. Ball mills are often used on softer solids, as the time taken for grinding is directly proportional to the hardness of the material. To ensure that none of the material that is being ground sticks to the walls of the mill during the grinding process, thereby producing larger pieces, the samples are typically dried to 100–110 °C prior to grinding to expel any water.

1.2.3.1 Sample Preparation for Inorganic Analysis

Most commercially available instruments for quantitative analyses in chemical and biological sciences are designed for the analysis of liquid samples. Because of this, solid samples that are to be analyzed are typically dissolved in a suitable solvent, usually following conversion to a powder by one of the previously described methods. The solvent chosen for this dissolution process may be either polar (e.g., water) or nonpolar (e.g., benzene) depending on the polarity and reactivity of the sample. In order to ensure that the entire analyte has been dissolved in the solution of interest, a solvent is chosen that can dissolve the entire solid sample (analyte as well as other materials). If the sample cannot be readily dissolved in these mild conditions, many other techniques are available for dissolution. As inorganic materials often present the greatest difficulty in dissolution, this section will deal primarily with these materials.

1.2.3.1.1 **Acid Digestion** Acid digestion of inorganic materials is a common alternative to the mild solvents used for dissolution, as described above. When using acids to digest metallic materials, great care should be taken not to change the speciation of the metal or metallic species to be analyzed. When analyzing a reduced state of a metal or metallic species, several nonoxidizing acids can be used. These include HF, HCl, HBr, H_3PO_4, dilute H_2SO_4, and dilute $HClO_4$. These acids dissolve most metals with negative reduction potentials. However, in some cases (i.e., aluminum), a protective oxide layer is formed that prevents the metal from being dissolved, which must be removed prior to dissolution. Substances that cannot be dissolved in the nonoxidizing acids described above are often soluble in the oxidizing acids: HNO_3, hot and concentrated H_2SO_4, and hot and concentrated $HClO_4$.

In most cases, the solubility of a metal dramatically increases by heating the acid. To improve the dissolution of samples in hot acids, a device often referred to as a *digestion bomb* has been developed. This device is comprised of a Teflon™-lined sample container that can be sealed and placed in a microwave oven for heating. An alternative to using the digestion bomb is to heat the acids in an open container, thereby allowing volatile species created during the reaction (e.g., H_2S, H_3BO_3, etc.) to escape. However, in rare cases, some metal halides (e.g., $SnCl_4$, $HgCl_2$, OsO_4, and RuO_4) are volatile and can escape as gases.

1.2.3.1.2 **Nonoxidizing Acids** HCl and HBr are typically used for the dissolution of most metals, oxides, sulfides, phosphates, and carbonates. HCl and HBr digestions are typically performed with a concentration of 37% and 48–65%, respectively. When using hot acids, HCl has a constant boiling composition of 20% at 109 °C, and HBr has a constant boiling composition of 48% at 124 °C. H_2SO_4 is an excellent solvent for most materials when used at its boiling point, which is 338 °C. The composition of H_2SO_4 for digestion purposes is typically 95–98%. Heating H_2SO_4 causes the sample to become dehydrated while dissolving the metals and, in addition, causes any organic material to become oxidized. To dissolve refractory oxides that are insoluble in other acids, hot H_3PO_4 can be used at a concentration of 85%. As the temperature of the acid is increased, it dehydrates. At temperatures above 150 °C, it becomes anhydrous; at temperatures greater than 200 °C, it dehydrates to pyrophosphoric acid; and, finally, at temperatures greater than 300 °C, it is converted to meta-phosphoric acid. A 50% HF solution is often used for the dissolution of silicates. Since glass is comprised primarily of silica, HF must be used in Teflon, silver, or platinum containers. At 112 °C, HF has a constant boiling composition of 38%.

1.2.3.1.3 **Oxidizing Acids** HNO_3 is capable of dissolving most metals, with the exception of gold and platinum. To dissolve these two metals, a 3 : 1 volumetric mixture of HCl and HNO_3 (also known as *aqua regia*) can be used. As described above, H_2SO_4 is typically considered a nonoxidizing acid with respect to metals; however, it provides a useful means of oxidizing organic material in the sample. When the organic material in the sample cannot be oxidized by either HNO_3 or H_2SO_4, a 60–72% solution of hot $HClO_4$ can be used. In either cold or dilute conditions, $HClO_4$ is not oxidizing. However, at high temperatures, $HClO_4$ becomes an explosive oxidizer. Because of this extreme oxidizing potential, it is important to evaporate and destroy as much organic material as possible with hot HNO_3 prior to using $HClO_4$.

It should be noted that mineral acids used to digest solid samples may contain a large number of metals in different concentration ranges (usually parts per million or subparts per million levels) themselves. This could provide a source of contamination, especially significant for trace analysis work. One way to account for this contamination source is to include a blank preparation with the digestion procedure. This involves exposing an extra beaker or flask, identical to the one containing the sample, to the same digestion treatment (added acids, thermal treatment, dilutions, etc.) to which the sample was exposed. The blank solution prepared this way will contain an approximately equal amount of contaminants introduced to the sample by the acid digestion.

1.2.3.1.4 **Fusion Reactions** Fusion is a process by which a finely powdered sample is mixed with 5–10 times its mass of inorganic material (flux) and heated in a platinum crucible to temperatures of 300–1200 °C, thereby melting the flux and the sample. While in the molten state, chemical reactions between the flux and the sample produce new species which are more soluble. After the sample has been thoroughly melted, the molten solution is allowed to cool slowly. During this cooling process, the crucible is swirled to create a thin layer of solidified material on the walls of the container. The newly solidified material is then dissolved in a dilute acid. Many different flux materials have been used over the years, with Na_2CO_3, $Li_2B_4O_7$, $LiBO_2$, $Na_2B_4O_7$, NaOH, KOH, Na_2O_2, $K_2S_2O_7$, B_2O_3, and a 2 : 1 mixture (w/w) of $Li_2B_4O_7$ and Li_2SO_4 being the most common. Fluxes are typically classified as acidic, basic, or amphoteric, with basic fluxes being best suited to dissolve acidic oxides of silicon and phosphorus and acidic fluxes being best suited to the dissolution of basic oxides, alkali metals, alkaline earths, lanthanides, and aluminum. The basic fluxes listed above include Na_2CO_3, $LiBO_2$, NaOH, KOH, and Na_2O_2. The acidic fluxes include $Li_2B_4O_7$, $K_2S_2O_7$, B_2O_3, and $Na_2B_4O_7$.

Na_2CO_3 is one of the most common fluxes, and is typically used for dissolving silicates (e.g., clays, rocks, minerals, glasses, etc.) as well as refractory oxides and insoluble sulfates and phosphates. To dissolve aluminosilicates, carbonates, and samples with high concentrations of basic oxides, $Li_2B_4O_7$, $LiBO_2$, or $Na_2B_4O_7$ is typically used. Analysis of both silicates and SiC-based materials can be performed using a flux of either NaOH or KOH. When using these two fluxes, however, frothing may occur in the absence of water. Therefore, best results are often achieved by first melting the flux and then adding the sample. It is also important to note that, when using NaOH and KOH as fluxes, either a gold or silver crucible should be used for the reaction. For silicates that cannot be dissolved using

Na_2CO_3, a more powerful oxidant such as Na_2O_2 can be used. This flux is good for dissolving iron and chromium alloys and should be used in a nickel crucible. Owing to the strong oxidizing and basic properties of Na_2O_2, the crucible used for this reaction should be coated with a thin layer of Na_2CO_3, which melts at a higher temperature than the peroxide and therefore protects the crucible. To dissolve refractory oxides and not silicates, $K_2S_2O_7$ is the flux of choice. $K_2S_2O_7$ is prepared by either heating $KHSO_4$ until all the water is driven off and all the foaming has stopped or decomposing $K_2S_2O_8$ with heat. B_2O_3 is a very useful flux for the dissolution of oxides and silicates. Its main advantage over the other fluxes listed previously is that the flux can be removed from the crucible completely, following reaction with the sample, as a volatile methyl borate, by simply washing several times with HCl in methanol. For relatively fast dissolution of refractory silicates and oxides (10–20 min at 1000 °C), a 2 : 1 mixture (w/w) of $Li_2B_4O_7$ and Li_2SO_4 works well. One gram of this flux can dissolve 0.1 g of sample, and the resulting material can be easily dissolved in hot HCl. While fusion has proven to be a necessary method for the dissolution of many compounds, it should be used only as a last resort, because of the possibility of introducing impurities into the sample as well as being a very time-consuming process.

1.2.3.2 **Decomposition of Organics**

1.2.3.2.1 **Ashing** When elemental analysis of an organic sample or quantitative analysis of inorganic species complexed with organic species is desired, the first step of the process is to decompose the organic material. This process of decomposition of organic matter is often termed *ashing*. Ashing is typically subdivided into two different categories: those processes that do not require the use of a liquid, that is, dry ashing; and those processes that rely on liquids for the decomposition, that is, wet ashing. Fusion can be used as a type of ashing, with the most common fluxes used in these processes being Na_2O_2 and alkali metals, but the simplest and most common form of dry ashing is via combustion. In this procedure, the organic material is burned in a stream of oxygen gas, with catalysts added for more complete combustion. The released CO_2 and H_2O are then trapped and analyzed quantitatively. Variations of this procedure are also used to perform quantitative analyses of nitrogen, sulfur, and halogens in organic matter.

Wet ashing methods have existed for over several hundred years. One such method, which has been used since 1883, is known as the *Kjeldahl procedure*. This procedure is one of the most accurate and widely applicable methods for determining the nitrogen composition of organic matter. The first step in this procedure is to digest the organic matter in boiling H_2SO_4, which converts the nitrogen atoms in the sample to NH_4^+ while oxidizing other elements such as carbon and hydrogen. To speed up the process, K_2SO_4 can be added, which increases the boiling point of the H_2SO_4 to 338 °C.

Another common procedure that has been developed is known as the *Carius method*. This procedure, which involves the digestion of organics in fuming HNO_3, is carried out in a heavy-walled, sealed glass container that is heated to 200–300 °C.

A very powerful technique that can be widely applied to the decomposition of organic matter is refluxing the sample in a mixture of HNO_3 and $HClO_4$. However, perchloric acid is a strong explosive, and great care should be taken by the experimentalist to shield himself/herself from the digestion process. In this procedure, the sample is first heated in boiling HNO_3, and the solution is then evaporated until almost dry. This process is repeated several times to remove any easily oxidized material that might explode in the presence of $HClO_4$. The sample is then collected and the process repeated with $HClO_4$.

One of the fastest and easiest methods of wet ashing organic matter involves the use of a Teflon-lined digestion bomb (described earlier in the section on dissolution) and a microwave oven for heating. While many different procedures have been developed for various analyses, they all generally involve the addition of the sample and a liquid into the digestion bomb, which is then placed in the microwave oven and heated. An example of such a procedure is the decomposition of animal tissue using a 1 : 1 mixture of HNO_3 and H_2SO_4 and heating it in a microwave oven for 1 min. Another example is a modified version of the Kjeldahl reaction in which H_2SO_4 and H_2O_2 are mixed in a Teflon-lined bomb and heated, thereby reducing the digestion time to approximately 15 min.

In contrast to these wet ashing procedures that rely on concentrated acids, a mild form of wet ashing has also been developed. This procedure uses hydroxyl radicals that are produced using Fenton's reagent, a combination of H_2O_2 and $Fe(NH_4)_2(SO_4)_2$, to oxidize the organic materials. The mixture is then heated to 50 °C with the organic material present, allowing the radicals to oxidize the sample (Table 1.1).

Table 1.1 Various sample preparation methods for solid samples.

Dissolution of solids

Acid digestion
- Nonoxidizing acids
  - HF, HCl, HBr, H_3PO_4, dilute H_2SO_4, dilute $HClO_4$
- Oxidizing acids
  - HNO_3, hot and concentrated H_2SO_4, hot and concentrated $HClO_4$

Fusion reactions
- Basic fluxes
  - Na_2CO_3, $LiBO_2$, NaOH, KOH, Na_2O_2
- Acidic fluxes
  - $Li_2B_4O_7$, $K_2S_2O_7$, B_2O_3, $Na_2B_4O_7$

Decomposition of organics

Ashing methods
- Dry ashing
  - Combustion in O_2, and fusion with Na_2O_2 or alkali metals
- Wet ashing reagents
  - Hot H_2SO_4, fuming HNO_3, $HClO_4$, hydroxyl radicals (H_2O_2 and $Fe(NH_4)_2(SO_4)_2$)

1.2.4
Liquid Samples

1.2.4.1 Extraction/Separation and Preconcentration

Once a liquid sample has been obtained, either from an original liquid object or from the dissolution of a solid object, the various species of interest must be isolated for analysis. In the case of a liquid suspension, filtration or centrifugation is often performed prior to analysis to remove any solid particles. In the case of a solution, there are many methods available for isolating analytes, including complexation, separation, or extraction. These procedures are performed prior to analysis, for many reasons. Most often, these procedures are performed either to remove any species that may cause interferences in the particular analysis or to provide a means of concentrating the analyte prior to analysis.

1.2.4.1.1 **Extraction** Extraction has historically been one of the most common means of isolating a particular species from a solution. Several different types of extraction are commonly used for analyte isolation, including liquid/liquid extraction and solid-phase extraction. In any extraction procedure, the isolation of particular components is based upon the affinity of the particular species for two different phases. In liquid/liquid extractions, the two phases are both liquid and are immiscible in each other (e.g., an aqueous phase and an organic phase), creating two layers with a distinct boundary. The affinity of the various components within the sample for each of the two layers is used to separate them. The distribution of the analyte or solute between the two different phases is described as the partition coefficient (the ratio of the solute's concentration in one solvent to its concentration in the second). Therefore, the ideal extraction would happen with either a very large or a very small partition coefficient. When this is not the case, and the solute is only slightly more soluble in one solvent than the other, multiple extractions may have to be performed to remove most of the solute. In addition, as this extraction is based on fractional partitioning of the solute, it is impossible to extract 100% into any one phase. Therefore, to determine the amount of analyte that has been extracted, one needs to keep track of the number of extractions that were performed and the partition coefficient of the process.

Another type of extraction commonly used on liquid samples is based upon the partitioning of an analyte between the liquid in which it is dissolved and a solid support. Such extractions are typically based upon adsorption of the solute onto the solid. An example of such an extraction is in the adsorption of hydrocarbons in an aqueous solution onto activated charcoal. This process has long been used in such areas as pollution control (e.g., oil spills in water) and much more recently is beginning to be implemented more in trace analysis procedures as a technique called *solid-phase microextraction*. The main disadvantage of extraction techniques is typically the time that is required to recover most of the solute. Because of this problem, extraction in quantitative analyses is typically performed as a last choice.

1.2.4.1.2 **Complexation** To increase the specificity of a particular analysis, it is often necessary to remove components from the solution that could produce erroneous results. One means of performing this task is through complexation reactions. One such procedure, known as *masking*, involves the complexation of an interfering species with a chelating agent. The reaction between the two species forms a stable complex which cannot undergo certain chemical reactions that are essential for quantification of the analyte. Therefore, by complexing possible interferents, a more selective measurement can be obtained. Another form of complexation that is often employed for the removal of interferences is precipitation. In precipitation reactions, an insoluble complex is selectively formed with either the interfering species or the analyte itself. Once the precipitate is formed, it can be removed and discarded in the case of an interfering species or analyzed in the case of the analyte. Complexation reactions typically involve elaborate procedures, and depend upon many parameters such as the chemical composition of the solution, its pH, and the temperature. When these factors are considered, complexation procedures can provide excellent results. For example, uranium can be isolated from associated metals in solution with the addition of carbonates. Carbonates form a soluble complex with uranium, while most other metals form insoluble carbonate of hydroxide precipitates. The complexation of a particular species is dependent on the chemical equilibria of the various species involved. Table 1.2 provides a general list of the most common complexing agents and the species with which they react.

Using Table 1.2 and the particular formation constants and solubility constants of the involved species, at the correct pHs and temperatures, determination of the best complexing agents for a liquid sample should be possible. In the case where two agents form complexes with the same elements, the particular solution parameters (e.g., pH) should be used to determine which is the most suitable. For

Table 1.2 Common masking agents.

Masking agent	Ions of elements complexed
1. Carbonate	Be, Th, U
2. Citrates and tartrates	Be, Mg, Ca, Sc, Ti, Cr, Mn, Fe, Ga, Sr, Y, Zr, Nb, Mo, In, Sb, Ba, La, Hf, Ta, W, Re, Tl, Pb, Bi, Ce, Th, U
3. Cyanide and amine	Co, Ni, Cu, Zn, Ru, Rh, Pd, Ag, Cd, Os, Ir, Pt, Au, Hg
4. EDTA	Mg, Al, Ca, Sc, Mn, Fe, Co, Ni, Cu, Zn, Ga, Sr, Y, Cd, In, acetic Ba, La, Pb, Bi, Ce, Th
5. Fluoro (F^-) agents	B, Al, Si, Ti, Zr, Nb, Mo, Hf, Ta, W
6. Halides (Cl^-, Br^-, I^-)	Ge, As, Ru, Rh, Pd, Cd, Sn, Os, Ir, Pt, Au, Hg, Tl
7. Oxalate	V, Cr, Fe, Co, Ni, Ge, In, Re, Tl, Bi
8. Oxo and hydride	Be, B, Al, P, V, Cr, Mn, Zn, Ga, Ge, As, Se, Mo, Ru, Sn, Sb, Te, W, Re, Os, Pb
9. Peroxo agents	Ti, V, Zr, Nb, Hf, Ta, U
10. Sulfide	As, Sn, Sb

EDTA, ethylenediaminetetraacetic acid.

instance, citrates usually form more stable complexes in acidic solutions, whereas tartrates are typically more stable in alkaline solutions.

1.2.4.2 Chromatographic Separation

With continued developments in chromatographic columns and equipment, separation of various analytes from a sample via chromatography has become the most common pretreatment to complex liquid samples [7]. The combination of chromatography and spectroscopy is described in detail later in the chapter on Hyphenated Techniques in this Handbook. This section only provides a brief discussion of the separation methods used in sample treatment prior to spectrochemical analysis. As with solid extraction procedures, chromatographic separation is based upon the partitioning of the various solutes between two different phases, namely a liquid phase and a solid phase. However, unlike extractions, the two different phases are not separated to allow removal of the component of interest. Instead, the liquid containing the solute is flowed across the solid phase, and the partitioning of the various components in the liquid between the two phases causes them to be retained temporarily and eluted from the solid matrix at different times. The time of elution from the solid matrix, or the retention time, is determined by the partitioning coefficient of the particular component between the solid and the liquid. Many chromatographic techniques exist for separating various solutes in liquids. These techniques are generally classified by the types of interactions that occur between the analytes and the solid phase, or matrix. These categories include (i) adsorption, (ii) ion exchange, (iii) partition, (iv) thin layer, and (v) size exclusion. In adsorption chromatography, the separation is based upon the polarity of the solid matrix and the solutes. Solid matrices for adsorption chromatography can include alumina, charcoal, clay, diatomaceous earth, silica, silica gels, cellulose, or starch, which are packed into a glass column. In the case of alumina, which is a polar matrix, the sample would be flowed down the column, with the nonpolar solutes eluting first and the polar solutes eluting later because of their stronger interactions with the matrix.

Ion-exchange chromatography is similar to adsorption chromatography, with the exception that elution of the various components is based upon the affinity of ions for the solid matrix. The solid support matrix for such separations is some form of ion-exchange resin, depending upon the materials to be separated. The mobile, or liquid phase, in ion-exchange chromatography is generally an aqueous solution. Ion-exchange chromatography is used to separate solute molecules based upon their charge. Under optimum conditions, ions of equal charge, such as the alkali metals, can even be separated in an ion-exchange column. In particular separations, the effectiveness of ion-exchange chromatography can be enhanced by the addition of chelating agents to the mobile phase, thus reducing the ionic interactions of particular species and making them elute earlier in time.

The third type of liquid chromatography, partition chromatography, is performed by placing the sample on a column of solid support that has been impregnated with a liquid. The sample is then flowed down the column, with a second liquid as the mobile phase and immiscible in the liquid used to moisten the column. Therefore, as the sample flows down the column, the various components are partitioned between the solid and liquid phases based upon their solubility in the two solvents, and thus elute at different times.

Thin-layer chromatography is performed using a glass plate that has been evenly coated with an absorbent such as alumina or silica gel. To ensure binding of the adsorbent to the glass, starch, plaster of paris, collodion, or a plastic dispersion is often added. The coated plates are then dried in an oven prior to use. Once dried, the sample is spotted on one end of the plate, which is then placed in a dish containing a solvent. The solvent then travels up the plate via capillary action, and the various components in the sample travel at a different rates and therefore different distances during a specific time depending upon their solubility in the solvent. Therefore, by changing the solvent used, the separation of the components can be varied until the particular analyte of interest is separated out from other components.

Another form of liquid chromatography that can be used for separation of components in a solution is known as *size-exclusion chromatography*. In this technique, the solid matrix, which has well defined pore sizes, is placed in a column through which the liquid sample is flowed. The size of the pores varies from matrix to matrix, and it is these pore sizes that are used to separate the compounds. As the components travel down the column, their elution times are based upon their size, with the larger unretained species eluting first and the smaller species being held up in the pores and eluting later. This technique typically works best for larger molecules such as biomolecules or polymers.

Another more recently developed means of separating components in a solution is known as *electrophoresis*. This technique is used for the separation of components based upon their ability to travel in an electric field. Many different matrices have been used for electrophoretic separations, including buffered solutions and gels (e.g., agarose gel). Gel electrophoresis has been used extensively for the separation of biomolecules; however, it is often slow and irreproducible. A faster and more reliable form of electrophoretic separation is known as *capillary electrophoresis*. In this technique, a buffer-filled capillary is used to span the distance between two containers of the same buffer solution. A potential of 20–30 kV is typically applied between the two containers, and a small amount of sample is injected into the capillary. The individual components of the sample are then separated, which is based on the combination of their overall charge and their friction within the solvent. The individual components can then either be collected or detected upon elution from the column.

Liquid and Solid Sample Collection

Paolo de Zorzi

2.1
Introduction

A variety of terms are used in the practice of sampling. However, many terms identify a specific (single) operation, and, in some cases, different terms are used to describe the same concept. Furthermore, it is quite usual in the scientific literature for different authors use different terms to describe the same operation or concept. Also, in works produced by standardization bodies, it is possible to find different terms for sampling operations as well as for the definition of sampling strategy. Depending on the matrix of interest, the definition related to the same term may be slightly different. The International Union of Pure and Applied Chemistry (IUPAC) recommendations, ''Nomenclature for sampling in analytical chemistry,'' published in 1990 [1], and the ISO standard 11074:2005 [2], are the most widely used terminology documents related to soil sampling. The IUPAC Recommendations ''Terminology in soil sampling'' [3] recently updated the terminology on soil sampling, which may be partly applicable for solid sampling. The IUPAC defines a sample as a portion of material selected from a larger quantity of material and sample preparation as the set of material conditions that may be necessary to transform an aggregate or bulk sample into a laboratory or test sample. With reference to liquid sampling, ISO standard 6107-2 ''Water quality-Vocabulary-Part 2'' [4] reports a different definition for the term *sample* as the portion, ideally representative, removed from a specified body of water, either discretely or continuously, for the purpose of examination of various defined characteristics. Therefore, it is important that, within a stated context, the terms used are intended by all in the same precise way, without any possible ambiguity.

A correct sampling requires, before starting, a plan of the activity based on clear objectives (general and specific) prepared by the person responsible of the whole process (sampling and measurement). Historically, the sampler, defined as the person or group of persons carrying out the sampling procedures, operates separately from the one responsible of the measurement. The latter knows exactly what the purposes of the measurement are, the quality of the data to be assured, and all aspects that may interfere (chemically, biologically, or simply operatively)

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

in the instrumental analysis. But on the other hand, the sampler should have the competence to perform the sampling in different contexts, know the criteria to be followed to implement a suitable sampling strategy and technique, and be aware of the factors potentially influencing the sample collection as well as the quality of the sample, including also aspects such as health and safety.

When the measurement result is used to assess the properties of a large batch of materials (be solid or liquid), such as from a contaminated soil area or a wide water basin (from which the samples analyzed are collected and prepared), the measurement process includes sampling. In this case, sampling, sample preparation (physical and chemical), and instrumental analysis can influence measurement results and their reliability. In this case, it is necessary to establish a good communication between the analytical scientist and the sampler in all phases of the measurement process.

However, a third party must be considered in the process: the ‘‘end user.’’ A measurement may be requested by many different subjects, such as a private individual (e.g., owner of a factory monitoring the industrial process), or by a public authority (e.g., responsible for controlling or authorizing a wastewater discharge), or maybe by the analytical scientist himself interested in studying the behavior (in time or space) of the property of interest in the environment. All of them will take decisions or will make evaluations on the basis of the measurement results that are unavoidably affected by the quality of the samples collected.

This chapter presents an overview of the sampling process, focusing on the collection of solid and liquid materials and on the implementation of quality assurance (QA)/quality control (QC) procedures for sampling.

2.2
Sampling Process

A typical sampling process, designed by Ramsey and Ellison [5] and shown in Figure 2.1, requires the definition of the measurand, that is, the quantity intended to be measured [6], before any other subsequent step. With reference to sampling, this means a clear statement about the following:

- the sampling target (the portion of material, at a particular time, that the sample is intended to represent [5]);
- the matrix to be sampled;
- the quantity (property of a phenomenon, body, or substances, where the property has a magnitude that can be expressed as a number and a reference [6]).

The critical definition of the sampling target may be given by a regulator body or by the experience and competence of the interested parties. For example, in the case of solid sampling, the measurand may be the hydrocarbon mass fraction (on dry mass basis), determined by infrared spectroscopy and expressed in milligram per kilogram, within a batch of 5000 kg of, say, contaminated soil; whereas, for a liquid sample, a measurand may be the copper mass concentration, determined by

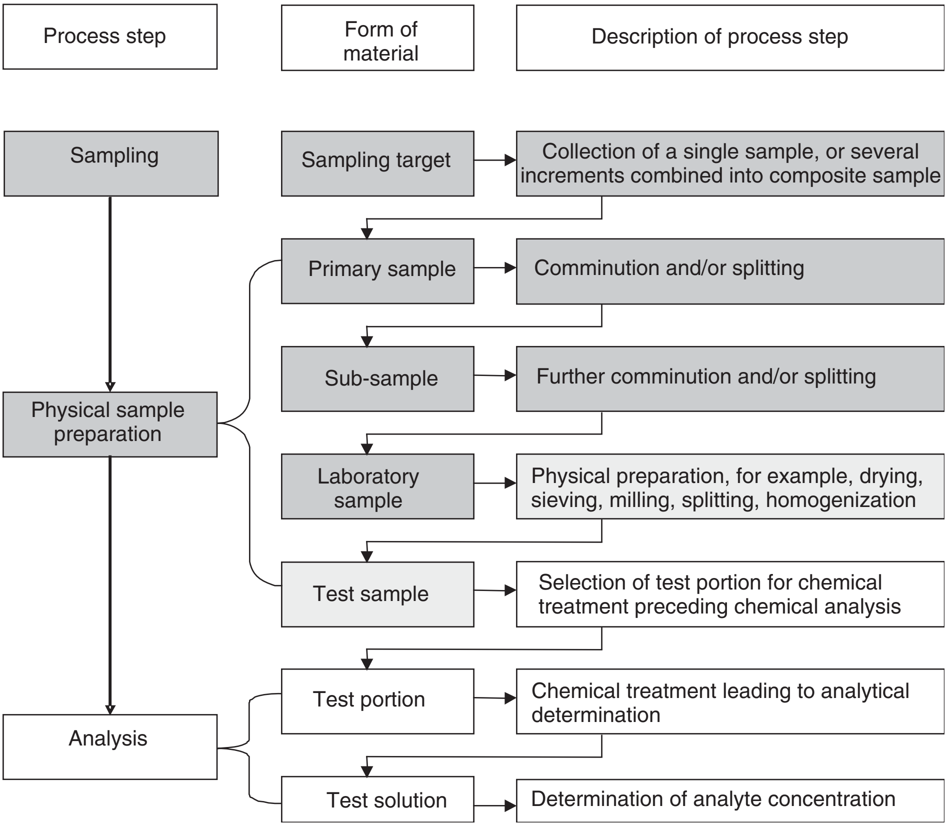

Figure 2.1 Schematic outline of the measurement process including sampling. (Scheme taken from 5.)

inductively coupled plasma mass spectrometry (ICP-MS) expressed as microgram per liter, within a batch of 10 000 l of, say, wine. The measurement results and the associated uncertainty (including the contribution arising from sampling) will be referred to the sampling target defined. In both the cases mentioned above, the final objective of the analyst is to measure the quantity of a substance contained in the test portion of few milligrams or aliquot of few microliters representing the whole batch from which it has been collected and then prepared.

The first operative step of sampling is the collection of samples at the sampling target. Depending on the objective stated in the sampling plan and on the sampling strategy chosen, the sampler will collect the primary samples as a single sample or composite samples (obtained pooling several increments). The size of the primary samples, in terms of volume and/or mass, and the overall amount of primary samples collected are parts of the strategy driving the sampling activity.

Commonly, it will be required to reduce the size (mass/volume) of the primary sample and, for the solid samples, its particle size, in order to obtain the laboratory sample. The operator may comminute the sample (reducing the particle size), mix, homogenize, split, and/or quarter in order to reduce the volume and the mass of the primary sample. All these operations, commonly carried out at the site and in different hierarchical order, produce subsamples till obtaining a laboratory sample of suitable size. The laboratory sample is delivered to the laboratory and stored under suitable conditions previously fixed.

The physical sample preparation, including some of the operations already carried out at the site, continues at the laboratory in order to obtain a test sample from which the final test portion or aliquot is taken. The general aim of the operation carried out in the laboratory is to condition a sample to a state that will allow subsequent analysis or long-term storage.

2.3
Sampling Strategy and Collection

The definition of the sampling strategy is aimed at giving possible answers to specific questions such as the type and the number of samples to be collected, the size of the sample, the sampling techniques, the pattern to apply, and the selection of the sampling points. In general, the sampling strategies consider patterns falling into the following four categories with possible variations depending on the situation encountered:

- random sampling
- systematic sampling
- stratified random sampling
- judgmental sampling.

The first three sampling patterns belong to the common class of probabilistic sampling, that is, based on the principle that each element of a (statistical) population intended to be assessed has an equal chance to be selected. In random sampling, the selection of the sampling point is done independent of other sampling points. Stratified random sampling is based on the principle that the sampling target is better represented by strata in which the property of interest (e.g., the trace element content) is supposed to be homogeneously distributed. The strata are randomly sampled. The systematic method is based on sampling performed by some logical and organized way which means collecting samples, for example, at regular temporal intervals or spatial distances. The two ways of applying systematic sampling are referred to properties of a population that vary in space or change over time within the sampling target. The fourth category is represented by the judgmental sampling. In some cases, the specific knowledge of the sampling target, combined with expert and professional judgment of the sampler, allows the application of this strategy which is not based on probabilistic assumptions.

The different strategies have to be applied properly, considering the objectives given. Commonly, the measurement results obtained by analyzing the samples collected are subjected to statistical assessment (e.g., statistical distribution, mean, median, variance, etc.). To this end, all the probabilistic sampling strategies are suitable, while any statistical assessment is applicable using judgmental sampling. Other criteria must be followed in the selection of the most suitable strategy: the budget available to perform the sampling and the subsequent measurements; the time needed to collect the samples; the need to obtain information about the variability of the property of interest (over space or time) in the sampling target (or even more in each stratum in the case of stratified sampling); the request of specific quality objectives for sampling; and the possibility to modify easily the sampling design.

Type of samples. Each measurement process (including sampling), based on a stated sampling strategy, is characterized by the constitution of different types of samples. The related terms and typology reflect the stage of the sampling process.

The main classes are

1) Primary sample – increment – single sample;
2) Composite sample;
3) Subsample;
4) Laboratory sample;
5) Test sample or test portion.

The primary sample is related to one or more increments or units initially taken for a population and refers to the first stage of the sampling process. When more increments are pooled together, a composite sample is obtained. IUPAC [3] defines the composite sample as the collection of more increments/subsamples mixed together in appropriate portions, either discretely or continuously, from which the average value of a desired characteristic may be obtained. Composite samples might be of both large and small size (it depends on the increments) and they are normally split and/or comminuted to obtain subsamples. The choice of collecting composite samples is useful when detailed information about the distribution of the property (in space and time) are not of interest; otherwise, it is necessary to collect and process single samples. With certain limitation, composite samples are useful to increase the amount of material available for the analyses if the limit of detection of the method is an issue. The compositing is considered also the way by which it is possible to reduce the analytical costs, reducing the number of single samples to be measured; for this reason, this approach is commonly appreciated. A sampling target may be characterized by analyzing five single samples and averaging the measurement results. A similar result may be obtained by pooling the five single samples (increments) into one composite sample to be homogenized, processed, and then analyzed once. In the first case, information about the heterogeneity (variance) of the sampling target is known; in the second one, such information, together with information on possible contamination due to a specific increment, is not available. Subsamples obtained from the primary samples (composite or single) are obtained, by definition, from a population. They may be formed using the same method applied for forming the primary sample or by using appropriate devices aimed at reducing the sample size (mass, volume, etc.). The sample sent to the laboratory and intended for inspection or testing is the laboratory sample. It may be directly a primary sample or the result of an *in situ* sample preparation from a primary sample. For example, within the context of the environmental analysis, typical laboratory samples may be

- 1 l of groundwater bottle potentially contaminated by polychlorinated biphenyls (PCBs);
- grams of soil contaminated by trace elements;
- kilograms of vegetation harvested containing unknown activity concentration of radionuclides.

The test sample is prepared from the laboratory sample. The test portion is formed for testing or analysis. Test sample represents the last stage of sampling, even though it is obtained within the laboratory, and may be considered the ‘‘object of desire’’ for the analyst who is not interested in sampling.

2.3.1
Liquid Sampling

Regardless the context in which the sampler has to operate (environment, food, industry, etc.), liquid sampling means having to deal with at least three different categories of materials:

- homogeneous solutions
- liquids in a flowing sample
- immiscible mixtures.

Homogeneous solutions (or reasonably considered homogeneous with reference to the property of interest) are the simplest type of liquids to be collected. For example, a sampling target represented by a basin of water solution, containing anions and cations, may be sampled by taking few single samples from any point of the basin to represent the whole sampling target. However, this is only a general consideration. In the real world, such as in environmental sampling, a typical situation of water sampling may be from a lake or a reservoir. As the water may be considered a homogeneous system, the water column, at different depths or positions, constantly shows relevant variability in composition. In these cases, it might be necessary to collect single samples at different depths (stratum) and maintain them separately if one is looking at the variability of the concentrations with depth, or to collect composite samples if looking at the mean value along the whole water column.

The second category of liquid that is often encountered is a flowing sample that is constantly changing (e.g., a polluted river, a process stream at a plant, etc.). The material to be sampled may vary over a given time period, both in terms of flow rate and/or quality (e.g., mass concentration of the property to be measured). To account for this constantly changing composition of the sampling target, increments of the same size (volume) can be taken at regular time intervals (time-weighted sampling). In some cases, when the flow of a stream varies with time, is useful to apply a flow-weighted sampling: (i) increments of different volume depending on the flow and collected at regular intervals and (ii) increments of the same volume collected at irregular time intervals depending on the flow.

For all these types of sampling, manual systems are widely used but sometimes they may not be cost effective. In most cases (e.g., monitoring the discharge at a manufacturing facility), a large number of primary samples must be taken over an extended period, such as sampling once every hour through the day, and manual sampling is not practical or impossible. For these reasons, automatic samplers are commonly considered the most suitable systems. A wide variety of automatic sampling equipment are today available with different designs and accessories, depending on the sampling purposes, which are able to be programed and operated without the constant control of the operator. The use of an automatic sampler, however, does not solve all the problems. The correct application of the automatic procedures, with respect to the sampling objectives, needs always skilled and experienced operators and a planned sampling strategy fitting the purposes. Moreover, with the advent of faster and more sensitive detectors and analysis systems, the possibility of real-time analyses being performed on samples has dramatically improved. To obtain samples for such analyses, short bypasses are often introduced into flow lines. These can divert a small amount of the total liquid into the particular instrument being used for analysis (e.g., spectrophotometers, etc.). When such bypasses are inserted into the overall flow of the reaction process, it is important to ensure that they do not change the flow of the original system, possibly skewing the sample that is being analyzed [7].

The last type of liquid specimen that can be encountered in the real world is an immiscible mixture (e.g., a mixture of organic compounds or lubricants and water). In such cases, the sampler must take into account the evident differences in the layer composition and in the proportion between the two phases. The strategy may require the collection of single increments from each layer and the subsequent constitution of composite samples. Subsampling of the primary samples (composite), if needed, may require a preliminary homogenization in order to minimize any loss of representativeness.

Owing to the chemically dynamic state of the samples collected, the preservation and the storage conditions present a critical issue. An incorrect application of the fundamental principles aimed at preserving the sample's integrity/stability over the time will nullify any subsequent measurement and assessment about the property investigated. Any decision taken on the basis of measurement results obtained by analyzing an incorrect sample will be misleading. Hopefully, this issue will be always tackled by the responsible analyst, together with the responsible sampling that is involved in the first stage after the sample collection. The main elements to be taken into accounts are

- the property of interest (e.g., trace element, organic substances)
- the suitability of the containers
- preservatives
- storage condition (temperature, light, time).

The analytical method will guide the sampler in the correct selection of the containers. The volume capacity should be appropriate to perform all the measurements requested (independent replicates commonly are necessary), and there may be differences between volumes sampled for inorganic and organic analyses. The latter, for example, not only in the case of very low mass concentration, may require laboratory samples higher than 1 l in order to apply the extraction phase needed. In this phase, the aspects to be considered are as follows:

- reducing the contamination of the container (including the cap) due to the release of inorganic interferences from the glass or organic and trace elements (metals) from plastics;
- the chance to clean easily the inner surface (decontamination);
- biological and chemical inactivity of the container to prevent cross-contamination between sample and container;
- avoiding adsorption phenomena with the container surface (e.g., metals are easily adsorbed on glass surfaces, whereas organics, such as oils or pesticides, are likely adsorbed on to the sides of plastic containers);
- shock resistance;
- ease in opening and closing.

Most of the above-mentioned aspects may be solved by using inert containers in Teflon and or glass for the organics. Inert plastic containers are used for storing liquids for inorganic analyses. The use of suitable preservatives (e.g., adding nitric acid until a pH less than 2 to a sample to be analyzed for trace inorganic element content) allows the prevention of chemical degradation of the sample collected before the analyses and increase the time within which the analysis may be carried out. Containers with dark colored walls could minimize the photodegradation of samples. Recommendations about the correct combination containers and the property of interest are commonly listed in the ISO standard related to the preservation and handling conditions (e.g., ISO 5667-3 [8]).

2.3.2
Solid Sampling

The way to perform the sampling of solid material is strongly dependent on the heterogeneity of the material itself. Homogeneity, even of the finest powder observed, is an illusion, and heterogeneity is considered the only state in which a set of material units (fragments) can be observed in practice [9]. Nevertheless, the measurand, as already reported, will allow the sampler to select the best sampling technique and sample preservation methods. The knowledge about the behavior of the property of interest in respect of the matrix sampled is mandatory to reduce the risk of biased samples. For example, a trace element (such as a metal) is uniformly associated with fine particles of a soil (e.g., silt), or an organic substance (such as hydrocarbons) may be distributed on the surface of solid fractions (e.g., above 1 cm). In these cases, the sampler must operate appropriately, and avoid discarding the fractions of interest and thus losing important information about the composition of the whole sampling target from which the sample was collected.

The general criteria to be followed in solid sampling must be stated in the sampling strategy. Variability of a property over time and space (also three dimensional) requires that single samples are collected in different sampling points or at different times and analyzed separately. Statistical analyses (classical statistics and/or kriging interpolation) allow the assessment of such spatial and temporal variability. In other cases, compositing several increments (e.g., in waste pile analyses, product lot characterization, or food analyses) may be the most appropriate method; the average composition of the sampling target, possibly highly heterogeneous, is known and the variance effects between the increments collected is minimized. In any case, depending on the objectives of the measurements and the specific context investigated, it is possible to combine single samples and composite samples. To assess the variability of a property on a large scale, ruling out small space/time variability of the sampling target, the constitution of several composites samples and polling increments collected at short time/distance may be pursued.

The sampling techniques and devices differ from one sampled material to another, reflecting their different characteristics. A wide set of corers, augers (hand and motor-powered), scoops and spatulas, and other devices are available on the market to sample under different conditions. The devices are designed (shape, dimension, material, etc.) in order to respond to the different problems to be solved.

Solid materials may be sampled to determine the content of both inorganic elements and organic substances. Their behavior will force the sampler to adopt any cautions and procedures that may reduce the risk of an artificial change in the composition of the sample collected till its analysis. As in the case of liquid samples, even solid samples are affected by degradation phenomena (biological and chemical). Once the primary (solid) sample has been obtained, it is important to select the appropriate container for its storage. For example, in environmental analysis, trace elements (metals) are quite stable within the matrix, and plastic containers are suitable for storage. Organic substances, because of adsorption phenomena, commonly require the use glass containers with inert caps (such as Teflon) and dark containers to prevent the risk of photodegradation (e.g., dioxins). For other samples of different composition and reactivity, various other precautions should be observed during storage to ensure that the sample does not change from its original composition.

2.4
QA/QC in Sampling

It is commonly accepted that an analytical laboratory aimed at obtaining reliable measurements results and comparable all over the world and at maintaining the measurement system under statistical control has to implement quality assurance/quality control procedures. These include the validation of measurement methods, routine internal QC procedures, and independent external QC procedures. The importance of QA/QC in sampling activity, mainly when it is considered part of the overall measurement process, is also recognized now. Whatever the objectives of the sampling, it is recommended to apply sampling procedures validated and follow sampling quality control procedures. Validation allows the evaluation of the sampling quality under stated (routine) conditions and provides an estimation of the contribution of sampling to the measurement uncertainty (including the analysis). In 2005, with reference to the quality management system practices, the ISO/IEC standard 17025 [10] on the competence of testing laboratories reported sampling as a factor to be considered in the total uncertainty of measurement. In 2007, the Eurachem/CITAC (The Cooperation on International Traceability in Analytical Chemistry) Guide on measurement uncertainty arising from sampling [5] provided a guide to the methods and approaches for the estimation of the contribution of sampling (and sample preparation) to the requested measurement uncertainty, as an independent component from the analytical uncertainty. Through the application of the proposed approaches to tackle this issue, a basis for the validation of sampling procedures was defined, regardless the field of investigation (industry, food, environment, etc.)

In the field of environmental sampling, for example, sampling validation include replicate (duplicates) samples (not less than eight) collected at the same site differing as little as possible from each other over space and time, or running a sampling interlaboratory comparison exercise.

The simplest way to assess the component of uncertainty arising from sampling is the quantification of the random component of uncertainty (repeatability). By replicating the analyses on each duplicate collected (and prepared), the contribution due to the analytical phase is also evaluated. Generally, sampling is performed to determine the content of a very wide range of substances in a sampling target, and it is not practicable to validate all the properties of interest. For this reason and for minimizing the additional costs (more samples, more analyses), in this kind of QC activity request the sampling quality performance may be assessed only for the selected measurand (e.g., chromium). Once a sampling quality requirement is fixed (by a regulator organization or by the laboratory itself), the sampling procedure performance may be maintained under control during routine sampling activity, applying on the same sampling target the same sampling procedure previously validated. Replicates samples, as in the validation, should be collected and a quality control chart should be implemented.

By following the examples provided by the Eurachem/CITAC Guide, it is possible to estimate the contribution of sampling to the overall measurement uncertainty within the framework of the characterization of a contaminated soil area of about $10\,000\,\text{m}^2$. The experimental design proposed, the so-called balanced empirical duplicate, is based on the duplication of sampling and analysis. The area is divided into 100 sampling targets. Two duplicate primary samples (Sample 1 and Sample 2) are taken at the sampling target, repeating the same sampling procedure. One test sample is obtained from each primary sample. On each test sample, analyses of the duplicate test portion are performed. This is followed for a fixed ratio (10%) of all the sampling targets (Figure 2.2). The application of the two-way robust

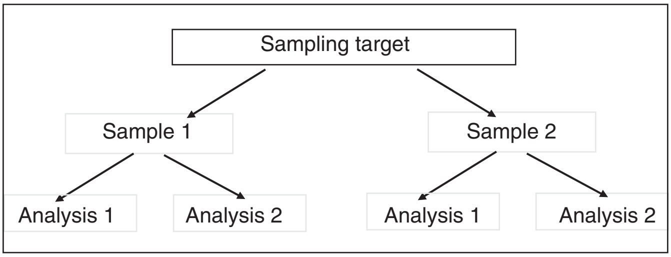

Figure 2.2 Design outline of the (balanced) empirical-duplicate approach. *Note*: the "*duplicate design*" is based on the duplication of sampling and analysis. Sample 1 and Sample 2 are duplicate primary samples taken at one sampling target repeating the same sampling procedure. One test sample is obtained from each primary sample. Analysis 1 and Analysis 2 represent the duplication of the analysis of the test portion taken from each test sample. This scheme is followed for all the sampling targets randomly selected (10%).

analysis of variance (RANOVA) allows the separation of the variability due to spatial distribution of the property of interest (e.g., lead), sampling, and measurements.

The evaluation of the performances of different sampling strategies, through sampling interlaboratory comparison exercises, is a challenging task and requires tools well characterized and stable over time, in analogy with the reference materials used for interlaboratory exercise for analytical laboratories, called *reference sites*. The IUPAC [3] recently defined the reference site for soil sampling as an area, one or more of whose element concentrations are well characterized in terms of spatial and temporal variability.

A number of soil sampling intercomparisons in the field of environmental analysis have been realized at the international level for various aims: comparison among soil sampling guidelines; estimation of bias and measurement uncertainty due to the sampling process; evaluation of sampler performance and their ability to delineate spatially a contaminated area; harmonization of the sampling strategies used at the national level [11].

QA/QC is not limited to the implementation of the above-mentioned practices and procedures, but should include a list of other elements, such as the following:

- basic knowledge on sampling
- availability of appropriate sampling equipment
- competence of the samplers (continuous training and practice)
- written sampling procedures and documentation
- use of QC samples.

Quality is to be pursued not only in the laboratory but also in the field. To this end, the sampler must operate according to a well-defined sampling plan, and any deviation from it and any observed aspects potentially affecting the final result have to be reported (e.g., the laboratory samples must be transported and stored as defined and documented in the plan). Field sampling documentation and sample chain-of-custody procedures are mandatory in a sampling QA/QC system. The correct application of sampling procedures as well as the attitude of not overlooking them can be reached through continuous training of the samplers. In some cases, as a quality objective, it may be requested that the sampler be certified according to ISO standard 17024:2012. Furthermore, the correct application of specific health and safety procedures may reduce the risks for the operator and ensure an improvement of the sampling activity.

An important role in controlling the quality of the sampling operation and assessing data quality is played by the regular use of QC samples. Besides the already mentioned replicate (duplicate) samples used to estimate the variance due to sampling, other QC samples may control some specific aspects (cross-contamination, transportation, storage, etc.). Blank samples, that is, clean matrix samples processed to detect artifacts in the measurement process, and trip blanks, that is, clean matrix sample transported to the field (sampling site) and returned to the laboratory without being exposed to sampling procedures, allow the identification of the contamination (e.g., due to the containers). In addition, field blanks (clean samples transported to the field and exposed to the sampling location) and equipment blanks (clean samples collected by using the same device used in the field and delivered to the laboratory) may be used, for example, to detect the correct application of decontamination on the sampling tools [12].

Section II
Methods 1: Optical Spectroscopy

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

Introduction

Optical spectroscopy techniques have become customary in day-to-day laboratory work, and routine procedures often dominate the actual image of optical spectroscopy. The enormous development during recent years is often underestimated.

Optical spectroscopy, nowadays, refers to all techniques that use nonionizing radiation. This covers the region from the far ultraviolet (UV) to the far infrared (IR). The latter is now often called the *terahertz region* [1]. Sometimes X-ray spectroscopy is also (or still) considered as part of optical spectroscopy, but the current rise of the field of biophotonics has contributed greatly to the restriction to nonionizing radiation. Analytical (bio-)photonics may now be seen as the contemporary term for optical (bio-)spectroscopy.

While there is a wide range of energies between the UV and the far IR, all these spectroscopic techniques share a common theoretical background. Certain types of spectrometers are used at all wavelength ranges, and there are common requirements for basic operations, from sample preparation to data evaluation, that exist for all techniques. For this reason, the subsequent chapters are not organized according to wavelength ranges, but according to the universal topics: (i) basics of optical spectroscopy, (ii) instrumentation, and (iii) measurement techniques. Dedicated applications for the distinct measurement techniques are collected in the final chapter of this section, starting at the low-energy side with the mid IR, and going up to the energy-rich fluorescence. Typical experimental parameters for all major techniques are compiled in tables.

Compared to the previous edition, all chapters of the Optical Spectroscopy Section are expanded. This section now includes the terahertz region, spectroscopic imaging, nonlinear techniques of optical spectroscopy, as well as the utilization of nanoparticles and quantum dots for spectroscopic purposes. Owing to the required abandonment of solvents, various reflection methods and microscopic techniques are increasingly used. This is reflected in the subsequent chapters on optical spectroscopy as well.

A particular potential of optical molecular spectroscopy – the unique combination of high structural sensitivity and excellent time resolution – has attracted great interest. This combination permits analyzing and understanding of biological processes on the molecular level. The range of applications extends from investigations of the fastest molecular processes to single molecule analytics. Proteins exert their biological functions via a sequence of structural changes, with

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

movements occurring in the range between picoseconds and seconds or even beyond. Spectroscopic techniques can be used to record processes such as electron transfer, proton transfer, hydrogen bonding, and chromophore isomerization at excellent sensitivity and rate. All these processes are crucially important in many functional molecules. Molecular imaging and fluorescence spectroscopy techniques have made particularly vast accomplishments here. The complicated situation of a fluorescing chromophore in interacting solvents can now be handled much more easily. Technical developments now permit the investigation of particularly sensitive proteins, label-free, and in their native environment [2]. In particular, nonlinear spectroscopic methods have the potential to provide the required information very fast without impacting the investigated system [3]. Even novel procedures for *in vivo* diagnosis based on optical fibers are expected.

Current imaging spectrometers may provide several thousands of complete spectra within seconds. Nobody is able to manually inspect the quality of this huge amount of spectra, but spectra of border regions of the sample or even of regions outside the sample shall inevitably be collected. Such spectra of inferior quality in the data set may even preclude chemometric evaluation procedures from achieving useful results. This is a standard problem in spectroscopic imaging, as homogeneous sample areas are normally not imaged. Thus, in spectroscopic imaging, approximately 10% of the required time is used for sample preparation and measuring the spectra, and the remaining 90% for thorough chemometric evaluation of images. The basics for these elaborate evaluations are given both within this Optical Spectroscopy Section as well as in Chapter 53 General Data Treatment/Optical Spectroscopy.

Basics of Optical Spectroscopy

Martin Hof and Radek Macháň

3.1

Absorption of Light

The theoretical description of light can be performed in two ways: light can be regarded as a stream of corpuscles (photons) or as an electromagnetic wave. In case of corpuscle description, the behavior of the photons, and in particular the interaction between photons and molecules, might be described by the laws of quantum optics. In case of electromagnetic description, the interaction of the electromagnetic wave with a medium is described by the electromagnetic theory comprising *Maxwell*'s equations [1].

In the first case – corpuscle description – the energy of the photons is

$$E = h\nu \tag{3.1}$$

where h is the Planck constant ($h = 6.626 \times 10^{-34}$ J s) and ν the frequency of light. The light velocity in vacuum c and the wavelength λ are related to each other by

$$\nu = \frac{c}{\lambda} \tag{3.2}$$

Thus, the energy of electromagnetic waves is directly proportional to the reciprocal wavelength. In particular, in vibrational spectroscopy, the reciprocal wavelength is used and denoted as wavenumber k

$$E = hck \tag{3.3}$$

Usually, the wavenumber k is written in the form

$$k\ (\text{cm}^{-1}) = \frac{10\,000}{\lambda\ (\mu\text{m})} \tag{3.4}$$

In the second case – describing light as electromagnetic wave – its propagation may be written as

$$A(\phi) = A_0(\phi)\mathrm{e}^{i(\omega t - \delta)} \tag{3.5}$$

where A is the amplitude, ω the circular frequency, t the time, δ the phase angle, and ϕ the polarization angle. The circular frequency may be expressed by the

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

wavelength λ and the refractive index n

$$\omega = \frac{c}{\lambda n} \tag{3.6}$$

Equation (3.5) applies for the propagation of light in a nonabsorbing medium. In case of an absorbing medium, Eq. (3.5) has to be modified by replacing the refractive index n by its complex form n^*

$$n^* = n + i\kappa \tag{3.7}$$

where n and κ are always nonnegative. In case of an absorbing medium, the absorption coefficient α is often used

$$\alpha = \frac{4\pi\kappa}{\lambda} \tag{3.8}$$

On the basis of Eq. (3.5), the light intensity I can now be described as

$$I = I_0 \mathrm{e}^{-\alpha l} \tag{3.9}$$

where l is the path length of light within the absorbing medium. The Beer–Lambert law results directly from Eq. (3.9)

$$I = I_0 \mathrm{e}^{-\varepsilon c l} \tag{3.10}$$

with ε as molar absorption coefficient and c as concentration of the absorbing compound. The Beer–Lambert law is usually expressed in its logarithmic form

$$\log\left(\frac{I0}{I}\right) = A = \varepsilon c l \tag{3.11}$$

Note that the absolute value of ε changes by a factor of 2.303 if "ln" is used instead of "log."

In the medium, absorption of light causes a transition from an energetic ground state to a particular excited state. Depending on the energy of light and on the chemical nature of the interacting compound, the excited states may differ very much in nature (cf. Figure 3.1). Rotations and vibrations are excited in the infrared spectral range. In the UV–vis range, absorption of light causes electronic and vibrational excitations. Relaxation of excited states back to the ground state may cause emission or luminescence, which are also evaluated spectroscopically. Electronic and vibrational transition can be excited simultaneously (vibronic transitions), but owing to the large differences in their transition energies, the different types of optical excitation (electronic transitions, vibrational, and rotational motions) can be discussed separately (Born–Oppenheimer approximation). Spectral band parameters are the position of the band maximum (wavenumber k or wavelength λ), the intensity of the band (height or area above the baseline), and the band shape (influenced by the environment of the vibrating group) [2].

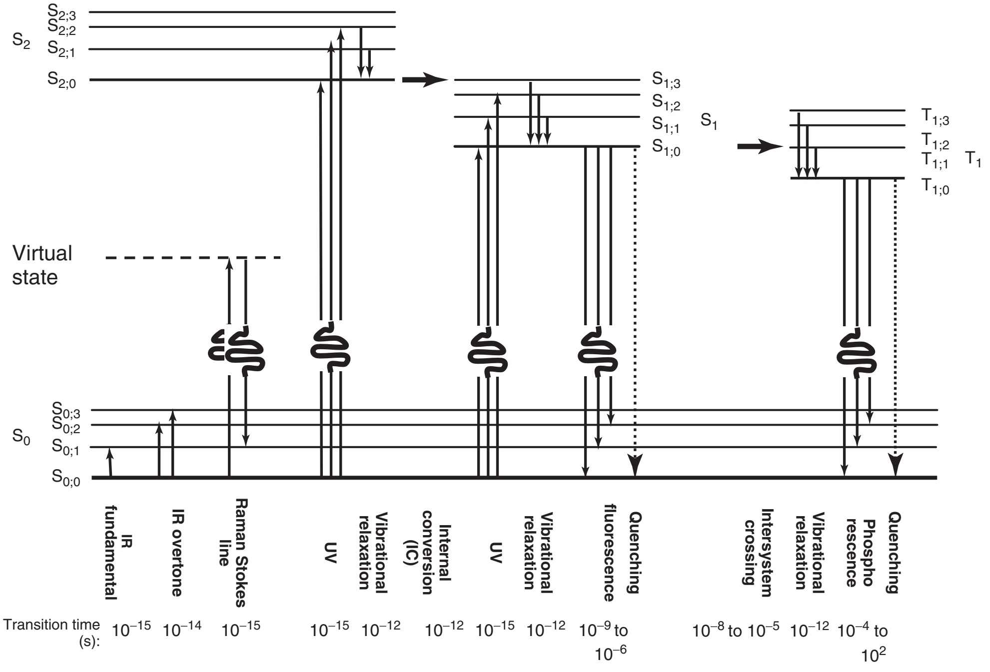

Figure 3.1 Schematic depiction of vibrational and electronic transitions described in this chapter. The distance between electronic states has been compressed by a factor of at least 10 compared to the distance of vibrational states.

3.2
Infrared Spectroscopy

The mid (fundamental) infrared (IR or MIR) region extends from 4000 cm^{-1} ($\lambda = 2.5\,\mu$m) to 400 cm^{-1} (25 μm). It is surrounded by the far infrared (FIR) region from 400 cm^{-1} (25 μm) to 10 cm^{-1} (1 mm) and the very important near infrared (NIR) region from 12 500 cm^{-1} (800 nm) to 4000 cm^{-1} (2.5 μm). Infrared spectroscopy is the most used spectroscopic technique. There are a number of reasons for its great success and dissemination. The method is rapid, sensitive, easy to handle, and provides many different sampling techniques for gases, liquids, and solids. Important aspects are the convenient qualitative and quantitative evaluation of the spectra.

The standard format of an IR spectrum is transmittance T (%) versus wavenumber (cm^{-1}). According to IUPAC recommendations, the values of the wavenumber axis diminish toward its right end [3]. This recommendation is, however, not always obeyed because of limitations in commonly used computer programs for spectra processing. The features of an IR spectrum (number of infrared absorption bands, their intensities, and their shapes) are directly related to the molecular structure of a compound. The IR spectrum is a unique physical property of an individual compound; it is its molecular fingerprint [4].

The IR region comprises fundamental vibrations of bound atoms. Whenever such bound atoms vibrate, they absorb infrared energy, that is, they exhibit IR absorption bands. The condition for a normal vibration j to be IR active is a change in molecular dipole moment μ during vibration

$$\mu_j = \mu_0 + \left(\frac{\delta\mu}{\delta q_j}\right) q_j + \frac{1}{2}\left(\frac{\delta^2\mu}{\delta q_j{}^2}\right) q_j{}^2 + \cdots \tag{3.12}$$

q stands for the normal coordinate describing the motion of atoms during a normal vibration.

With respect to the direction of the vibrational movement, we may distinguish between stretching vibrations (changes of bond lengths) and deformation vibrations (changes of bond angles). Deformation vibrations may be subdivided into bending modes, twisting or torsion modes, wagging modes, and rocking modes. Further subdivisions refer to the symmetry of the vibration (e.g., symmetric or antisymmetric, in-plane or out-of-plane) [5].

Complications in evaluation of IR spectra are the overlapping of individual bands and the appearance of additional bands, for example, overtone and combination bands, which may be caused by anharmonicity of some vibrations. In the NIR region, all bands are overtone and combination bands. They are always weaker in intensity than the corresponding fundamental bands. Originally considered as a drawback, the weak intensity of the NIR bands turned out to be the background for the large success of NIR spectroscopy in process analysis [6, 7].

The concept of characteristic vibrations is used for qualitative analysis of polyatomic molecules [8]. In organic compounds, characteristic vibrations occur usually between 4000 and 1500 cm^{-1}. Inorganic compounds containing heavy atoms may exhibit characteristic vibrations at much lower frequencies [9]. Characteristic vibrations are based on motions, mostly stretching vibrations, that are localized in and characteristic of typical functional groups. While individual bands are not sufficient in confirming the identity of a molecule, they provide useful information about the type and abundance of substructures that make up a molecule. All frequencies of organic compounds below 1500 cm^{-1} involve molecular vibrations, usually bending motions that represent a characteristic fingerprint of the entire molecule or large fragments of the molecule. The comparison of the spectrum of an unknown compound with spectra stored in spectra libraries together with corresponding search programs are an excellent possibility for qualitative analysis. Currently, these programs offer search routines based on complete spectra, compound information, molecular structures, and substructures (see Chapter 53).

The intensities of the bands in pure components and in mixtures are proportional to the concentrations of the components. The relation between measured intensities and concentration is expressed in the Lambert–Beer law (Eq. (3.11)). Thus, it is possible to carry out quantitative investigations by methods based on band heights or preferably by methods based on integrated intensities. Both single-component analysis and multicomponent analysis by multivariate methods (see Chapter 53.3.3) can be performed.

3.3
Raman Spectroscopy

The Raman effect is a light-scattering effect. The exciting monochromatic beam has to be of high intensity (laser beam) in order to induce in the molecule a virtual energy state (cf. Figure 3.1). Most of the molecules relax directly back to the $S_{0;0}$ state, whereby light of the same wavelength as the exciting light is emitted (Rayleigh scattering). Only a very small percentage of the excited molecules relax back to a vibrationally excited state, hence the emitted photons have smaller energy than the exciting photons (Stokes lines). Because only a very small percentage of molecules uses this relaxation pathway, Raman scattering is always of very low intensity, its investigation requires high-quality instrumentation. Molecules, which were originally in a vibrationally excited state, can after excitation relax to the ground state emitting photons of higher energy than the exciting ones (anti-Stokes lines). The fraction of molecules residing initially in the vibrationally excited state is given by factor $\exp(-E/bT)$, where E is the energy difference between ground and excited state, b is Boltzmann's constant, and T is temperature. The intensity of anti-Stokes lines is, therefore, much smaller than that of Stokes lines and the ratio of their intensities can be used for *in situ* monitoring of temperature [10]. The Raman effect can be excited in the UV region, in the visible region, or in the NIR region.

The condition for a molecule to be Raman active is a change in the polarization (deformation) of the electron cloud during the interaction with the incident radiation. In case of Raman scattered radiation, the magnitude of the field vector E of the exciting radiation is modulated by the molecular vibrations. The induced dipole moment μ' is

$$\mu' = \chi_1 E + \frac{1}{2}\chi_2 E^2 + \frac{1}{6}\chi_3 E^3 + \cdots \tag{3.13}$$

χ_i is the molecular polarizability, a three-dimensional (tensor) term, whereas the dipole moment (Eq. (3.12)) is a two-dimensional (vector) term. At commonly employed field strength values (laser output up to 1 kW per line), Eq. (3.13) can be reduced to its linear term. Nonlinear terms have to be taken into account only in case of very high intensity of the exciting light (above 1 MW per line). On the basis of this situation, the conventional Raman effect is often denoted "linear Raman effect," in contrast to "nonlinear Raman effects" observed with very strong laser excitation [11]. χ_2 contributions lead to the hyper-Raman effect, χ_3 contributions to the stimulated Raman scattering (SRS), and the coherent anti-Stokes Raman spectroscopy (CARS), cf. Section 4.8.

SRS is described as a two-photon stimulated process. Only Raman modes with the highest gain factors give rise to stimulated Stokes emissions. All active Raman modes can, in principle, be observed if the molecular system is provided with an intense external Stokes field by using a second laser beam for excitation (three-wave mixing). The superposition of two electromagnetic waves of the frequencies ω_1 and ω_2 generates a third electromagnetic wave at the difference frequency (difference frequency generation, DFG, $\omega_1 - \omega_2$), the second harmonic in case of

$\omega_1 = \omega_2$ (second harmonic generation, SHG, $\omega_1 + \omega_2$), or the sum frequency in case of arbitrary ω_i (sum frequency generation, SFG, $\omega_1 + \omega_2$). The intensities of harmonics emitted by oscillating dipoles depend on the square of the vibrational amplitudes.

The Raman method is the complementary method to IR spectroscopy, where the excited vibrational state is directly approached. The Raman spectrum is the plot of Raman intensity versus Raman shift. Raman band parameters are band position in the spectrum (Raman shift), intensity of the band, and band shape. As in case of the IR spectrum, the features of a Raman spectrum (number of Raman bands, their intensities, and their shapes) are directly related to the molecular structure of a compound [11, 12].

The complementarity of IR and Raman spectra is based on the different excitation conditions: change of dipole moment (vector quantity) in case of IR spectrum, change of polarization (tensor quantity) in case of Raman spectrum. Because a tensor is a three-dimensional quantity, the depolarization ratio ρ can be obtained by measuring Raman spectra with polarized light (polarization directions parallel and perpendicular to the optical plane)

$$\rho = \frac{I_{||}}{I_{\perp}} \tag{3.14}$$

The qualitative analysis by group frequencies and the quantitative analysis procedures for single and multicomponent analysis are, in principle, the same as in IR. A severe limitation in application of Raman is the fluorescence phenomenon. Fluorescence can be up to 10^7 times stronger than Raman scattering. Fluorescence of trace impurities may, therefore, render observation of the Raman spectrum of the analyte impossible. In order to avoid the masking of Raman scattering by fluorescence, the gap between the virtual energy state and the electronically excited state S_1 has to be sufficiently large (choice of excitation wavelength between UV, MIR, and NIR). NIR excitation is often preferred because there are very few electronic transitions in the NIR. The drawback of NIR excitation is the severely reduced Raman scattering intensity (proportional to $\lambda_{\text{exc}}^{-4}$).

3.4
UV–vis Absorption and Luminescence

UV–vis absorption and luminescence spectra are related to electronic and vibrational transitions. The term *luminescence* summarizes a combination of basic processes such as fluorescence and phosphorescence, which are described subsequently. Transitions occur between energy levels described as in $S_{n,v}$, where S points to an electronic singlet state and n,v to the corresponding electronic (n) and vibrational (v) excitation levels. The intensity of a transition from an electronic and vibrational ground state $S_{0,0}$ to a corresponding excited state $S_{n,v}$ is proportional to the square of the transition dipole moment $\boldsymbol{M}$, which itself can be separated in an electronic part $M_{0;n}$ and the vibrational contribution $F_{0,0;n,\nu}$

$$\boldsymbol{M} = M_{0;n} F_{0,0;n,\nu} \tag{3.15}$$

$F_{0,0;n,\nu}$ represents the so-called vibrational overlap integral of the vibronic wavefunctions $\chi_{0,0}$ and $\chi_{n,\nu}$, given by

$$F_{0,0;n,\nu} = \int \chi_{0,0}\chi_{n,\nu}\mathrm{d}r \tag{3.16}$$

where r is the internuclear distance. The square of $F_{0,0;n,\nu}$ is known as the *Franck Condon factor*, which is a measure of the transition probability between the vibrational ground state of S_0 and a vibrational excited state of $S_{n.}$ Individual Franck Condon factors are directly related to the intensity of the vibrational bands and thus determine the vibrational fine structure of the absorption spectrum. The electronic transition dipole moment $M_{0;n}$ is defined as

$$M_{0;n} = \int \psi_0 \boldsymbol{\mu} \psi_n dq_{\mathrm{e}} \tag{3.17}$$

where ψ_0 and ψ_n are the electronic wavefunctions of ground and excited states, respectively, $\boldsymbol{\mu}$ is the electric dipole moment operator, and q_{e} are the electron coordinates. The probability of an electronic transition is directly related to the square of the value of cos ζ, where ζ is the angle between the plane of oscillation of the electrical vector of light and the direction of the electronic transition dipole moment $M_{0;n}$.

After the creation of the so-called "Franck Condon state" $S_{n,\nu}$ by "ultrafast" absorption of light (10^{-15} s), the molecule usually relaxes within 10^{-12} s into the lowest excited state ($S_{1,0}$). Although some rare examples of direct fluorescence from the $S_{2,0}$ exist, they are considered as curiosities and do not find application in material or life sciences [13]. The photophysical processes populating the $S_{1,0}$ are vibrational relaxation and internal conversion (e.g., $S_{2,0} \rightarrow S_{1,\nu}$). Subsequently, the molecule can return back to the ground state $S_{0,\nu}$ by fluorescence (typically between 10^{-9} and 10^{-6} s). As the vibrational fine structure of the fluorescence spectrum is again determined by the Franck Condon factors for the possible $S_{1,0} \rightarrow S_{0,\nu}$ transitions, the emission is for most chromophores the mirror image of the $S_{0,0} \rightarrow S_{1,\nu}$ transition. Alternatives to the light emission are several radiationless deactivation pathways from the $S_{1,0}$ state. The most fundamental processes are the intramolecular processes internal conversion ($S_{1,0} \rightarrow S_{0,\nu}$) and intersystem crossing ($S_{1,0} \rightarrow T_{n,\nu}$), as well as intermolecular interactions such as collisional quenching or resonance energy transfer. After the population of an excited triplet level $T_{n,\nu}$ by intersystem crossing, vibrational relaxation and internal conversion lead again to the population of the lowest triplet excited state $T_{1,0}$. The luminescence from the $T_{1,0}$ state is called *phosphorescence* and is spin forbidden, hence relatively low in intensity and relatively slow (typically between 10^{-4} and 10^{2} s). It is quite common at temperatures of liquid nitrogen or helium, but rare at room temperature and even rarer at physiological temperatures. Thus, phosphorescence as well as the rare process of delayed fluorescence will be skipped when further discussing practical limits and possibilities of luminescence. It has to be stressed that the described picture (summarized in Figure 3.1) does hold only for measurements in the gas phase and in nonpolar solvents as well as in the absence of special intramolecular photochemical processes. The real situation of a chromophore in interacting solvents is much more complicated. One must include interaction with the surrounding molecules, transfer of the excitation energy from one molecule to another, variety of photochemical processes, effects of polarized excitation and detection, different mechanisms of quenching, and relaxation of the solvent [13, 14]. Those processes that yield information when applied in material and life sciences are discussed in Section 6.5.

4
Instrumentation

Valdas Sablinskas

There are a few basic types of instruments that are used in optical spectroscopy for the determination of absorption, fluorescence, or Raman spectra of condensed and gaseous samples. These basic types are monochromators, interferometers, and polychromators. The wavelength range of conventional optical spectroscopy extends from 200 nm (UV) to 500 μm far infrared (FIR). In very modern applications, the long wavelength region is even reaching 1 cm (or 0.03 terahertz (THz)). This region is called *terahertz spectral region*. It is impossible to build one single spectral instrument capable of covering the region completely and to provide information about the different processes of absorption, emission, and scattering of light. Light sources, detectors, and other optical components have limited operational ranges, caused by the underlying physical work principles. The choice of the appropriate instrument type depends on the application. The interaction process of light with the material and the spectral interval of interest have to be taken into account. Traditionally, spectrometers for absorption measurements are optimized for UV/vis (175–750 nm), near-infrared (NIR) (0.75–2.5 μm), mid-infrared (MIR) (2.5–50 μm), FIR (50–1000 μm), and THz (1–10 mm) ranges. Some commercial spectrometers are capable of covering neighboring spectral regions (for instance, UV/vis/NIR or MIR/FIR).

Spectrometers for investigation of scattering and emission of light belong to a second class of instruments. Some recently developed spectral instruments for studying the emission of light as a result of nonlinear interaction of radiation with matter, such as sum frequency generation (SFG) spectrometers, also belong to this second class.

Spectrometers can be combined with appropriate microscopes and collect spectral information from selected small areas of the sample. This combination is sometimes called *microspectrometer*. A motorized x,y stage or an array detector may be added to the microscope in order to produce detailed chemical maps of the sample. Such spectrometers are often described as spectral imaging devices.

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

4.1
MIR Spectrometers

There are two types of MIR spectrometers, dispersive and Fourier transform (FT) spectrometers. Currently, the predominantly used spectrometers are FT spectrometers. The most significant advantage of FT spectrometers is that radiation from all wavelengths can be measured simultaneously, whereas in dispersive spectrometers all wavelengths are measured consecutively. Therefore, an FT spectrometer is much faster and more sensitive. Nowadays, dispersive MIR spectrometers are not anymore available on the market, but they still are in use in laboratories.

Information about absorption of infrared (IR) radiation in the sample is obtained by measuring the intensity ratio of the radiation before and after the sample. In order to obtain this ratio with sufficient accuracy, IR absorption spectrometers should be double channel instruments.

4.1.1
Dispersive Spectrometers

Basically, dispersive instruments are much simpler than FT ones, as they measure the spectrum directly (Figure 4.1). The IR beam from the source of IR radiation is directed both to a sample and a reference position inside the sample chamber (double-beam principle). After passing the sample chamber, both beams are combined into one common path by means of a rotating chopper mirror. The combined beams enter the grating monochromator and, finally, reach the detector. By turning the grating, all spectral elements are eventually directed to the detector. The spectrum is recorded in real time as ratio of the sample beam intensity (I) to the reference beam intensity (I_0). Usually, one grating is not sufficient to cover the complete MIR spectral range. Up to four different gratings are subsequently used for the region 4000–400 cm^{-1}.

The great advantage of the double-beam principle is the automatic compensation in the spectra of most of the external disturbances, such as contributions by optical components or absorptions due to solvents or atmospheric water and CO$_2$. Regardless of this automatic compensation, no meaningful results are obtained

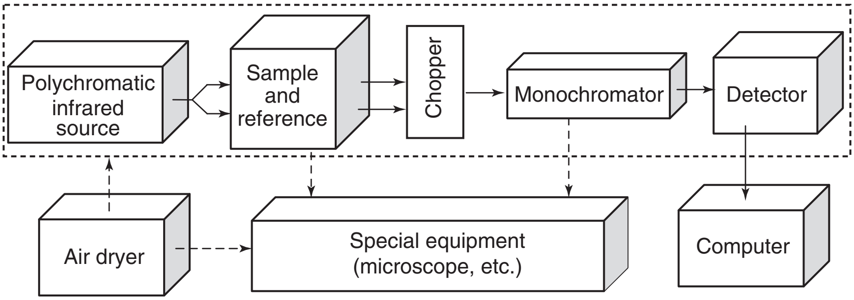

Figure 4.1 Block diagram of a dispersive IR spectrometer.

if the absorption due to these disturbances is too strong. Such regions are called *dead spectral regions*. For instance, because of the strong absorption of CO_2 around $2450\,cm^{-1}$, this region may be blocked in conventional MIR spectrometers. The problem of dead spectral regions can be overcome by purging of the spectrometer with dry and CO_2-free air or evacuating it. An air dryer can be installed to any MIR spectrometer as an option. Vacuum spectrometers are usually more expensive than purged ones. Moreover, vacuum-tight sample cells may be needed.

The most common source in MIR spectrometers is a glowing ceramic bar, a so-called glowbar (or globar). More intense emission is provided by the Nernst glower because of its higher operation temperature (black body radiator). A thermocouple or a thermopile is commonly used as detector. The response behavior of such detectors is slow, what prevents rapid scanning by dispersive MIR spectrometers.

4.1.2
Fourier-Transform Spectrometers

FT-IR spectrometers cannot be built as double-beam instruments. Unlike dispersive instruments, FT-IR spectrometers acquire single-channel spectra of sample and reference, their ratio is calculated afterwards (Figure 4.2). Sample and reference may automatically be replaced by a sample slider, or the IR beam may be switched between sample and reference by flip mirrors. In case of higher accumulation numbers, the instrument switches repeatedly between sample and reference scan.

The heart of any FT-IR spectrometer is an interferometer. The Michelson interferometer consists basically of a beamsplitter and two flat mirrors. One of the mirrors is fixed in one interferometer arm, and the other mirror is movable in the second interferometer arm. Most common MIR beamsplitters are made of KBr with a multilayer coating. The beamsplitter should have a reflectivity of 50% and no absorption across its range of use.

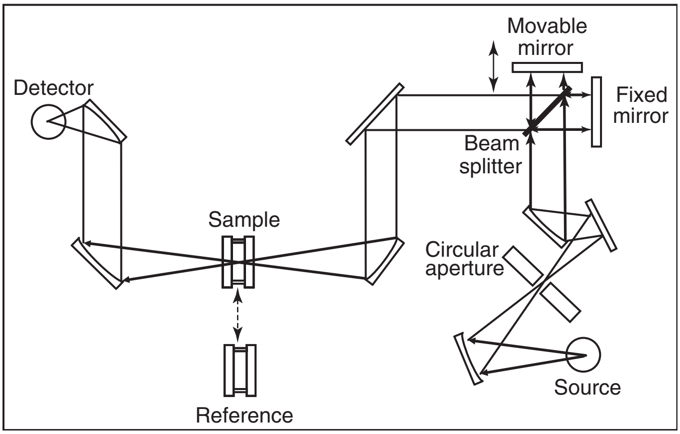

Figure 4.2 Diagram of an FT-IR spectrometer with a Michelson interferometer.

The operation of a Michelson interferometer is based on a collimated IR beam. The latter is directed to the beamsplitter, which divides the beam into two parts of equal intensity (in the ideal case). The divided beams are reflected by the fixed and the movable mirrors back to the beamsplitter, where they recombine and interfere. The displacement of the movable mirror causes changes in the optical pathlength between the two beams, so that the conditions for constructive and destructive interference as well as all intermediate states between the two are consecutively met. The recombined IR beam passes the sample (or the reference) and reaches the detector. Position and movement of the movable mirror are controlled by a helium–neon laser ($\lambda_{\mathrm{HeNe}} = 632.8\,\mathrm{nm}$). The interferogram of the helium–neon laser is used to control the sampling of the IR interferograms in steps down to $\lambda_{\mathrm{HeNe}}/2 = 316.4\,\mathrm{nm}$.

The mathematical procedure, which is employed to convert the IR interferogram (intensity vs time, also called *time domain*) to an IR spectrum (intensity vs frequency, also called *frequency domain*), is called *Fourier transformation*. Sample and reference interferograms are separately transformed. Afterwards, the ratio of both is automatically calculated and displayed as instrument-independent IR transmittance spectrum (Figure 4.3).

Resolution in an FT-IR spectrometer is mainly defined by the maximum path difference between the interferometer arms. It is crucial to maintain the optical

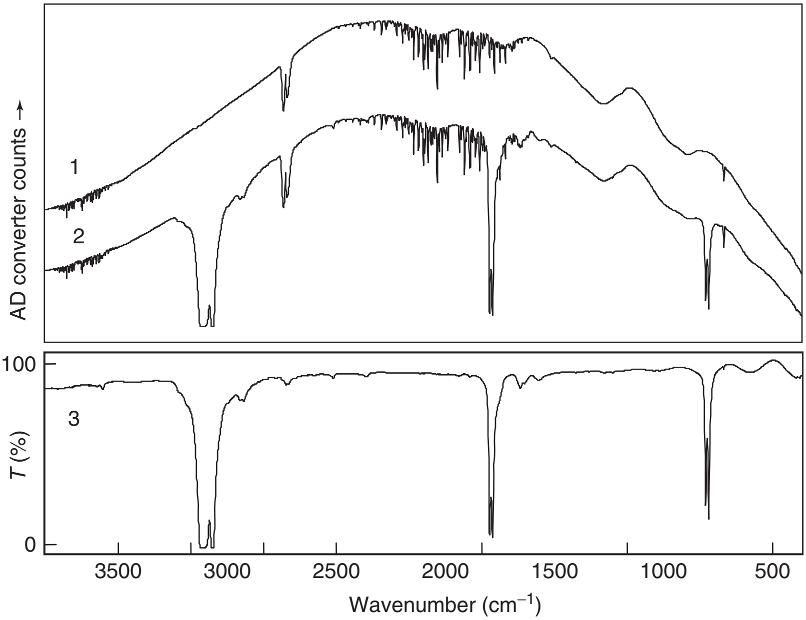

Figure 4.3 IR absorption spectrum of polyethylene: (1) single-eam reference spectrum (without sample); (2) single-beam sample spectrum; and (3) ratioed transmittance spectrum.

alignment of the interferometer during mirror movement; hence, the efficiency of the device for moving the mirror (the so-called scanner) is very important. Most interferometers employ either a mechanical pivot bearing, a mechanical slide bearing, or an air bearing to translate the mirror along a linear path. Alternatively, an optical retardation can be introduced by rotating a pair of planar mirrors instead of translating one mirror. The larger the angle of the mirror rotation, the greater is the achieved optical retardation. Regardless of the type of mirror drive, it moves continuously and does not stop during data collection at each interferogram sampling point (continuous-scan operation). In order to correct for alignment errors during mirror movement, newer interferometers employ fast-response piezoelectric crystals to align the position of the fixed mirror during the scan. Moving mirror tilt may also be eliminated optically by using the so-called corner cube mirrors. This method is preferable for high-resolution instruments, where the moving mirror displacement may be as large as a few meters.

Traditionally, FT-IR spectrometers used to be divided into two groups, routine and research spectrometers. Both have an affiliated PC for data processing and handling. Routine spectrometers usually have a resolution limit at about 1 cm^{-1}. Research spectrometers can achieve resolution as high as 0.001 cm^{-1}. Sources, beamsplitters, and detectors are exchangeable in research spectrometers, so one could use these spectrometers from 40 000 down to 20 cm^{-1} (from UV to FIR). In some spectrometers, different sources and detectors are installed permanently. They can be switched on or off by means of flip mirrors. Nowadays there are no designated limits anymore between routine and research instruments.

The high efficiency of FT-IR spectrometers is mainly attributed to the so-called Jacquinot advantage, that is, the optical throughput is not anymore limited by a relatively narrow monochromator slit. Interferometers have circular apertures, whose diameter depends only on the desired spectral resolution. In general, the beam cross section of an FT instrument is usually 75–100 times larger than the slit opening of a dispersive instrument. Correspondingly, a much larger amount of IR radiation reaches the detector of an FT instrument. The diameter of the aperture in FT instruments is limited by the chosen spectral resolution. The better the needed resolution, the smaller the computer-controlled diameter of the aperture and eventually the signal at the detector.

Another important advantage of FT-IR spectrometers is their outstanding frequency accuracy (Connes advantage), the basis for all achievements in difference spectroscopy. This accuracy of spectral frequencies is due to the precise and stable collection of the interferogram signal, triggered by the helium–neon laser. An accuracy in wavenumber of better than 0.01 cm^{-1} can be achieved.

The third advantage is high speed and/or high sensitivity (Fellgett advantage). The time needed by the movable mirror for one scan cycle varies between 0.01 and 1 s, depending on the spectral resolution as well as the detector response. Typically, 20–200 scans are accumulated in one measurement to acquire a sufficient signal-to-noise ratio. The number of accumulations depends on the experimental condition and can be much higher if least spectral effects have to be studied.

4.1.2.1 **Detectors**

The standard detector in routine FT-IR instruments is the pyroelectric DTGS (deuterated triglycine sulfate) detector, whose response in the MIR range is wavelength independent. The detector operates at ambient temperature and shows good linearity across the whole transmittance scale. The DTGS detector responds to signal frequencies of up to several thousand hertz, and hence the time needed to scan one spectrum at a resolution of 4 cm^{-1} is in the order of 1 s.

The MCT (mercury cadmium telluride) detector is much more sensitive and faster than the DTGS detector. Operation of the MCT detectors is based on an internal photo effect. Each IR radiation quantum excites one bound electron of the detector material to a free state, that is, the electrical conductivity of the MCT detector element increases. A serious drawback of the MCT detector is its spectral working range. Low-energy photons are not able to promote the bound electrons to the free state (low wavenumber cut-off of MCT detector at 600 cm^{-1}). In some MCTs, this cut-off is even higher (750 cm^{-1}) because of absorption in the detector optical window. Owing to its low operating temperature, the detector element is covered by a vacuum enclosure with an optical window in front of the detector element. The vacuum housing makes the MCT detector rather expensive. Furthermore, the MCT detector shows a nonlinear response, which can be minimized by special electronics and software. The time needed to scan one spectrum is only 0.01 s; that is, rates of 100 scans per second are achieved. The MCT is the detector of choice for experiments in conditions of low radiation levels.

FT-IR spectrometers with array detectors can be considered a new class of IR instruments. The size of an array detector chip with its sensitive elements placed in one plane (because of this arrangement called *focal plane array* (FPA)) is usually about 4 mm × 4 mm and, depending on the number of individual MCT detector pixels in the array, a large number of interferograms is collected simultaneously. In case of an FPA detector with 64 × 64 individual pixels, 4096 interferograms are collected simultaneously and the spectral imaging of a sample area of 4 mm × 4 mm can be completed in a few seconds. Images from areas as small as 250 μm × 250 μm can be acquired by combining the FT-IR imaging spectrometer with an IR microscope. As the read-out electronics needs some time to collect signals from all MCT elements of the FPA detector, the scanner speed has to be reduced substantially. For this reason, interferometers in imaging instruments are commonly operated in the step-scan mode.

4.1.2.2 **Step-Scan Operation**

In the step-scan mode, the moving mirror of the interferometer is stopped at each data acquisition point and held for some time (seconds to minutes), during which data are acquired. Interferograms collected in the step-scan mode contain the same information as those collected in the continuous-scan mode, only the time required to complete an experiment is much longer. Under stroboscopic measuring conditions, a time resolution of 100 ns can be achieved. This technique can be applied to processes, which can repeatedly be started under highly reproducible conditions. The step-scan technique can also be applied for the acquisition of voluminous data. This is the case for FPA detectors, where data points from a vast number of individual detector elements have to be collected.

4.1.2.3 **Combined Techniques**

Many FT-IR spectrometers have external ports for optical coupling to dedicated accessories. The IR radiation is conveniently directed to/from the external ports by computer-controlled flip mirrors. A large variety of accessories such as IR microscopes, interfaces for gas chromatography (GC/FT-IR), high-performance liquid chromatography (HPLC/FT-IR), thin layer chromatography FT-IR (TLC/FT-IR), and so on, is commercially available. This type of method combination is usually called *hyphenated techniques*. FT-IR spectrometers can even be supplemented by an FT-Raman accessory. The versatile combination of FT-IR spectrometers with other instruments have substantially contributed to their abundance in most analytical laboratories.

4.2
NIR Spectrometers

Absorption of electromagnetic radiation in the NIR region is caused by overtone and combination vibrations. Polyatomic molecules exhibit many overtone and combination vibrations, their spectral bands overlap and make typical NIR bands look very broad and featureless. Nevertheless, NIR spectra comprise molecular information about the sample, and this information can be extracted by means of chemometric methods (cf. Chapter 53). The prerequisite for chemometric evaluations is a high quality of the collected spectral data. Therefore, wavelength validity (accurate and precise) resolution, photometric validity, and signal-to-noise ratio are important criteria for the selection of an NIR spectrometer.

Among all optical spectroscopic methods, NIR offers the greatest diversity of instrumentation principles, and the market for commercially available instruments is in continuous change and growth. NIR has an enormous variety of applications, for example, in agriculture, in food processing, in medical and in pharmaceutical applications, in polymer and plastics processing, in environmental analysis, in material recycling, and in satellites or aircrafts for remote sensing. Commercial NIR spectrometers vary remarkably with respect to cost, to size and portability, to measurement time, and to environmental conditions for in-line applications in industry. According to their measurement principles, NIR spectrometers fall into one of the six categories:

1) Fourier transform spectrometers
2) Scanning-grating spectrometers
3) Diode array spectrometers (fixed-grating spectrometers)
4) Filter spectrometers
5) LED (light-emitting diode) spectrometers
6) AOTF (acousto-optical tunable filter) spectrometers.

4.2.1
FT-NIR Spectrometers

These are identical to FT spectrometers already described in Section 4.1.2. The most used light source for the FT-NIR spectrometer is the tungsten-halogen lamp. Such a lamp delivers high and constant energy throughout the NIR range, is very stable, and has a long lifetime. Beamsplitters for FT-NIR spectrometers are usually made from CaF_2 with working range 10 000–1600 cm^{-1} (1000–6000 nm). There is no detector available to cover the complete NIR range or to suit all types of NIR spectrometers. A list of detectors and their application ranges is given in Table 4.1. Most used detectors in the range 1100–2500 nm are PbS and PbSe detectors, whereas Si diodes are preferred in the range 400–1100 nm.

4.2.2
Scanning-Grating Spectrometers

These spectrometers and their basic construction have already been described in Section 4.1.1. Scanning-grating NIR spectrometers often permit continuous scans from the UV through vis to the NIR region; therefore, they have two detectors, one for the UV/vis (Si) and one for the NIR regions (mostly PbS). Because NIR spectral bands of solid or liquid samples are rather broad, NIR spectrometers usually do not provide high spectral resolution. For many NIR applications, a resolution of 10 nm is sufficient. This allows rapid scans across the entire NIR range in only 0.1–1 s. The broad spectral range of such spectrometers, their speed, and accuracy are great advantages of these instruments. Full-range spectrometers are rather expensive; hence, they are mainly found in research laboratories.

Table 4.1 NIR detectors and their application ranges.

Detector	Working temperature (K)	Application range (nm)
Ge detector	77	From 600 to 1800
Si detector	300	From 400 to 1100
InGaAs detector	300	From 900 to 1700
PbS detector	196	From 1100 to 3500
InAs detector	77	From 1500 to 3500
Extended InGaAs detector	300	From 1100 to 2800
Ge detector	300	From 600 to 1900
InSb detector	77	From 2000 to 4000
PbS detector	300	From 1000 to 3000
PbSe detector	300	From 1100 to 4000

4.2.3
Diode Array Spectrometers

These have no moving parts. NIR radiation is spread by a fixed grating across the diode array detector, so that a definite wavelength range is directed toward each detector element. Diode arrays usually consist of 256 or 512 InGaAs and InSb detector elements. The spectral resolution depends on the number of elements in the array and the wavelength range. The great advantage of these spectrometers is the possibility of miniaturization. Such spectrometers can fit on a PC plug-in card. NIR radiation is delivered from the lamp via sample to the detector by optical fiber cables (single fiber of 50–1000 μm diameter or bundles of up to 80 single fibers). If the wavelengths to be investigated are known in advance, one may use a set of bandpass filters to send radiation of only discrete wavelengths through the sample to the detector array.

4.2.4
Filter Spectrometers

These may have several filters mounted on a rotating wheel. The wheel has either a set of filters with predefined wavelength regions for a specific application or a customary set of filters for the NIR region of interest. The advantages of these spectrometers are their robustness and low cost.

4.2.5
LED Spectrometers

These work at predefined wavelengths, they have no moving parts. Because LEDs emit radiation of discrete wavelengths, these instruments do not need any wavelength selector (filter, monochromator, etc.). Additional interference filters can be used in order to limit the spectral bandwidth (SBW). Advantages are the possibility of miniaturization and the high stability of these light sources.

4.2.6
AOTF Spectrometers

These are built around a birefringent crystal, which is used for rapid and precise wavelength selection. Usually it is a TeO_2 crystal with one or more piezoelectric transducers. The working principle is based on a phonon–photon scattering mechanism. Broadband randomly polarized light is incident on the AOTF crystal, where it is separated into ordinary and extraordinary polarized components. When radio frequency acoustic waves are coupled into the crystal via a piezoelectric transducer, the refractive index is spatially modulated, producing a phase grating that diffracts one specific wavelength of the incident light. This light is symmetrically deflected into two orthogonal polarized beams on exit from the crystal, one of which is imaged on to the detector; all other wavelengths travel through the crystal without being diffracted along the incident ray. By changing the frequency of acoustic waves, the wavelength of diffracted light is changed. Spectral resolution depends on the size of the crystal. Advantages of such a spectrometer over a filter wheel or a grating monochromator include high resolution, high speed, random or sequential wavelength access, no moving parts, compact size, and imaging capabilities. A disadvantage is the high cost of the instrument.

Some types of the described spectrometers can be applied for NIR imaging purposes. FT-NIR and AOTF imaging spectrometers are already available on the market.

4.3
Terahertz Spectrometers

THz spectral instruments differ significantly from those for NIR, IR, and FIR spectroscopy. Figure 4.4 shows a typical schematic setup for coherent THz time-domain spectroscopy. The major components of a THz time-domain spectrometer are a femtosecond laser, a THz emitter, and a THz detector. Additionally needed are focusing and collimating optics for laser and THz radiation, a motorized delay line,

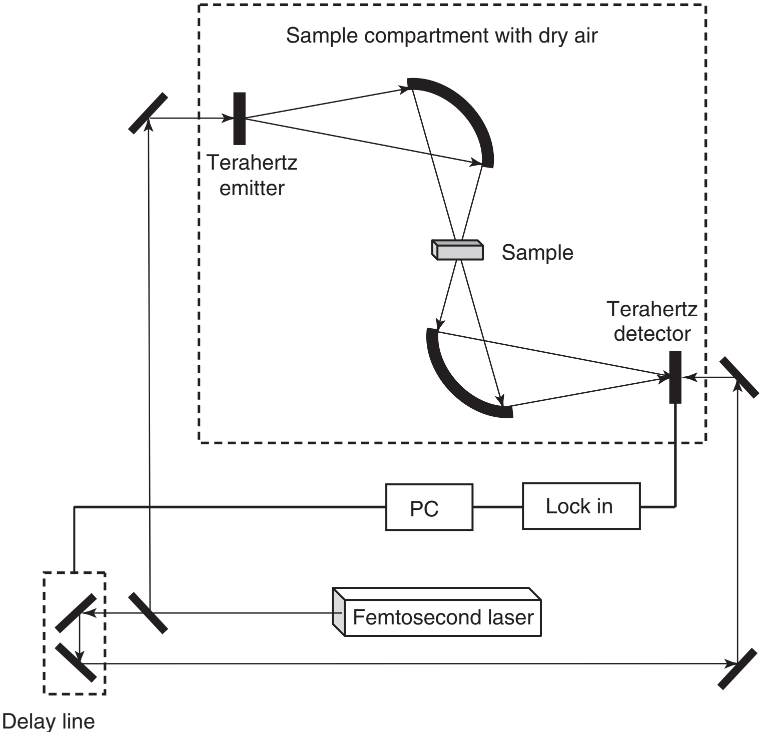

Figure 4.4 Setup of a terahertz spectrometer.

a lock-in amplifier, and a data acquisition system (PC). In contrast to conventional IR spectroscopy, THz radiation sources generate pulsed and coherent radiation. The THz source works like a photoconductive semiconductor antenna. When a femtosecond laser pulse is absorbed at the surface of a semiconductor, a single cycle THz transient is emitted. The surface of some semiconductors (for instance, InAs crystals) is a very efficient generator of THz radiation.

Neither a monochromator nor an interferometer is needed to obtain a THz spectrum. After Fourier transformation of the signal before the sample (reference) and after sample (reflection or transmission), the THz absorbance spectrum is obtained. Measured quantities are amplitude and phase of the THz pulse reflected by or transmitted through the sample. Therefore, both the absorption coefficient and the refractive index of the sample are measured directly.

4.4
Raman Spectrometers

Raman spectrometers are used to analyze light scattered by molecules. A major advantage of Raman spectroscopy is the high spatial resolution that can be obtained, typically in the order of 1 μm (compared to approximately 10 μm in case of IR).

In conventional Raman experiments, the sample is illuminated by monochromatic light. The registration of low-intensity Raman scattering in the presence of strong Tyndall and Rayleigh scattering implies special requirements to Raman spectrometers. A Raman spectrometer has to combine very good filter characteristics for eliminating Rayleigh and Tyndall scattering with high sensitivity for detecting very weak Raman bands. Currently, there are three types of Raman instruments available on the market:

1) Raman grating spectrometer with single channel detector
2) FT-Raman spectrometer with NIR excitation
3) Raman grating polychromator with multichannel detector.

All three types of the instruments have particular advantages and disadvantages for a given analytical task.

4.4.1
Raman Grating Spectrometer with Single Channel Detector

The Raman grating spectrometer with single channel detector is the conventional type of Raman instruments. It consists of three main parts: a monochromatic light source, a grating monochromator, and a single-channel detection system. Light sources in Raman spectrometers are lasers. The laser power impinging on the sample may vary between 10 and 1000 mW depending on the thermal stability of the latter. The laser may be continuous or quasi-continuous. The longer the wavelength of the laser the lower is the probability of generating fluorescence. On the other hand, the Raman scattering intensity diminishes proportional to the

Table 4.2 Lasers used with dispersive Raman instruments.

Laser	Type	Type of radiation	Wavelength (nm)	Maximum power (W)	Beam diameter (mm)	Price; comments
Ar^+	Gas	CW	488.0 514.5	4 4	1.5	Medium; standard source
Kr^+	Gas	CW	647.1 725.5	4	1.8	Medium; standard source
He–Ne	Gas	CW	632.8	0.05	1.1	Low; not intense
Liquid dye	Liquid	CW, pulsed, tunable	Depends on dye	0.1		Low; used mainly for RRS
Ti-sapphire	Solid	CW, pulsed, tunable	720–980	2	0.95	High; used mainly for RRS
Diode	Solid	CW	700–900	0.5		Very low; modern source

RRS, resonance Raman scattering.

fourth power of the laser wavelength. A list of most frequently used lasers in dispersive Raman instruments is given in Table 4.2.

Lasers with short pulses are not used in Raman spectrometers, mainly because detectors in Raman spectrometers are tuned to high sensitivity. Such detectors are very easy to saturate and this is a case when short and intense laser pulses are employed for excitation of Raman scattering. It must be noted, that gas lasers are not perfect sources of monochromatic radiation. Together with intense coherent radiation such lasers produce weak incoherent radiation, caused by different transitions between electronic energy levels of the gas. The intensity of this incoherent and noncollimated radiation can be suppressed by increasing the distance between the laser and the sample, by placing a spatial filter (consisting of two lenses and a pinhole) or a narrow-band filter (usually an interference filter) in to the laser beam.

The monochromator is the main part of a grating Raman instrument. Single monochromators should not be used in Raman spectrometers because of their insufficient performance in eliminating Rayleigh and Tyndall scattering. Instead, double or even triple monochromator systems are well suited. The common configuration for double monochromator systems is the so-called Czerny–Turner arrangement (Figure 4.5). Two identical monochromators are placed in such a way that their angular dispersions are coadded (additive mode). The slit between monochromators (intermediate slit) acts as a filter to prevent stray light from the first monochromator to enter the second one. In general, entrance, intermediate, and exit slit widths in a double monochromator Raman spectrometer are of the same size. A triple monochromator is preferred when very low-frequency Raman bands (frequency range close to laser frequency) have to be recorded. In addition

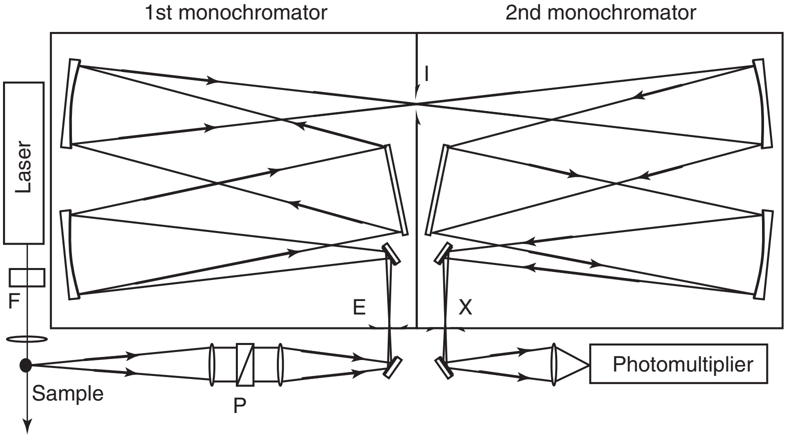

Figure 4.5 Dispersive grating Raman spectrometer with a single channel detector and double monochromator in Czerny-Turner configuration. F, narrow band filter; P, polarizer; E, entrance slit; I, intermediate slit; X, exit slit.

to their very low stray light level, triple monochromators in additive mode have high angular dispersion and permit the recording of Raman spectra with very good resolution.

4.4.1.1 **Detectors**

Detectors are crucial parts of Raman spectrometers because of the low intensity of Raman bands. Photomultipliers have excellent characteristics in ultraviolet and visible spectral regions; hence, they are preferred detectors in single-channel dispersive Raman spectrometer. The sensitivity of photomultipliers is limited by their dark current (residual electrical detector signal observed in the absence of any light). Dark current increases with temperature, that is, cooling increases the signal-to-noise ratio of photomultipliers. Liquid N_2 cooling provides the best performance, but for routine Raman experiments Peltier cooling often is sufficient.

4.4.1.2 **Calibration**

In case of dispersive instruments, the Raman spectrum is obtained as a function of the rotation of the dispersive element (prism or grating). In modern dispersive Raman instruments, a cosecant drive mechanism is used (usually, stepping motor), which provides a nearly linear relation between grating angle and Raman shift scale. In all cases, a calibration of the Raman shift scale by recording a well-known spectrum with narrow spectral bands is necessary. Atomic emission spectra are well suited as well. Very often an ordinary neon lamp is used, whose emission lines are narrow, intense, and distributed over a wide range in the visible. The line positions can be found in any catalog of atomic emission spectra. A frequently used calibration is the use of plasma lines of the Raman excitation laser itself: after setting up the Raman experiment, the laser resonator mirrors are slightly deadjusted. Under

Table 4.3 Intensities and positions of plasma lines of the Ar^+ laser.

such conditions, the laser emits weak atomic radiation, whose intensity is usually strong enough to obtain an atomic calibration spectrum. Intensities and positions of plasma spectral lines of the Ar^+ laser are listed in Table 4.3.

4.4.2
FT-Raman Spectrometers with Near-Infrared Excitation

Interferometers are superior to monochromators in obtaining spectra of electromagnetic radiation, but technical problems prevent interferometers from being used in routine spectrometers at wavelengths shorter than NIR. Fortunately, Raman excitation by NIR radiation is just possible (λ^{-4} law, cf. Section 3.3).

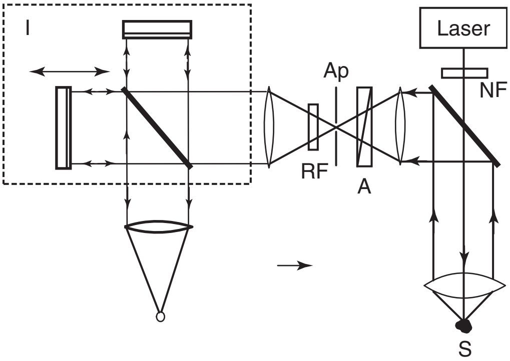

Figure 4.6 Basic diagram of an FT-Raman spectrometer. S, sample; NF, notch filter for rejecting not lasing radiation from laser; A, analyzer; RF, Rayleigh filter for rejecting radiation at laser frequency; Ap, aperture wheel; I, interferometer.

The laser in FT-Raman spectrometers (Figure 4.6) is the continuous wave Nd^{3+}/YAG system operating at 1064 nm with output power up to 2000 mW. The laser is optically pumped by either a lamp or a diode system. In both cases, nonlasing lines are generated. They have to be removed by very effective notch filters (NFs); otherwise, they get mixed up with the Raman spectrum and produce the so-called laser line artifacts.

The scattered radiation in an FT-Raman spectrometer contains Rayleigh and Tyndall radiation at laser frequency. Usually, scattered radiation at laser frequency is up to eight orders of magnitude more intense than the Raman scattering; hence, it can cause satusration or even damage of the detector. A so-called Rayleigh filter (RF) for filtering out radiation at laser frequency is an obligatory part of any FT-Raman spectrometer. The best RFs have a cut-off frequency closer than 50–40 cm^{-1} to the exciting laser frequency. RFs remain the main limiting factor, preventing application of FT-Raman spectrometers in low-frequency Raman spectroscopy.

4.4.3
Raman Grating Polychromator with Multichannel Detector

Conventional multichannel Raman instruments consist of a double monochromator working in the subtractive mode and a polychromator (Figure 4.7). The double monochromator acts as a filter for rejection of stray light at laser frequency. Common detectors in such instruments are nitrogen-cooled charge-coupled device (CCD) cameras with up to 1024 pixels in a row. This limited number of the pixels in a row does not allow to fully exploit the spectral resolution power of the polychromator in only one measurement. In order to obtain a complete Raman spectrum with spectral resolution 1 cm^{-1}, the spectrum should be measured with the above-mentioned configuration in at least four steps by measuring spectral intervals up to 1000 cm^{-1} and mechanically rotating the monochromator grating between measurements. After completion of the successive measurements, the

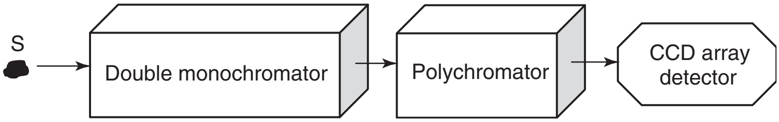

Figure 4.7 Block diagram of a conventional multichannel Raman spectrometer. S, sample. *Note*: the double monochromator is operating in subtractive mode.

spectra from different spectral regions are merged together by the instrument's software. In this kind of multichannel Raman instruments, rather sophisticated mechanical systems for rotating of gratings and changing opening of the slits of monochromators and spectrograph are used.

Recent achievements in the design of NIR diode lasers, of volume-phase transmission multiplexed holographic gratings and of sensitive CCD arrays allow to build very efficient multichannel Raman grating spectrometers, which can be considered as a new class of Raman instruments. In such modern spectrometers, a small holographic NF is used to reject the stray light at laser frequency instead of a large double monochromator (Figure 4.8). The reflectivity of the NF is very high and its bandwidth very narrow. The transmission at the center of the notch is less than 0.0001% and half maximum of the notch corresponds to 175 cm^{-1}. An NF is usually operated at normal incidence. Tilting the filter at a small angle (typically 15°) shifts the rejection band to lower frequencies. This allows one to use the NF line for low-frequency Raman applications as close as 40 cm^{-1} to the exciting laser. The conventional spectrograph is replaced by holographic transmission gratings. Several of such gratings may be assembled in order to extend the operating range of the system. Each grating may deflect the light to different areas on the CCD array detector. In such a way, modern multichannel Raman instruments permit the acquisition of complete Raman spectra at a spectral resolution of 2 cm^{-1} at once without rotating any grating.

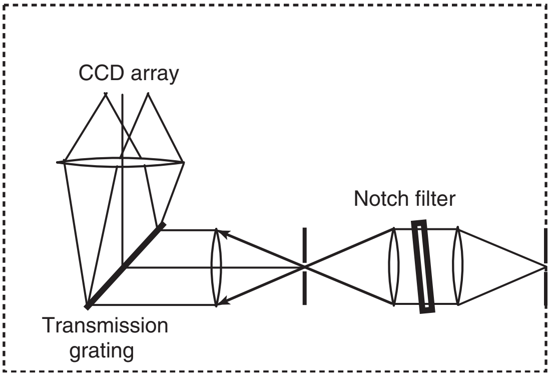

Figure 4.8 Basic diagram of an axial transmissive multichannel Raman instrument.

4.4.4
Handheld Raman Spectrometers

Recently, a new class of portable Raman instruments – the so-called handheld Raman spectrometers – was introduced to the market. The development of handheld Raman spectrometers has drastically changed the way (i) industry conducts quality control for incoming raw materials and (ii) security scans are performed. Such spectrometers permit tests of samples directly through transparent packing material such as glass or plastic. This approach minimizes risks of exposure and contamination of the material under study.

Handheld Raman spectrometers are based on grating polychromators equipped with CCD detectors. These spectrometers usually have no moving parts and the whole spectrum can be acquired at once. Their technical parameters are comparable to bench top Raman spectrometers, and they perform sufficiently well for express analysis of chemical materials. Typical parameters of handheld Raman spectrometers are summarized in Table 4.4.

The general layout of handheld Raman spectrometers is presented in Figure 4.9. The Raman signal is collected from the focal point of the microscope objective (located at working distance of the spectrometer), which focuses the laser beam on the surface of the sample under investigation. A long-wave pass (LWP) filter insures that only Stokes-Raman scattered light enters the grating polychromator. If the sample is packed, usually the packing material does not touch the sample surface and the laser beam remains unfocused across the packing material, which ensures only very weak Raman signals of the packing material. This signal does not disturb the Raman signal of the sample under investigation. When packed samples have to be analyzed with the handheld Raman spectrometer, the main requirement is the transparency of the packing material to the laser light at 785 nm.

Handheld Raman spectrometers are usually equipped with various accessories – sample holders, fibers, and probes – for measuring Raman spectra of samples in liquid, amorphous, and crystalline states.

Table 4.4 Typical parameters of handheld Raman spectrometers.

Raman spectral range (Raman shift)	170–2900 cm^{-1}
Spectral resolution	From 7 to 11 cm^{-1}
Excitation laser	Diode laser at 785 nm
Laser power	Up to 300 mW
Working distance	116–200 mm
Laser spot diameter	0.2–2.5 mm
Detector	Thermoelectrically cooled linear CCD array
Weight	1–2 kg
Maximal working time on battery	Up to 5 h

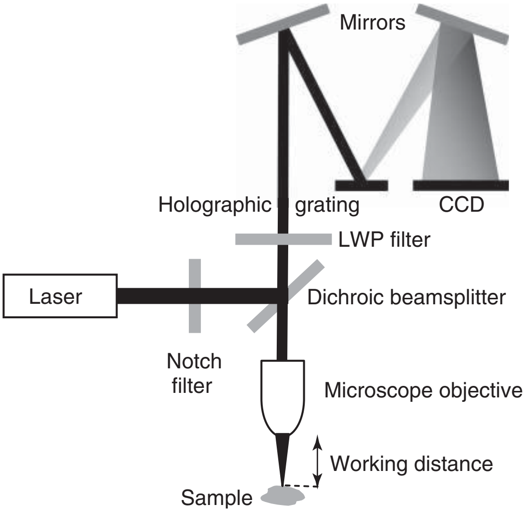

Figure 4.9 General schematics of a handheld Raman spectrometer.

4.5
UV/vis Spectrometers

The UV/vis spectral region extends from 190 to 400 nm (UV range) and from 400 to 780 (visible range). In order to obtain complete spectra in the UV/vis range, dual beam dispersive scanning instruments or dispersive multichannel instruments are employed. UV/vis scanning spectrometers consist of a light source, a monochromator, a chopper (rotating sector mirror or rotating sector disk) to generate a sample and a reference beam as well as to recombine them, a sample and reference compartment, and a detector (Figure 4.10). Spectrometers, which permit a synchronous measurement of sample and reference beams, are denoted double-beam instruments (cf. Section 4.1.1). Note the position of sample and reference after the monochromator in this type of UV/vis spectrometer. There they are substantially less exposed to the high-energy UV radiation than directly after the source. The disadvantage of this optical layout is its sensitivity to ambient stray light, which may directly reach the detector if the sample chamber is not fully covered.

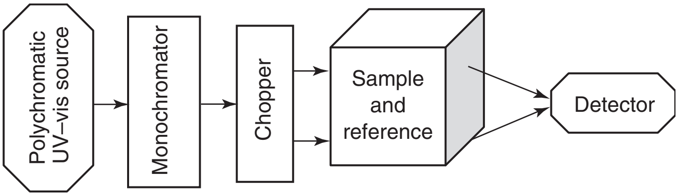

Figure 4.10 Block diagram of a UV/vis scanning spectrometer.

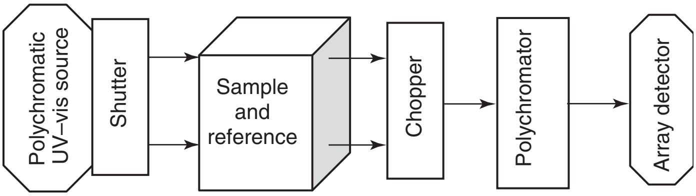

Figure 4.11 Block diagram of a UV/vis multichannel spectrometer.

A multichannel spectrometer has a light source with shutter, a sample and reference compartment, a grating polychromator, and a diode array detector (Figure 4.11). All spectral elements are recorded simultaneously by the array detector, that is, the measuring time with the shutter in its open position is very short. The short illumination time permits the sample and reference positions immediately after the light source. Multichannel spectrometers may also be constructed as double-beam instruments. For special measurements, for example, rapid kinetic investigations, when the chopper frequency is too low with respect to the speed of the process under investigation, double-beam instruments with two separate detectors are used.

UV/vis absorption spectra may be obtained with single-beam instruments as well. In single-beam spectrometers, the background and sample spectra are measured one after the other. As chopper and reference chamber are not needed, single-beam instruments are usually cheaper than double-beam instruments.

4.5.1
Sources

The most used light sources are deuterium lamps in the region from 180 to 350 nm and tungsten filament and halogen lamps in the region from 330 to 900 nm. A light source for the complete range is the xenon arc from 175 to 1000 nm. Furthermore, for special applications such as high-resolution studies, tunable lasers can be used. For time-resolved measurements, pulsed arc lamps can be used.

4.5.2
Monochromators

The cheapest versions for dedicated applications are filter monochromators. Monochromators in routine spectrometers usually have a prism or diffraction grating. The complete spectrum can be measured by turning the prism or grating. The slit width and the dispersion of the monochromator determine the SBW. The SBW of single monochromators does not extend below 5 nm. For applications that require higher resolution, the use of double monochromators with SBWs down to 1 nm is necessary. In addition, double monochromators improve the stray light rejection and allow measurement of samples with high optical density. The drawback of double monochromator systems is their lower optical throughput, which deteriorates the signal-to-noise ratio.

4.5.3
Detectors

Standard UV/vis detectors are photomultipliers and silicon diodes. Silicon diodes are smaller and cheaper, whereas photomultipliers have a higher sensitivity. Most research instruments are based on photomultipliers. The recent development is the use of photomultiplier arrays and CCD cameras as in all other spectroscopic methods.

An important consideration for all types of instruments is the linear absorption range, that is, maximum absorption measured at a predetermined accuracy. The photometric accuracy depends on the instrument's electronics, which may be sensitive to ambient temperature and humidity. Spectrometers should be calibrated from time to time. Commonly used for absorbance calibration are neutral density filters of well-defined absorbance. Solutions of potassium chromate and potassium dichromate are also widely used as reference standards for validating the photometric scale. Current estimations for linear absorption limits are 1 absorption unit for multichannel instruments or scanning dispersive instruments with single monochromator, and 2.5 absorption units for dispersive instruments with double monochromator.

The exit beam from the monochromator includes some amount of unwanted stray radiation. This is partly caused by imperfections in the diffraction grating (or prism) and partly by undesired reflections at optical surfaces. For accurate results of the measurements, it is vital to use a spectrometer with stray light levels as low as possible. Hence it is desired to have a method for measuring such levels. The usual method for the measurement of stray light in a spectrometer is to insert into the optical path a blocking filter that absorbs nearly completely at the wavelength of interest while passing radiation at other frequencies unattenuatedly. A signal observed by the detector under these conditions at the wavelength of interest is due to stray radiation. Materials for checking and calibration of UV/vis spectrometers recommended by the U.S. National Bureau of Standards are listed in Table 4.5.

As in case of dispersive Raman spectrometers (cf. Section 4.4.1), it is necessary to calibrate the wavelength scale of dispersive UV/vis spectrometers. The most accurate standards for checking the UV/vis wavelengths are lasers of various types. The inexpensive helium–neon laser can be used to check at 632.8 nm. For spectrometers with a deuterium source, spectral lines at 486.6 and 656.1 nm can be used for calibration. A common method for wavelength calibration is the use of optical filters. A filter of didymium glass has many sharp absorption peaks, which can be used as a second wavelength standard (precision within 0.5 nm).

If measurements have to be done in the UV region below 240 nm, it is necessary to purge the spectrometer with dry nitrogen gas in order to remove oxygen. Oxygen absorbs at wavelengths shorter that 240 nm and is transformed into ozone. Absorption by oxygen molecules inside an instrument can make measurements

Table 4.5 Standard reference materials (SRMs) for UV/vis spectrophotometry used at the National Bureau of Standards (NBS).[a]

SRM number	Type	Parameter checked	Wavelength range (nm)
930Dmm	Glass filters	Transmittance	440–635
931d	Liquid filters	Absorbance	302–678
932	Quartz cuvette	Pathlength	—
935	Potassium dichromate	UV absorbance	235–350
2009	Didymium-oxide glass	Wavelength	400–760
2031	Metal-on-quartz filters	Transmittance	250–635
2032	Potassium iodide	Stray light	240–280
2034	Holmium oxide solution	Wavelength	240–650
936	Quinine sulfate dihydrate	Fluorescence	375–675

[a] A more complete description can be found in R. Mavrodineanu, J.I. Schultz, and O. Menis, *Accuracy in Spectrophotometry and Luminescence Measurements*, National Bureau of Standards Special Publication 378, National Bureau of Standards, Washington, DC, 1973.

below 240 nm meaningless. Moreover, ozone is very reactive and can cause damage to optical and mechanical components of the spectrometer.

4.6
Fluorescence Spectrometers

Basically, instruments for measuring fluorescence and phosphorescence spectra have similar construction and should be called *luminescence spectrometers*. But the group of molecules that exhibit fluorescence is by far larger than that exhibiting phosphorescence; hence, the term *fluorescence spectrometer* is used. The main spectral features of luminescence are spectral distribution, polarization, and radiation lifetime. For analytical purposes, mainly spectral distribution and polarization are used. Measuring of the lifetimes requires rather sophisticated time-resolved spectroscopic techniques. The latter is very seldom used for analytical purposes and will not be discussed in this chapter.

Two basic types of spectra can be produced by a conventional fluorescence spectrometer. In the emission spectrum, the wavelength of the exciting radiation is held constant (at an absorption wavelength of the analyte) and the spectral distribution of the emitted radiation is measured. In the excitation spectrum, the fluorescence signal is measured at a fixed wavelength of the emission selector, as the wavelength of the exciting radiation is varied. An analyte can fluoresce only after it has absorbed radiation, and an excitation spectrum identifies the wavelengths of light that the analyte is able to absorb. Thus, the excitation spectrum of a molecule should be the same as its UV/vis absorption spectrum.

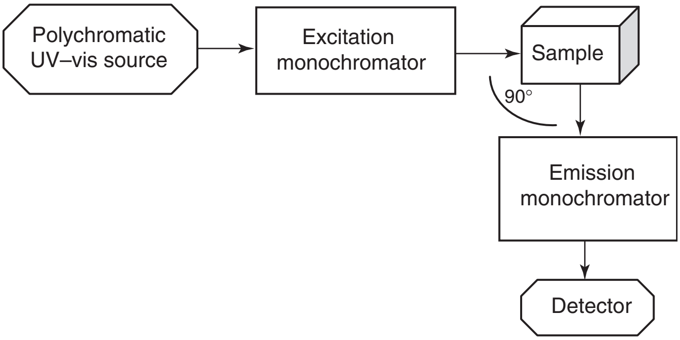

Figure 4.12 Block diagram of a fluorescence spectrometer.

A general layout of a fluorescent spectrometer is shown in Figure 4.12. The instrument contains the source of UV/vis radiation, an excitation wavelength selector, an emission wavelength selector, a sample chamber, and a detector. Basically this is a single beam instrument. The fluorescence emitted by the sample is usually measured at 90° in order to avoid disturbances by nonabsorbed excitation radiation.

The excitation wavelength selector can be either a filter or a monochromator. Filters offer better detection limits, but do not provide spectral scanning capabilities. Often, a filter is used in the excitation beam along with a monochromator in the emission beam to allow emission spectra to be acquired. Full emission and excitation spectral information can be acquired only if monochromators are used in both the excitation and emission beams. In modern instruments with array detectors, a polychromator is used in the emission beam instead of a monochromator. Recent research instruments are able to scan both excitation and emission automatically and combine all data into a 2D excitation–emission spectrum. In lifetime spectrometers, a pulsed light source and a gated detector are synchronized in order to measure the time dependence of the luminescence emission.

The luminescence intensity is directly proportional to the intensity of the light source, and a high-intensity light source can therefore be used to increase the sensitivity and to lower the detection limits for luminescence analyses. The xenon arc lamp is a commonly used source. The Xe lamp emits continuously over a broad wavelength range and is therefore well suited for spectral scanning. Another common source is the high-pressure mercury arc lamp. Its output is a continuum with a line spectrum superimposed, making the mercury lamp better suited to nonscanning filter instruments. Other sources include halogen lamps and combined xenon-mercury lamps. Lasers are also used in luminescence experiments, in which continuous scanning of excitation is not required. Tunable lasers can be used to provide multiwavelength excitation capabilities. The excitation laser beam must often be greatly attenuated in order to avoid photodecomposition of the sample.

Pulsed sources, including both lamps and lasers, are used for special applications such as dynamic measurements of luminescence lifetimes and time-resolved elimination of background signals.

Photomultiplier tubes (PMTs) are the most commonly used detectors, and various types are available for different applications. In general, they are sensitive in the range from 200 to 600 nm, with maximum sensitivity obtained in the 300–500 nm range. Red-sensitive PMTs are also available for investigations beyond 600 nm. The PMT housings are sometimes cooled to temperatures as low as −40 °C to minimize temperature-dependent noise.

Among the more commonly used multichannel detectors are diode arrays, vidicons, silicon intensified target vidicons, CCD and charge-injection devices, and numerous other devices made available by recent technological advances. The use of multichannel detectors in fluorescent spectrometers has increased the range of applications of luminescence experiments to include real-time experiments, kinetic measurements, and on-line detection for chromatography and other flow systems. The ability to acquire complete spectral information nearly instantaneously has also greatly facilitated qualitative analysis by reducing the time required per analysis.

Fluorescence spectrometers can be used to measure fluorescence polarization by placing polarizers in the excitation and emission beams. High-quality instrumentation for polarized fluorescence measurements is commercially available.

As most fluorescence spectrometers are single-beam instruments, different kinds of distortions may be found in excitation and emission spectra. These distortions are mainly due to variations of source power or detector sensitivity with wavelength. Spectra of the same sample obtained using two different fluorescence spectrometers may therefore be quite different. Even changing the source or detector in a spectrometer may alter the apparent fluorescence or excitation spectrum of a compound. These artifacts can be eliminated instrumentally, and several instruments that can produce corrected spectra are commercially available. Unfortunately, most published spectra are uncorrected; they cannot be fully reproduced by other investigators. There exist only few extensive and broadly used databases of fluorescence spectra.

4.7
Spectral Imaging Devices

A spectral image of some area of a sample can be obtained using one of two experimental approaches: (i) only a very small sample area is illuminated by the light beam and the light-response from the sample is collected by a single detector and (ii) the whole area of interest is illuminated by the light beam and the light-response from the sample is collected by a two-dimensional detector array (FPA). In the former case, a spectral image can be composed after measuring at one point and subsequently moving the sample step by step by a motorized x,y stage. The point-by-point measurement of a spectral image is correctly called *spectral mapping* (Figure 4.13a). In the latter case, a complete spectral image is directly delivered by the detector array (Figure 4.13b). If small samples or small areas of interest are to be imaged, a microscope is necessary in order to focus the sensing light beam precisely and to select the sample area for imaging exactly. Usually, commercial IR

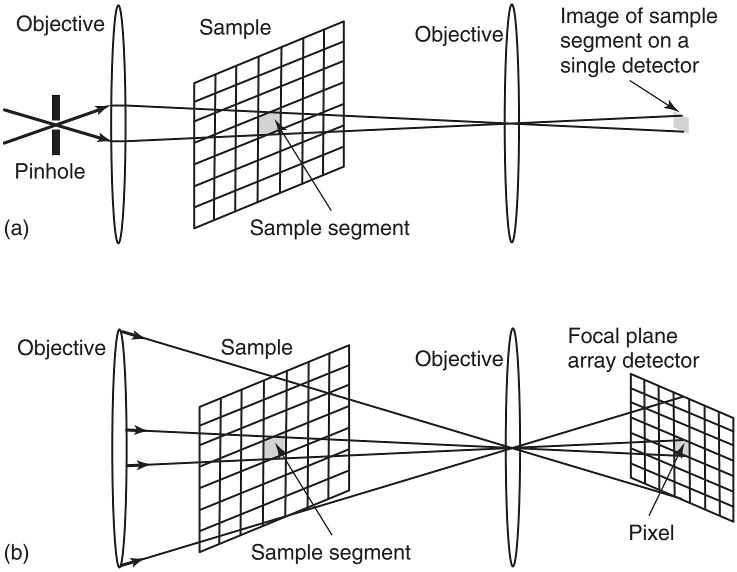

Figure 4.13 Simplified drawing of the concepts of (a) spectral mapping with a single detector and (b) spectral imaging with a focal plane array detector.

microscopes can be used in both modes – mapping and imaging. Larger samples can either be placed in the usual position in the sample chamber and imaged at a relatively low spatial resolution or they can be placed under the microscope, and the area of interest can be covered by a sequence of small images at high spatial resolution. This procedure is often called *tiling*.

The layout of the required microscope strongly depends on the spectral experiment. An example of an experimental setup for the imaging in NIR and MIR spectral regions is presented in Figure 4.14. This setup is rather common nowadays.

The instrument consists of a commercially available IR Michelson-type step-scan interferometer coupled to an IR microscope. Two identical IR objectives are used to illuminate the sample and to collect the signal. The IR objectives consist of mirrors in Cassegrainian configuration in order to reduce the required focal length and to maintain perfect focusing throughout the whole IR spectral region. Moreover, Cassegrainian objectives in comparison to conventional ones do not suffer from absorption within the objective material. The signal is detected either by an MCT detector for the MIR spectral region or by an indium antimonide detector for the NIR spectral region.

FT-IR imaging simultaneously collects full IR spectral data from a wide sample area. The FPA detector is an IR camera consisting of many single detectors. Typical array sizes of the FPA detectors are 32 × 32, 64 × 64, 128 × 128 detector elements. An IR spectroscopic image can also be obtained with a linear array of individual detectors (16 × 1 up to 256 × 1 detector elements) in combination with an x,y scanner to produce a spectroscopic map. Linear array detectors may be advantageous in case of small sample areas, which can be captured rapidly.

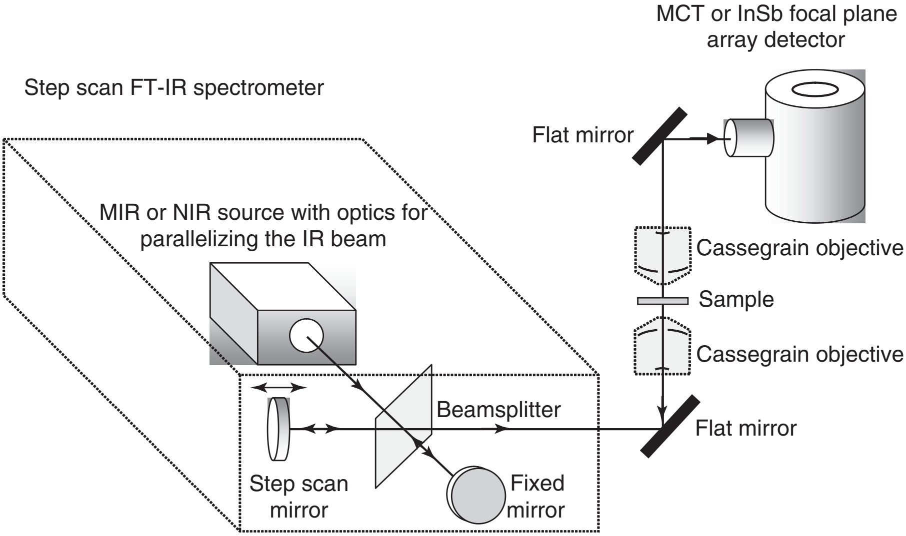

Figure 4.14 Block diagram of an FT-IR imaging spectrometer.

In standard IR microscope configurations, the array detector comes as 64 × 64 pixel array, but higher resolution FPA detectors are already available on the market. Each of the 4096 pixels of a 64 × 64 FPA detector provides a full FT-IR spectrum. In case of standard 15× Cassegrainian objectives, each pixel covers approximately a 7–8 μm^2 sample area. Consequently, 4096 spectra are recorded simultaneously from a 170 μm × 170 μm sample area at a diffraction limited spatial resolution of 10 μm at a wavenumber of 1500 cm^{-1} or at correspondingly higher resolution at higher wavenumbers.

Reading data from a 64 × 64 or larger FPA array is a time-consuming process, because frame rates (time to read one complete image) do not exceed a couple of kilohertz. This is much too slow to capture the interferogram produced by a continuously scanning interferometer with sufficient precision. For this reason, a step-scan interferometer has to be used. The step-scan process involves data collection at exact time intervals during the cycle of mirror displacement. Unlike the continuous process that collects frequency data continuously as a function of time and mirror displacement, frequency data are collected on a step-scan optical bench at each step for a fixed time through the displacement sequence.

There are a couple of sample handling modes available in IR imaging. This includes specular reflection, attenuated total reflection, and grazing angle reflection. A special objective is required for each imaging mode. The objectives can be obtained from manufacturers of IR microscopes. The imaged area of the sample can be increased either by tiling (see preceding text) or by using objectives with lower magnification together with a so-called macrochamber – a special compartment that accommodates the sample and the objectives.

4.8
Instrumentation for Nonlinear Vibrational Spectroscopy

Recent advances in laser technology made high-power tunable lasers available at moderate prices. This development provides easier access to investigation of various spectroscopic multiwave mixing processes. Hyper Raman scattering (HRS), stimulated Raman scattering (SRS), second harmonic generation (SHG), SFG, and coherent anti-Stokes Raman scattering (CARS) are typical examples of such experiments. Some of them already found application in spectroscopic and spectromicroscopic structural studies of biological samples. Compared to conventional (linear) methods such as IR absorption and spontaneous Raman scattering (cf. Section 3.3), the main advantage of nonlinear methods of vibrational spectroscopy is their extremely high sensitivity. This enhanced sensitivity enables the investigation of smallest amounts of substance (low concentrated solutions, ultrathin films, interfaces) or permits mapping of chemical images. Some nonlinear spectroscopic setups are already commercially available. This is particularly true for SRS, SFG, and CARS spectrometers. General features of their setups are presented in subsequent text.

4.8.1
Stimulated Raman Scattering (SRS) Spectrometers

SRS is quantum mechanically described as a two-photon stimulated process where one pump photon at ν_p is annihilated (stimulated Raman loss (SRL)) and one Stokes photon at ν_t is created (stimulated Raman gain (SRG)), while the Raman medium makes a transition from the lowest vibrational state to the vibrationally excited state. SRS then appears in the form of a gain or a loss of the Stokes and pump laser beams on the sample, when the difference in laser frequencies matches a particular molecular frequency. An energy-level diagram for the SRS four-wave mixing process is presented in Figure 4.15a. When the difference frequency does not match any molecular frequency, no signal is generated. Thus, the SRS spectrum is essentially identical to a conventional Raman spectrum, making spectral assignment much easier than in CARS. Similar to CARS microscopy, SRS microscopy allows three-dimensional imaging of specific molecular species to a depth of about 0.3 mm.

The general experimental layout of an SRS microscope is schematically depicted in Figure 4.15b. The pump and Stokes pulse trains are provided by two electronically synchronized lasers (usually Ti:sapphire lasers). The wavelengths of both lasers are independently tunable. Both the pump and Stokes beams are expanded to fill the back aperture of the microscope objective before being combined on a dichroicbeam combiner (BC) and directed into a microscope. A microscope objective is used to focus the collimated and collinear pump and Stokes beams into the sample. The transmitted pump beam is collected in the forward direction by a second objective and spectrally isolated from the Stokes beam by a stack of short-pass filters.

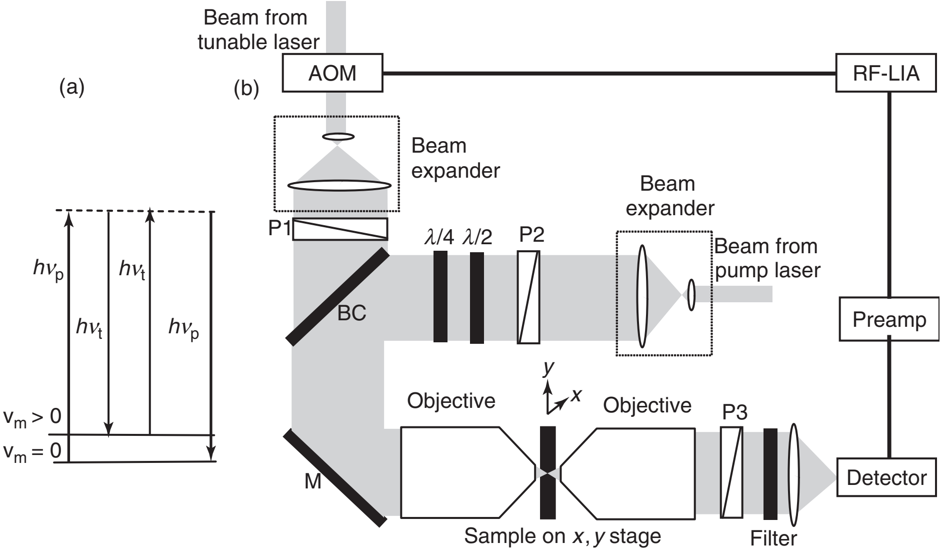

Figure 4.15 (a) Transitions between molecular energy levels during SRS: ν_p, frequency of high-power pump laser; ν_t, frequency of tunable laser; ν_m, quantum number of *m*-vibrational mode; (b) Layout of an SRS microscope: BC, dichroic beam combiner; P, polarizer; M, mirror; λ/2 and λ/4, phase plates; AOM, acousto-optical modulator; Preamp, preamplifier; RF-LIA, radiofrequency lock-in amplifier.

It is crucial to modulate the Stokes beam in the SRL experiment. The SRL (or SRG) in an SRS experiment is very small in comparison to the laser intensity. Therefore, the SRS signal cannot be measured directly. High-frequency modulation of tunable laser modulation has to be used. In the modulated signal, the AC component is proportional to SRS signal while the DC component is proportional to the tunable laser intensity. For the modulation, an acousto-optical modulator (AOM) operating at a frequency of a couple of megahertz is used. The modulation of the pump intensity due to SRL is detected by a diode detector, a current preamplifier, and a radiofrequency lock-in amplifier (RF-LIA). The SRS images can be collected by raster scanning the sample, using an *x,y,z* piezo-driven scanner, which limits pixel dwell times to a few milliseconds. The scanning can be significantly speeded up when laser beam-scanning schemes are used instead.

4.8.2
Sum Frequency Generation (SFG) Spectrometers

SFG spectroscopy is based on the fact that for most materials the second-order nonlinear susceptibility is nonzero only at the surface. Overlapping irradiation of a particular sample region by IR (ν_{IR}) and visible (ν_{vis}) laser beams may result in the generation of sum frequency (SF) radiation ($\nu_{SF} = \nu_{IR} + \nu_{vis}$). This excitation mechanism makes SFG spectroscopy an ideal method for studying molecules at

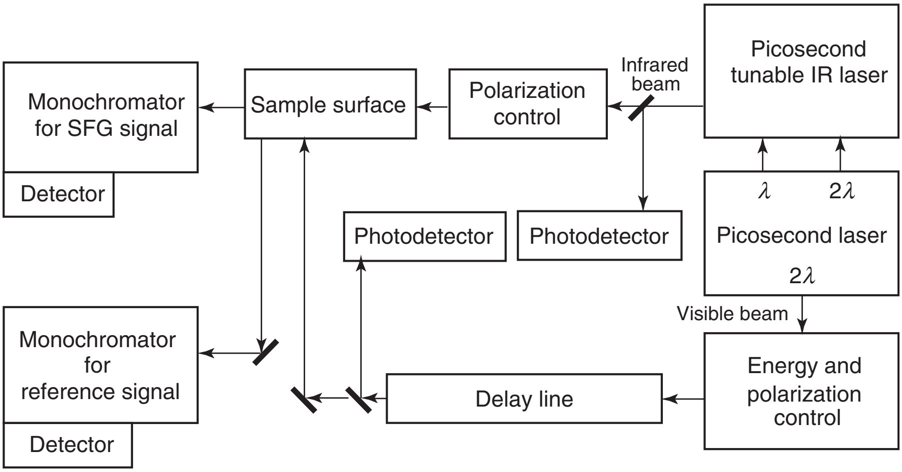

Figure 4.16 Block diagram of an SFG spectrometer.

surfaces and even at buried interfaces because of its selectivity to surface regions and its higher degree of molecular specificity.

At present, two basic SFG setups are used for the tunable radiation: (i) a picosecond system with tunable IR wavelength and (ii) a femtosecond system with large SBW. An example of a picosecond system is presented in Figure 4.16. In its standard configuration, a picosecond tunable laser (optical parametric generator) is used to generate IR light in the spectral region of about 4300–1000 cm^{-1}. This region is considered the easily accessible IR region for the SFG technique. Manufacturers of SFG spectrometers claim that this region can be extended down to 600 cm^{-1}.

Most of the SFG experiments are time resolved and employ a variable delay between the laser pulses. Initially, the system is brought out of equilibrium by an excitation (pump) pulse, afterwards the return to equilibrium is monitored by a delay (probe) pulse or a pair of probe pulses at different times after the pump pulse. The three scenarios of time-resolved SFG experiments are (i) two pulses – IR and vis – are slightly delayed with respect to each other but an overlap of the pulses in the time domain persists; (ii) two pulses – IR and vis – do not overlap in the time domain, the delay time between them may vary; and (iii) three pulses – one intense IR and an IR/vis pair – do not overlap in the time domain, the delay time between them may vary.

SFG spectrometers are still a state-of-the-art technique in nonlinear optics; hence, SFG spectroscopy cannot yet be considered a routine technique. Knowledge of basic and nonlinear optics is needed for running an SFG spectrometer.

4.8.3
Coherent Anti-Stokes Raman Scattering (CARS) Systems

CARS is a nonlinear Raman technique in which two lasers (a pump pulse and an anti-Stokes pulse from a tunable laser) interact with the sample. When the

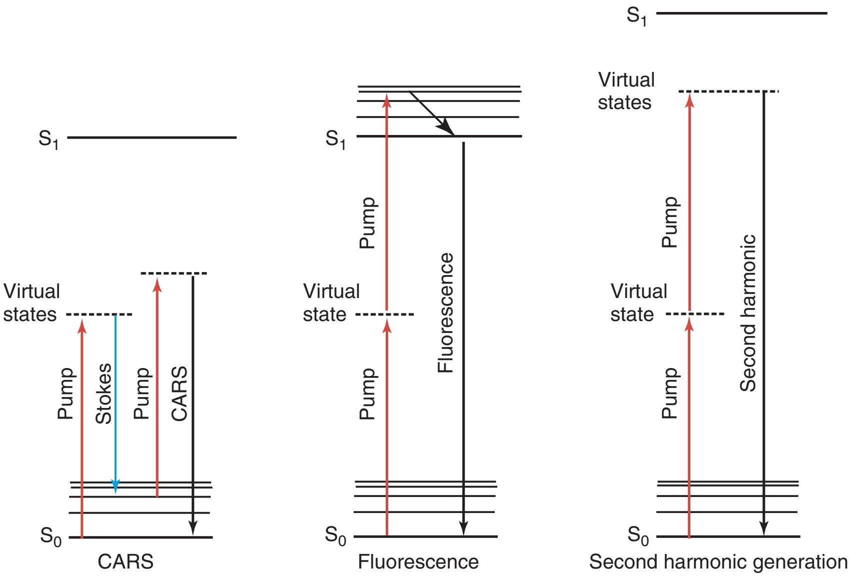

Figure 4.17 Jablonski diagrams of imaging techniques that can be used with a single setup.

difference in frequency between the two pulses matches a molecular vibrational transition, the anti-Stokes field will be resonantly enhanced. Because of its coherent nature, in which the molecular bonds oscillate in phase and interfere constructively, and its active pumping of the vibrational states, the CARS signal is at least five orders of magnitude more sensitive than spontaneous Raman scattering. One important exception in CARS is the symmetric CH_2 stretching mode at 2850 cm^{-1}. A limiting factor of CARS is the nonresonant background. The nonresonant background signal originates from instantaneous four-photon mixing processes. As the linewidth of most Raman active transitions is typically around 10–20 cm^{-1}, picosecond pulses are the optimum for a CARS setup. With spectrally broader femtosecond pulses, other multiphoton processes such as fluorescence or SHG can be used with the same setup. Figure 4.17 shows the Jablonski diagram of the CARS, fluorescence, and SHG processes.

The basic configuration of a CARS spectrometer is presented in Figure 4.18. Two lasers are used to excite the CARS signal. A powerful pump laser at the frequency ν_p excites the molecule to a virtual energy level. Lower energy (anti-Stokes) photons from the tunable laser ν_t initiate stimulated emission, when it is tuned to a frequency equivalent to the energy difference between the virtual and some excited vibrational ($\nu_m > 0$) state of the molecule under investigation. A second ν_p photon brings the molecule to another virtual state and finally the molecule returns to its initial vibrational state by emitting a photon in the anti-Stokes region. This secondary emission is coherent. Four wave vectors are involved in this process and the phase matching conditions has to be fulfilled. Therefore, the collinear beam

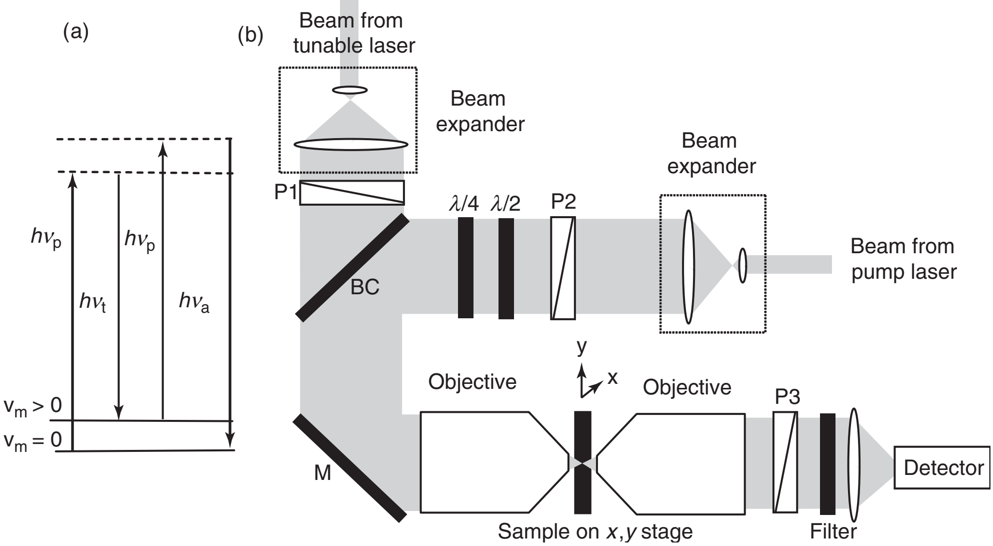

Figure 4.18 (a) Transitions between molecular energy levels during CARS: ν_p, frequency of high-power pump laser; ν_t, frequency of tunable laser; ν_a, frequency of coherent anti-Stokes Raman scattering band; ν_m, quantum number of *m*-vibrational mode; (b) Layout of a CARS spectrometer: BC, dichroic beam combiner; P, polarizer; M, mirror; λ/2 and λ/4, phase plates.

geometry became the configuration of choice in CARS microscopy. The CARS signal can be observed either in forward direction (depicted in Figure 4.18) or backward direction. For investigation of a backscattered CARS signal, the mirror M in the spectrometer setup has to be replaced by some dichroic beamsplitter. The CARS signal emitted by the sample is accompanied by radiations from pump and tunable lasers. These radiations are usually removed by placing a high-pass filter between sample and detector. The filter transmits only CARS radiation owing to its higher frequency.

Very important issues in the construction of CARS spectrometers are the large diameters of both parallel laser beams and the very short focal length of the objective used to focus the beams on the sample. The phase-matching conditions in collinear CARS microscopy can only be fulfilled by tight focusing: a small dimension of the excitation volume and a large cone angle of wave vectors compensate the wave vector mismatch induced by the spectral dispersion of the refractive index of the sample. Beam expanders are used to condition the beams. Expanded beams from pump and tunable lasers are combined by means of the BC. Another important issue concerning the CARS signal is the strong background. Electronic contributions to the third-order susceptibility of sample and solvent cause a nonresonant background signal, which provides no vibrational contrast. In addition, the solvent water has strong resonant signals of broad spectral width. Both background signals often overwhelm the CARS signal from small objects and limit the sensitivity. Polarizers P and phase plates $\lambda/2$ and $\lambda/4$ are used to diminish the level of this background and to increase the signal-to-noise ratio of the CARS signal. Another way to suppress the background involves a slight rearrangement of the experimental setup in order to observe the SRS (see preceding text) instead of the CARS signal. The CARS signal from an area of the sample as small as $0.5\,\mu m \times 0.5\,\mu m$, defined by the size of the focused laser beams on the sample, can be measured in a fraction of milliseconds. This makes CARS very attractive for chemical imaging.

CARS imaging has emerged in recent years as a new imaging technique. In CARS microscopy, both laser beams are collinearly directed into a microscope so that the pulses overlap in space and time. As they are raster scanned across the sample, the intensity of the anti-Stokes signal is captured point by point and transferred into a two-dimensional image. The scanning rate is often in the range of video rates. A CARS image of a sample area equal to $100\,\mu m \times 100\,\mu m$ using a high-speed x,y piezo stage can be obtained in a couple of minutes. 3D CARS images can be obtained by adding the third coordinate to the sample stage. CARS spectra can be measured over a wide frequency range. The low-frequency limit is usually located at $400-500\,cm^{-1}$. This limit is related to the insufficient steepness of the filter used to prevent the lasers beams from reaching the detector.

5
Measurement Techniques

Gerald Steiner

Upon interacting with a sample, incident light of intensity I_0 may partly be reflected at optical interfaces (I_R), it may be scattered (I_S) and absorbed in the sample (I_A), the remaining part will be transmitted (I_T) (Figure 5.1).

According to the law of conservation of energy, the energy balance for the incident light may be written as

$$I_0 = I_A + I_T + I_R + I_S \tag{5.1}$$

The light intensities I_0, I_T, I_R, and I_s can easily be measured by placing a detector at the corresponding position. All chemical information about the sample goes into I_A, but this value cannot directly be measured. I_A can only be accessed by evaluating Eq. (5.1). In all commercial spectrometers, only one detector is used to measure a particular couple of intensity values (I_0 and either I_T, I_R, or I_S; cf. Table 5.1). It is the goal of sample preparation to bring the remaining intensities to zero (or at least very close to it). Neglecting these basic considerations will result in measurement errors, which can never be eliminated by subsequent digital data treatment.

5.1
Transmission Measurements

Transmission spectroscopy is the most widely used measurement technique. It is simple and can be applied to characterize gases, liquids, and solids. Quantitative evaluations are based on the Beer–Lambert law as described in Chapter 3. Typical sample cells for gases and liquids are shown in Figure 5.2. Note the polished windows in the light path, while the other cell walls may be opaque. Polished windows must not be touched or even scratched. Fingerprints in the light path cause light scattering, and hence deteriorate the accuracy of the measurement. Normal incidence of the incoming light is required in order to minimize reflection.

The range of use of a particular cell depends on the window material. Most common materials for optical windows or fibers are summarized in Table 5.2. The refractive index of the window material should be very close to that of the sample in order to avoid reflection or scattering contributions.

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

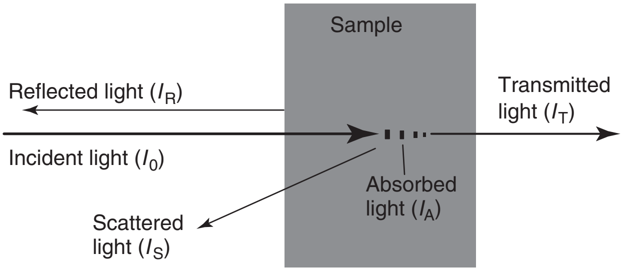

Figure 5.1 Energy balance of incident light on interaction with a sample.

Table 5.1 Measured and illicit contributions of light.

Measured	Aim of sample preparation	Evaluation	Experimental technique
I_0, I_T	$I_R = I_S = 0$	$I_A = I_0 - I_T$	Transmission measurement
I_0, I_R	$I_T = I_S = 0$	$I_A = I_0 - I_R$	Reflection measurements
I_0, I_S	$I_T = I_R = 0$	$I_A = I_0 - I_S$	Diffuse reflection measurements

Table 5.2 Window or fiber material for optical spectroscopy.

Material	Transmission range (μm)	Refractive index (@ 20 °C)	Used for	Solubility
Optical glasses (SiO_2) Quartz	0.2–2.2	1.6 @ 0.2 μm 1.5 @ 2 μm	Windows, fibers	High resistance to acids (except hydrofluoric acid)
Fused silica	0.2–2.5	1.55 @ 0.2 μm 1.44 @ 2 μm		
Sapphire (single crystal Al_2O_3)	0.2–4.5	1.73 @ vis, 1.65 @ 4 μm	Fibers, ATR crystals	High resistance to acids and alkali at temperatures up to 1000 °C very hard
KBr	0.25–25	1.5	Windows, pellets	Soluble in water (53 g/100 ml H_2O) and alcohol
KRS-5 (TlBr/TlI)	0.3–40	2.4	Windows	Slightly soluble in water (0.02 g/100 ml H_2O), vulnerable to organic solvents, toxic
CsI	0.3–60		Windows	Soluble in water (44 g/100 ml H_2O) and alcohol
NaCl	0.3–16	1.55	Windows	Soluble in water (36 g/100 ml H_2O), slightly soluble in alcohol
CaF_2	0.2–10	1.4	Windows	Soluble in solutions of ammonium salts
Silicon (Si)	1.5–10	3.5 @ 1.5 μm 3.4 @ 10 μm	ATR crystals	Hard
Germanium (Ge)	2.0–15	4.1 @ 2 μm 3.9 @ 15 μm	ATR crystals	Soluble in mixtures of HCl and HNO_3 and H_2O_2
Zinc selenide (ZnSe, Irtran-4)	0.6–15	2.5 @ 0.6 μm 2.3 @ 15 μm	ATR crystals, windows	Soluble in acids, solubility in water @296 K: 0.001 g/100 H_2O
Zinc sulfide (ZnS, Irtran-2)	0.5–18	2.3 @ 0.5 μm 2.0 @ 18 μm	ATR crystals, windows	Soluble in acids, slightly soluble in water
AMTIR-1 $Ge_{33}As_{12}Se_{55}$)	1–14	2.5–2.6	ATR crystals, windows	High homogeneity, not soluble in water
Polyethylene	to 1000	1.5	Windows	Not soluble in water, organic solvents, and acids; used for far infrared
Silver halides	1–15	1.6	Fibers, windows	Soluble in NH_3, sensitive to UV and visible light
Chalcogenides (e.g., As_2S_3, $As_{40}Se_{35}S_{25}$)	0.8–10	1.56	Fibers	Sensitive to water
Diamond (C)	0.2 to >20	2.4	ATR crystals, windows	Extremely hard, high resistance to acids and alkalis at temperatures up to 1200 °C

5.2
Reflection Measurements

Reflection measurements at *optically flat interfaces* can be performed in two basic configurations, external and internal reflection. In case of external reflection (also called *specular reflection*), light propagates within the optically rare medium (e.g., air), whereas in the case of internal reflection (usually employed as attenuated total reflection (ATR)) light propagates within the optically dense medium (Figure 5.3).

5.2.1
External Reflection

The intensity distribution between reflected and transmitted light at plane optical interfaces is based on *Maxwell's* theory and *Fresnel's* equations. The reflectivity R relates the intensity I_R of the reflected light to the intensity I_0 of the incident light

$$R = |r|^2 = \frac{I_R}{I_0} \tag{5.2}$$

where r denotes the amplitude of the reflected wave.

The measured reflectivity R is polarization dependent, the amplitude coefficients for parallel polarization $r_{||}$ and perpendicular polarization $r_\perp$ are

$$r_{||} = \frac{n_2 \cos\alpha - n_1 \cos\beta}{n_2 \cos\alpha + n_1 \cos\beta} \tag{5.3}$$

$$r_\perp = -\frac{n_2 \cos\beta - n_1 \cos\alpha}{n_2 \cos\beta + n_1 \cos\alpha} \tag{5.4}$$

At the *Brewster angle* or polarizing angle α_B, no parallel polarized light is reflected ($r_{||} = 0$). Beyond the critical angle α_C, the incident light undergoes total reflection

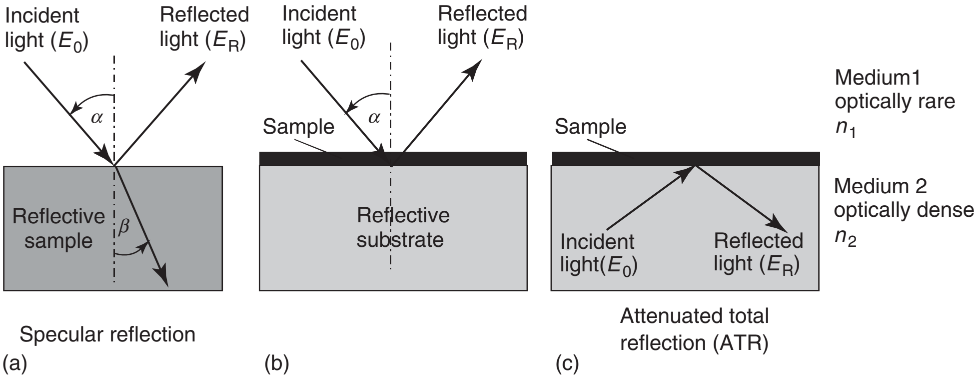

Figure 5.3 Measurement of (a) external reflection, (b) reflection absorption, and (c) internal reflection. Reflection and transmission of light at a plane optical interface with $n_2 > n_1$ (α, angle of incidence; β, angle of refraction). Parallel polarized light has its electric vector parallel to the plane of incidence.

at the interface

$$\alpha_C = \arcsin\left(\frac{n_1}{n_2}\right) \tag{5.5}$$

In order to calculate the transmitted intensity $T = (1 - R)$ immediately after the interface in a manner similar to that in Eq. (5.2), the intensity in the different media has to be taken into account

$$I_T = (1 - R)I_0 \tag{5.6}$$

In the usual case of absorbing media, the refractive index n has to be replaced by its complex form

$$n^* = n(1 - i\kappa) \tag{5.7}$$

where κ denotes the absorption index, which is related to the absorption coefficient a (cm^{-1}) and the decadic molar absorptivity ε ($\mathrm{l\,mol^{-1}\,cm^{-1}}$) in the *Beer–Lambert* law $A = \varepsilon c d$

$$a = 4\pi k\kappa = \frac{\varepsilon c}{\ln 10} \tag{5.8}$$

In an absorption region, the real part n of the complex refractive index n^* exhibits an anomaly, as schematically shown in Figure 5.4.

This effect occurs especially in the infrared range because narrower absorption bands affect a stronger anomaly of n. As a consequence, band shapes in IR reflection spectra differ severely from those in corresponding transmission spectra (Christiansen effect). The *Kramers–Kronig* relation can be used to analyze reflection spectra and to relate them to transmittance data.

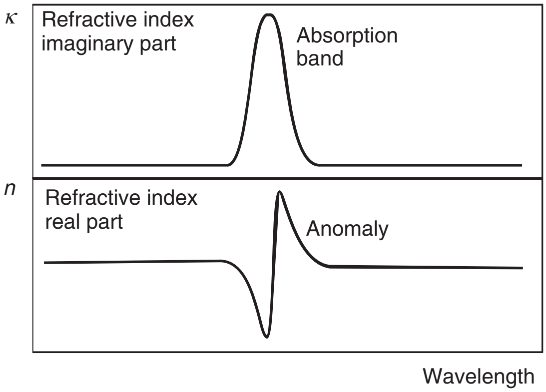

Figure 5.4 Anomaly in the real part of the complex refractive index within an absorption region.

5.2.2
Reflection Absorption

Reflection absorption measurements are performed by placing the analyte on a reflective substrate (Figure 5.3). The reflective substrate might be either optically flat or diffusely reflecting. Incident light passes the analyte twice, and a sort of transmission spectrum is obtained (sometimes called the *transflection spectrum*). The greater the angle of incidence, the larger is the effective path length in the analyte. The technique is known under the acronyms IRRAS (infrared reflection absorption spectroscopy) and RAIRS (reflection absorption infrared spectroscopy). The extreme case is the so-called grazing incidence technique, where the area illuminated by the incident beam is maximized (maximum number of molecules in the beam).

Reflection absorption experiments on samples with a thickness larger than the wavelength used give absorbance values corresponding to the enlarged effective pathlength described earlier. In case of sample thickness in the order of the wavelength or even below, the Beer–Lambert law is not anymore valid, because the field amplitude of the standing wave emerging during reflection varies regularly. In case of a very thin sample layer, its transmission is not only dependent on its optical properties but on the regular field variations in the vicinity of the reflecting surface as well. Additional enhancement factors may occur, which could provide submonolayer sensitivity. As the light of different polarization behaves differently upon reflection, a very complex situation results. In particular, in case of grazing incidence, only absorptions with components of the transition moments normal to the reflecting surface can be observed. Main application areas are surface coatings, very thin films, and adhesives on reflective surfaces as well as molecular orientation studies.

5.2.3
Attenuated Total Reflection (ATR)

A beam propagating in an optically dense medium with the refractive index n_2 undergoes total reflection at the interface with the optically rare medium (n_1) when the angle of incidence exceeds the critical angle α_C (cf. Eq. (5.5)). Upon total reflection, the electromagnetic wave propagates through the optical interface and generates an evanescent field, which penetrates the rare medium (Figure 5.5).

The evanescent field is a nontransverse wave along the optical surface, whose amplitude can be expressed as an exponential function along the z-axis into the rare medium

$$E_z = E_0 \mathrm{e}^{-z \frac{2\pi n_2}{\lambda_0} \sqrt{\sin^2\alpha - \left(\frac{n_1}{n_2}\right)^2}} \tag{5.9}$$

where E_z is the amplitude of the evanescent field at distance z, λ_0 the vacuum wavelength of the light used. The penetration depth z_p is defined as distance where

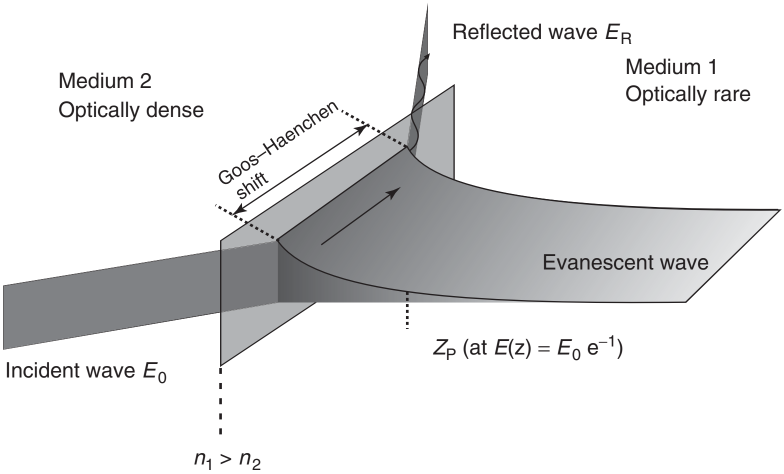

Figure 5.5 Strength and penetration of the evanescent field.

the exponent is equal to one

$$z_p = \frac{\lambda_0}{2\pi n_2\sqrt{\sin^2\alpha - \left(\frac{n_1}{n_2}\right)^2}} \tag{5.10}$$

If medium 1 is absorbing, the evanescent field will be absorbed and less intensity can be reflected (ATR). ATRs are similar to the conventional absorption spectrum except the band intensities at longer wavelengths. At longer wavelengths, the evanescent penetrates ever deeper into the sample, equivalent to an increasing sample thickness. Sometimes an empirical so-called ATR correction is applied in order to compensate across the spectrum for the linear wavelength increase in Eq. (5.10)

$$R_{\text{corr}} \sim R\frac{1}{\lambda} \tag{5.11}$$

Other differences may occur because of surface effects between the sample and the optical crystal or absorption changes across the sample. A single-reflection or a multireflection crystal may be used. The measured reflectivity depends on the number of reflections as well as on the efficiency of contact between sample and substrate surface.

An important advantage of the ATR technique is its applicability to turbid solutions, aqueous solutions included. Suspended particles are surrounded by a thin liquid film (hydrating shell). This shell forms also the phase boundary to the ATR crystal surface so that evanescent field will not be scattered by the particle.

ATR crystals for the UV, vis, and NIR ranges are usually made of quartz glass. Sapphire is used for special UV and NIR applications; it is one of the hardest of all optical materials so the surface is more resistant to scratches (Table 5.2). In the mid infrared (MIR), zinc selenide, silicon, germanium, and diamond are used. Zinc selenide is currently the most popular material for ATR crystals. Its most important advantage is its low absorbance at wavelengths over 10 μm, but zinc selenide scratches easier than germanium and silicon, and it is toxic. Amorphous material transmitting infrared radiation (AMTIR-1) is a glasslike amorphous material with a high homogeneity. The low thermal change refractive index of $7 \times 10^{-6}\,^{\circ}\mathrm{C}^{-1}$ is of advantage in optical systems.

5.2.4
Reflection at Thin Films

Thin films can be investigated either by reflection absorption or by a sort of internal reflection measurement using the occurrence of multiple reflections. In case of plane, parallel-sided, homogeneous, and isotropic thin films (Figure 5.6), the amplitude of the reflected light can be expressed in the form

$$r \sim \frac{r_{12} + r_{23}\mathrm{e}^{-2i\delta}}{1 + r_{12}r_{23}\mathrm{e}^{-2i\delta}} \tag{5.12}$$

where r_{12} is the reflection coefficient for the interface 1–2 and r_{23} for the 2–3 interface (cf. Eq. (5.3) and Eq. (5.4)). The term δ is given by

$$\delta = \frac{2\pi}{\lambda} n_2 d \cos(\beta) \tag{5.13}$$

where d is the layer thickness of the sample. For nonnormal incidence, the amplitude of the reflected light depends on the state of polarization of the incident light. If the film itself, or the surrounding medium, is absorbing, the reflection coefficients r_{ij} become complex (cf. Eq. (5.7)).

Spectral features arise from two properties: (i) the intrinsic absorption strength and (ii) the orientation of the transition dipole with respect to the wave vector of the incident light. In samples with random distribution, an averaged spectrum will be recorded. In highly ordered films, the absorption depends on the ordering within the film and the orientation of the sample. Therefore, the angle of incidence and polarization of the light have to be chosen carefully.

The analysis of thin films is often performed by infrared spectroscopy. Compared to reflection absorption measurements on metal surfaces using p-polarized light at grazing incidence, investigation of self-supported thin films or of thin films on

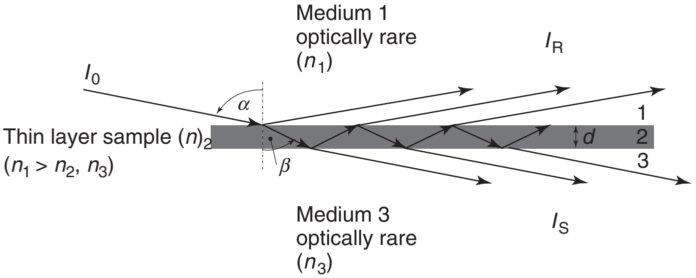

Figure 5.6 Reflection and transmission of light in a thin film.

transparent substrates shows weaker infrared absorption bands. Weaker absorption bands are caused by the absence of the surface enhancement mechanism and the poorer reflectivity. On the other hand – owing to the absence of the metal selection rule – spectra of p- and s-polarization can be recorded in case of free-standing films or of transparent substrates. Complex spectral features may arise from optical features of the substrate or in case of optical dispersion within the sample film.

5.2.5
Diffuse Reflection

Light incident at *optically scattering interfaces* (inhomogeneous samples such as powders) with roughness down to the range of the wavelength may partly be reflected regularly, partly scattered diffusely, partly entering the substrate. The latter part may undergo absorption within particles, diffraction at grain boundaries, reemerge at the sample surface, and intermingle with reflected parts. The measured reflectivity includes contributions from all mechanisms (Figure 5.7).

Quantitative evaluation of diffuse reflectance spectra requires "optically indefinitely thick" samples ($I_T = 0$; cf. Table 5.1). The reflectivity R_∞ of such a sample (in the IR, its thickness does normally not exceed a few millimeters) is

$$R_\infty = \frac{R_{\infty\,\text{(sample)}}}{R_{\infty\,\text{(reference)}}} \tag{5.14}$$

R_∞ is transformed by the empirical *Kubelka–Munk* relation into an absorption-proportional parameter $f(R_\infty)$

$$f(R_\infty) = \frac{1 - R_\infty}{2R_\infty} = \frac{k}{s} \tag{5.15}$$

where k describes the absorbing and s the scattering properties. The parameters k and s vary with particle size and packing density. It is assumed that s does not depend on wavelength and the sample is weakly absorbing. The former assumption has to be ensured by proper sample preparation, the latter by dilution of strong absorbers

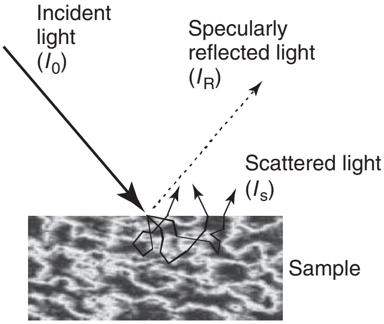

Figure 5.7 Schematic illustration of light trajectories in a scattering sample.

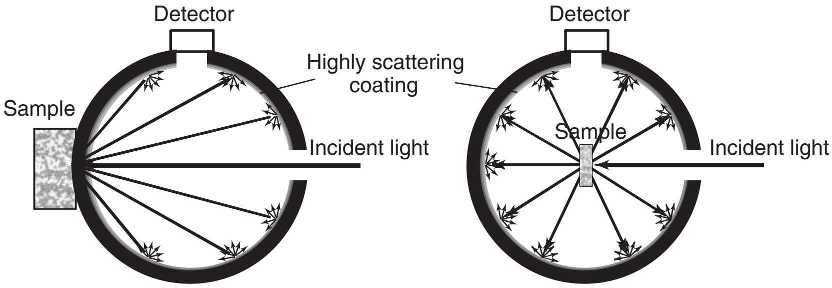

Figure 5.8 Two configurations of Ulbricht spheres for diffuse reflectance measurement. Large or thick samples are usually positioned at a sphere port, and small samples are mounted in the center.

with nonabsorbing substrate powder. In case of $R_\infty < 0.01$, the transformation is often done by the simpler functions $-\log R_\infty$ or simply by $1/R_\infty$. Such small R_∞ values are usually found in the NIR region.

Measurement of diffuse reflection spectra has a much longer tradition in UV/vis than in IR because (i) the scattering is much more efficient at shorter wavelengths and (ii) an ideal nonabsorbing scattering substrate is missing in the MIR.

UV/vis and NIR diffuse reflection spectra are usually measured by an integrating sphere. The inner surface of the so-called ‘‘Ulbricht sphere’’ (Figure 5.8) is coated with a strongly scattering, nonabsorbing powder. After repeated reflections at the inside of the sphere, all radiation will eventually reach the detector.

Of practical importance is the sphere factor K

$$K = \frac{\rho}{1 - \rho(1 - a)} \tag{5.16}$$

where ρ is the reflectivity of the cover and a the ratio between the area of all holes and the total sphere area. If the factor a does not exceed a range of 5–10%, K will essentially remain independent of sample properties.

Barium-sulfate-based coatings are mainly used in the UV/vis range; it is characterized by a reflectivity of up to 80% and an almost constant factor K throughout the vis range. Poly(tetrafluoroethylene) (PTFE) is suitable throughout the whole range from UV to NIR. In the NIR, a rough gold surface can be used as well.

In the MIR, diffuse reflectance is very weak and could only be measured after routine FT-IR spectrometers became available (DRIFT spectroscopy, diffuse reflectance infrared Fourier-transform spectroscopy). Owing to the lack of ideal nonabsorbing scattering substrates in the MIR, the diffusely reflected MIR radiation is generally collected by large ellipsoidal mirrors, which cover as much area above the sample as possible. Two optical configurations are commercially available, on-axis and off-axis designs (Figure 5.9).

In the on-axis configuration, the ellipsoidal mirror collects both diffusely and regularly reflected light. In the off-axis configuration, the ellipsoidal mirror is positioned off the plane of regular reflection; the latter influences the measurement

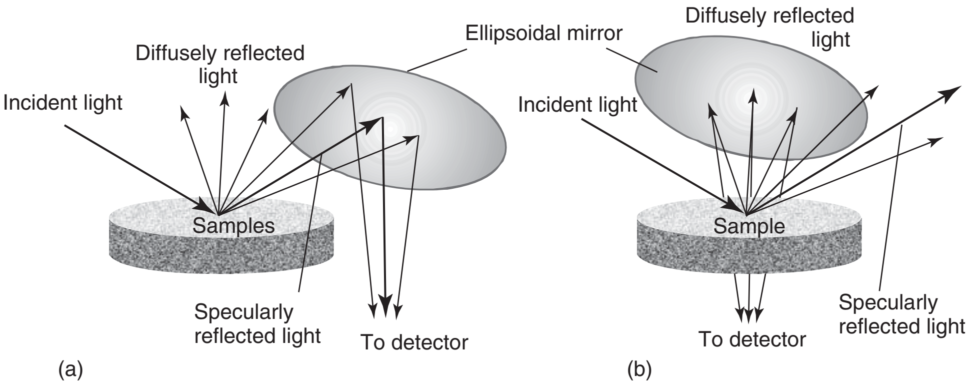

Figure 5.9 Optical layout for measurements of diffuse reflection in the infrared range: (a) on-axis arrangement with the collecting mirror in the optical plane of incident and specularly reflected light and (b) off-axis arrangement with the collecting mirror out of the optical plane of incident and specularly reflected light.

much less. While the on-axis design has the advantage of much simpler alignment in the interferometer, superposition of regular and diffuse reflection leads to both inferior sensitivity and reduced accuracy in quantitative analysis. Off-axis models provide superior sensitivity and accuracy at the expense of acquisition costs and laboratory experience. KBr or KCl powders are used as reference as well as dilutant for strong absorbers.

5.3
Spectroscopy with Polarized Light

Chiral molecules occur in pairs related by a symmetry plane; their mirror images cannot be superimposed (enantiomers). Such molecules exhibit optical activity, that is, they transmit left and right circularly polarized light in a different manner. The difference in the refraction indices for left and right circularly polarized light and is called *optical rotatory dispersion* (*ORD*), the corresponding difference in absorption coefficients is called *circular dichroism* (*CD*). ORD and CD can be related to each other by *Kramers–Kronig* transformation.

5.3.1
Optical Rotatory Dispersion (ORD)

Pairs of chiral molecules transmit left and right circularly polarized light by a different velocity. The two forms of chiral molecules have an asymmetric distribution of electrons, and hence they interact with right and left polarized light in opposite ways. If the index of refraction for right polarized light is larger than for left polarized light, the plane of polarization will be rotated toward left, and vice versa (Figure 5.10).

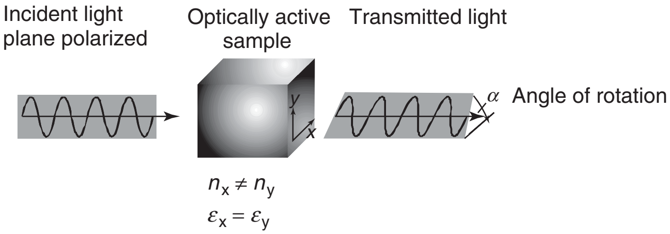

Figure 5.10 Optical rotatory dispersion: linearly polarized light can be considered as superposition of opposite circularly polarized light of equal amplitude and phase. Different velocities of left and right circularly polarized light lead to optical rotation of the polarization plane of the transmitted light.

The angle of rotation α at the wavelength λ is directly proportional to the concentration c

$$\alpha = [\alpha]_{\lambda}^{T} lc \tag{5.17}$$

where l is the path length of the sample cell. $[\alpha]_{\lambda}^{T}$ is the specific angle of rotation ($\mathrm{grd\,cm^{-3}}$), and it depends on wavelength and temperature. In polymer chemistry and biochemistry, the rotation is related to the molar mass, for example, to the average mass of all amino acids of the protein (mean residue weight, M_0)

$$[\mathrm{m}] = \frac{\alpha M_0}{10lc} \tag{5.18}$$

The obtained molar rotation [m] may be influenced by the refractive index n of the solvent. The corrected molar rotation is defined by

$$[\mathrm{m}]_{\lambda} = \frac{3}{n_{\lambda}^{2} + 2} \frac{\alpha M_0}{10cl} \tag{5.19}$$

5.3.2
Circular Dichroism (CD)

CD is observed when refraction indices as well as absorption coefficients are different for light and right circularly polarized light (Figure 5.11).

CD is measured by passing left circularly polarized light ($I_{\mathrm{T}}^{\mathrm{L}}$) and right circularly polarized light ($I_{\mathrm{T}}^{\mathrm{R}}$) consecutively through the sample and subtracting the observed intensities

$$\Delta I_{\mathrm{T}}(\lambda) = I_{\mathrm{T}}^{\mathrm{L}}(\lambda) - I_{\mathrm{T}}^{\mathrm{R}}(\lambda) \tag{5.20}$$

The difference in left and right polarized absorbance is usually in the range of 0.0001, corresponding to an ellipticity of approximately 0.01°. The molar ellipticity is defined as

$$[\Phi] = \frac{M\Phi}{10cl} \tag{5.21}$$

Φ is the measured ellipticity, c is the concentration, and l the path length of the sample cell.

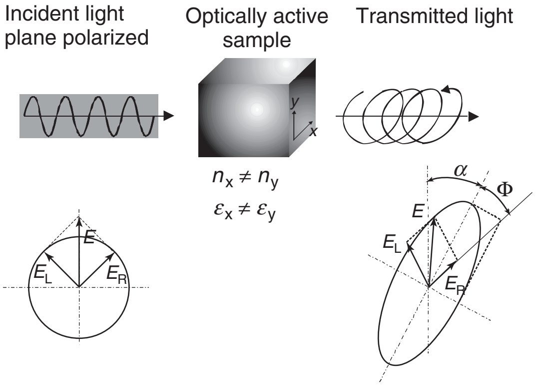

Figure 5.11 Principles of CD: similar to that in ORD, linearly polarized light can be considered as superposition of circularly polarized light of opposite direction of rotation but equal amplitude and phase. Differences in absorption of left and right polarized light lead to elliptic polarization of the transmitted light.

CD is a very sensitive method to study molecular conformation, in particular for analyzing secondary structures of proteins and nucleic acids in solution. Because different conformations have their characteristic CD spectra, the CD spectrum of a protein gives quantitative information about each kind of secondary structure. Moreover, CD is suited to study the rate of structural changes, and it can probe interactions such as protein–ligand, protein–protein, or protein–nucleic acid.

5.4
Photoacoustic Measurements

After selective absorption of radiation, excited molecules may relax either by emission of radiation or by nonradiative processes (cf. Chapter 3, Figure 3.1). In photoacoustic measurements, the conversion of absorbed radiation into thermal energy is utilized. This type of conversion results in changes of the sample's thermodynamic parameters such as temperature or pressure. Changes in pressure generate acoustic waves, which eventually will be transferred to the surroundings of the sample (Figure 5.12) where they can be measured by a sensitive microphone; see Figure 5.13 (photoacoustic spectroscopy (PAS)).

Acoustic waves are exclusively generated by the process of light absorption and subsequent relaxation; neither reflection nor scattering do produce PAS signals. For this reason, optical absorption in high-scattering samples and at optical interfaces can more accurately be measured by PAS. Moreover, the indirect measurement in PAS being more sensitive than optical transmission measurements, samples with low absorbance can well be investigated. Concentrations below 10^{-10} M or microsamples may even be measured. Some other key features are PAS is nondestructive, noncontactive, and macro as well as micro samples can be

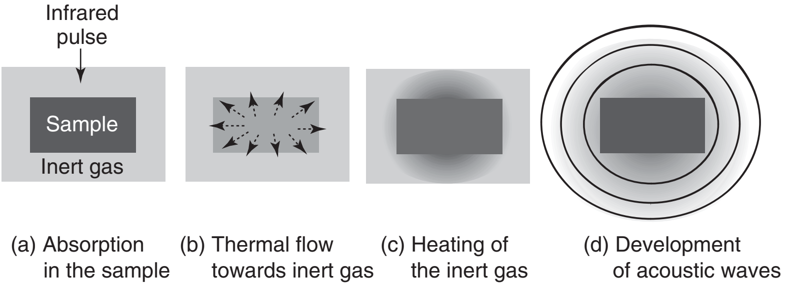

Figure 5.12 Photoacoustic signal generation: (a) IR pulses are absorbed by the sample, (b) the sample is heated and thermal pulses are generated, (c) thermal pulses are transferred from the sample to the surrounding gas, and (d) thermal pulses cause pressure waves (acoustic waves) within the surrounding gas. The PAS cell does not need to be closed for the measurement of the acoustic signal.

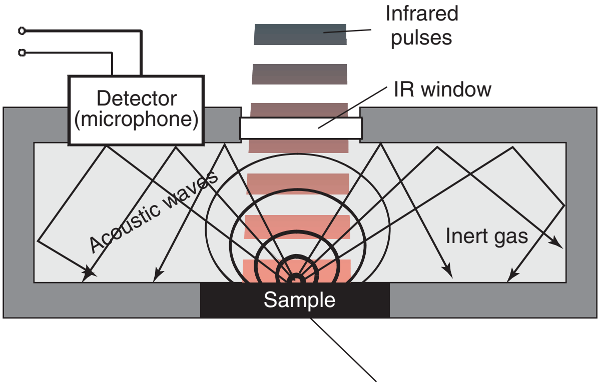

Figure 5.13 Schematic of photoacoustic cell.

investigated. The application range of PAS extends from the UV to the far IR. Because PA signals depend directly on light absorption, a PA spectrum looks like a conventional absorption spectrum. However, additional processes such as internal conversion, thermal diffusion, and other thermal effects may occur and render the spectrum more or less distorted.

One important application of PAS is the depth-resolved measurement of layered samples. As the thermal waves propagate from the point where absorption occurred to the sample surface, they decay rapidly. The intensity of thermal pulse is a square root function of the frequency at which the light is modulated (pulse repetition rate). The photoacoustic sampling depth l_{PA} is controlled by the modulation frequency

$$l_{PA} = \sqrt{\frac{D}{\pi f}} \tag{5.22}$$

where f is the modulation frequency and D the sample's thermal diffusion parameter. Typical values of l_{PA} are between 0.5 and 500 μm, depending on sample and wavelength.

5.5
Microscopic Measurements

Microscopes focus the light beam at the sample position to a very small area. Microsamples may fully fit this small area. The minimal diameter of the light spot in a conventional microscope may reach the order of the wavelength of this light (diffraction limit), but the optical conductance of microscopes is usually considerably lower than that of the spectrometer alone.

Every microscope is characterized by its numerical aperture NA, which describes the angle between the optical axis and the most remote point of the sample that can be observed. NA is directly proportional to the energy throughput. Objectives with infinity correction provide advantages such as sharper images and better signal–noise ratio. Infinity corrected objectives are increasingly used, especially in microscopic imaging with array detectors.

Because of the different capabilities of the various optical spectroscopic techniques as well as because of their distinct demands, special types of microscopes have been developed.

5.5.1
Infrared Microscopes

In contrast to vis microscopes with a system of glass lenses, IR microscopes are built around reflecting components. The heart of most infrared microscopes is a Cassegrainian or Schwarzschild objective (Figure 5.14).

Common IR objectives have NA values between 0.5 and 0.7, and typical magnification is 15 ×. Higher magnification objectives up to 36 × are available. IR microscopic measurements can be done in transmission, in external reflection, and in internal reflection. The latter requires a so-called ATR objective. ATR

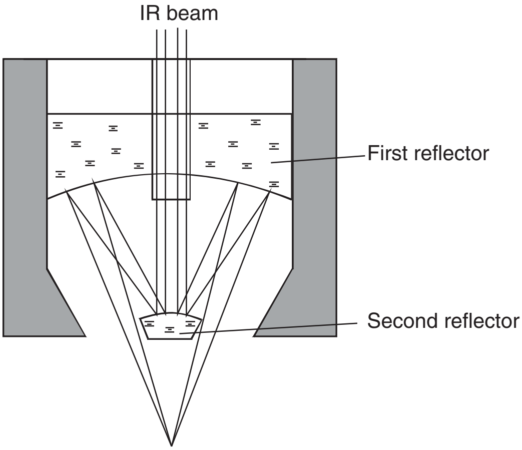

Figure 5.14 Optical setup of a Cassegrainian objective.

objectives permit *in situ* investigations of highly absorbing samples even without sample preparation.

The sample position is controlled by visible light. Thus, IR microscopes must transmit both IR and vis light; only small differences in coverage between IR and the vis images remain unavoidable because of aberration effects. Typical sample thickness in transmission is 5–50 μm. Investigations of strongly absorption or opaque samples are carried out in reflection mode. The latter has the disadvantages of lower signals due to the splitting between incident and reflected beams.

5.5.2
Confocal Microscopes

Confocal microscopes provide a particular good spatial resolution. They are mainly used in Raman and fluorescence measurements. The basic idea of a confocal microscope is that all structures being out of focus are suppressed at the detector. This is achieved by point illumination and a pinhole in front of the detector, as shown in Figure 5.15.

In contrast to a conventional microscope, the object is not being illuminated as a whole at the same time. The image will be reconstructed by stepwise moving the sample. Scanning in the plane as well as along the optical axis allows

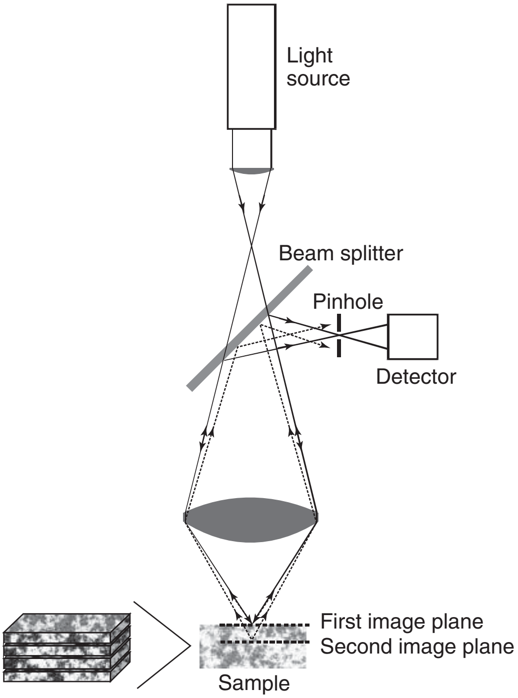

Figure 5.15 Optical layout of a confocal microscope.

three-dimensional investigations. Defocusing does not lead to blurring but it cuts out a part of the sample image as they move away from the focal plane so that these parts become darker or even disappear. This feature is also known as *optical sectioning*. The depth of the focus is determined by the objective's NA, the diameter of the pinhole, and by the wavelength.

5.5.3
Near-Field Microscopes

Near-field scanning optical microscopes (NSOM or SNOM) are mainly used in fluorescence and vis measurements. They provide optical images with spatial resolution less than the *Abbe's* limit of $\lambda/2$. The high lateral resolution is commonly achieved by using the optical near field, for example, in close vicinity of a very narrow fiber tip. Figure 5.16 illustrates the design of a near-field microscope.

Light can leave the extremely narrow orifice of the fiber tip only by a tunneling mechanism, which results in the generation of an evanescent field (or near field) outside the tip. The fiber tip must be positioned merely a few nanometers away from the sample surface by a device as is used in atomic force microscopy (AFM). A spatial resolution of approximately $\lambda/10$ can currently be achieved, limited by

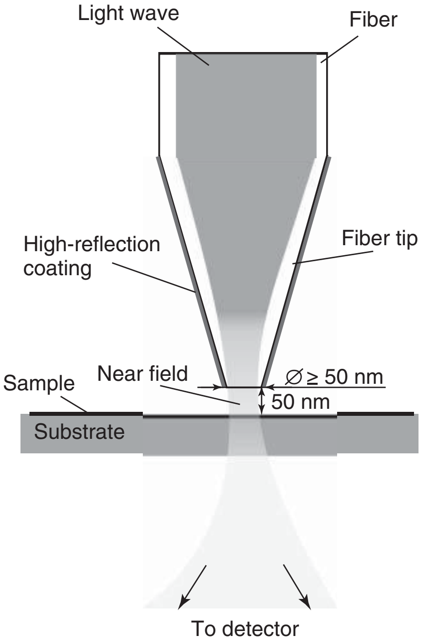

Figure 5.16 Scheme of a near-field microscope. Light is emerging from a fiber tip with the diameter of the orifice below the refraction limit. The configuration shown employs near-field excitation/far-field detection. The alternative configuration is far-field excitation/near-field detection.

the signal/noise ratio obtained at the detector and the distance of the fiber tip from the sample. Because of the extreme damping of the fiber tip, lasers are commonly used as light sources. The development of new powerful NIR and IR lasers makes near-field IR microscopy feasible for the near future.

Near-field microscopy was successfully applied in investigations of polymer surfaces, of biological samples, and of advanced inorganic film materials. No special sample preparation is required.

5.6
Infrared Spectroscopic Imaging

Spectroscopic imaging gained particular importance in the infrared spectral region. It can be done without a microscope (macrospectroscopic imaging) or with a microscope (microspectroscopic imaging). All detector elements of a focal plane array (FPA) detector (cf. Section 4.1.2.1) are read out simultaneously to provide a 3D data set (x and y dimensions of the sample plus IR intensities) from which spectroscopic images can be constructed. Typical array sizes of FPA detectors are 32 × 32, 64 × 64, 128 × 128 detector elements [Bhargava *et al.*]. Linear array detectors (cf. Section 4.7) may be advantageous in case of small sample areas, which can be captured rapidly.

Infrared spectroscopic imaging can be performed in transmission, reflection, transflection, or ATR mode. For microscopic investigations, the user can currently choose between four types of Cassegrainian objectives:

	Magnification	**NA**
	15×	0.4
	32×	0.65
	36×	0.5
Grazing angle	15×	0.99

NA, numerical aperture.

Because the spatial resolution (s_{res}) is determined by

$$s_{\mathrm{res}} = \frac{0.61\lambda}{\mathrm{NA}} \tag{5.23}$$

a microscopic objective with an NA of 0.65 allows a spatial resolution in the range of the used wavelength (λ). The sample area (a) can be calculated as

$$a = \frac{d_{\mathrm{FPA}} s_{\mathrm{D}}}{f_{\mathrm{obj}}} \tag{5.24}$$

where d_{FPA} is the number of the FPA elements in a row (e.g., 64, 128), s_{D} is the size of the detector elements (usually 40 μm), and f_{obj} is the magnification of the Cassegrainian objective. The registration time for one image ranges between few seconds and several minutes. ATR diamond objectives are also available for imaging purposes. An advantage of FT-IR ATR microimaging is the improvement in spatial resolution due to the high refractive index of the ATR crystal. The high refractive index causes a high NA and, in turn, a higher spatial resolution. Alternatively, FT-IR ATR macroimaging allows the investigation of larger samples under *in situ* conditions.

5.6.1
Analysis of Spectroscopic Images

A spectroscopic image may consist of thousands of individual spectra. Some or even many of those spectra may be of inferior quality (sample defects, sample edge, exterior areas). Spectra of inferior quality in the data set may preclude chemometric evaluation procedures from achieving useful results. This is a standard problem in spectroscopic imaging as homogeneous sample areas are normally not imaged. In consequence, the large imaging data set has to be subject to a sequence of processing steps.

Chemometric imaging is a term that encompasses a wide range of mathematical methods for evaluation of three-dimensional spectroscopic data sets. Advanced multivariate methods of data analysis are used in vibrational spectroscopic imaging to extract and to quantify relevant constituents, variations in the chemical structure, or composition. The common approach involves four steps (Figure 5.17): (i) detection and elimination of outliers, (ii) data preprocessing, (iii) feature selection and classification, and (iv) image processing.

During detection and elimination of outliers, all spectra of inferior quality or those that are not directly related to the sample are removed. The outlier spectra can be either removed from the data set or substituted by the spectral information from surrounding pixel. Table 5.3 summarizes some useful criteria for the detection of outlier spectra.

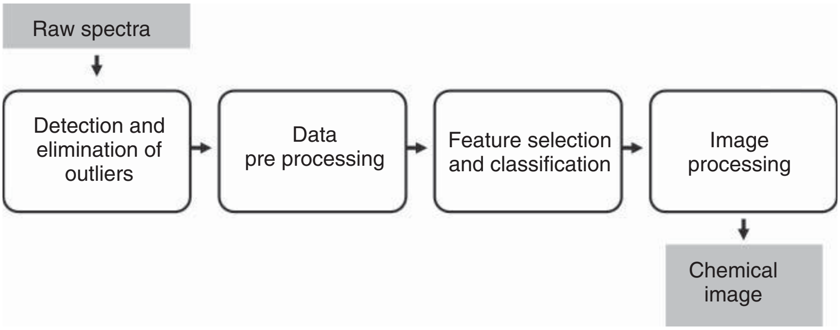

Figure 5.17 Recommended sequence of data treatment from spectroscopic raw data to a chemical image.

Table 5.3 Recommended criteria for the identification of outlier spectra.

Criterion	Comments and recommendations
Highest absorbance > 2	Useful, should always be used
Lowest absorbance < −0.5	Useful, should be used
Slope of the baseline > 0.5	Depends on the sample, can be corrected
Signal to noise ratio < 2	Useful, should be used when more than 10% of the spectra exhibit an SNR < 2
No characteristic bands	Useful when the sample spectrum is well known
Strong absorption bands of water and CO_2	Not recommended, can be compensated for
Oscillations (arise from the FPA electronics or from interferences of thin films)	Useful; however, hard to detect

Table 5.4 Selection of methods for data preprocessing.

Method	Comments and recommendations
Off-set correction	Should always be performed
Linear baseline correction	Should be used with care
Quadratic or higher degree baseline correction	Not recommended; should be used with care when a strong scattering occurs
Derivation	Can be used when spectra have good SNR
Normalization and centering	Recommended; optimized method has to be tested
Smoothing	Sometimes helpful when spectra have low SNR, usually in imaging spectroscopy not necessary
Extended multiplicative scatter correction	Recommended when scattering artifacts affect spectra

Data preprocessing is necessary to compensate for variations such as sample thickness or so-called dispersion artifacts. The latter are due to local variations in the sample refractive index. In general, data preprocessing includes routines that do not alter the information content of the spectra (cf. Table 53.1, Basic operations) and those that do (cf. Table 53.1, Manipulations). Improper manipulations cannot be compensated for anymore in later processing steps. Common manipulations are nonlinear background corrections, smoothing, derivation, or the removal of multiplicative and additive effects by extended multiplicative scatter correction (EMSC) [Gallagher *et al.*]. Common and often applied methods for data preprocessing are listed in Table 5.4. The best strategy for preprocessing is strongly depended on the quality of the data set. The outcome of preprocessing has to be evaluated carefully.

Feature selection and classification are used to extract the molecular information hidden in large spectral data sets. By feature selection those spectral regions

Table 5.5 Selection of multivariate pattern recognition methods.

Method	Basic function
PLS	Finds a linear model describing selected predicted variables
PCA	Calculates variances within the data set, identifies structure, and redundance
Wavelets	Extracts certain information from the data set
FA	Calculates variability of spectral information (linear combination)
Hierarchical CA	Assigns spectra into groups, represented as dendrogram
Partition cluster analysis	Assigns spectra to the cluster or computes a degree belonging to clusters whose center is nearest
Artificial neuronal networks	Finds patterns in the spectra set and shows relationships between spectra and additional information
SVM	Calculates and maximizes margin between the two or more classes
Discriminant analysis	Separates two or more classes by linear or function with higher degree

PLS, partial least-squares; PCA, principal components analysis; FA, factor analysis; CA, cluster analysis; SVM, support vector machines.

are identified that will best express the required molecular information in a most optimal way and at the same time at high specificity. Spectral information that is either redundant or irrelevant to the subsequent classification step is removed from the data set. Also, the noise level is reduced during the feature selection step. Multivariate methods for feature selection and classification can be roughly divided into classification and regression techniques. The family of classification techniques can be further divided into supervised and unsupervised methods. Supervised methods use prior knowledge of the data (training set), whereas unsupervised methods do not require additional information about the data. Supervised methods are often used for classification of spectra. Unsupervised methods are preferred to investigate similarities and/or variations between spectra. Table 5.5 summarizes important multivariate methods for the classification of spectra. Multivariate regression is applied to determine one or multiple constituents in a sample. Frequently used multivariate regressions are principle component regression (PCR) and partial least-squares regression (PLS).

Classification aims at assigning individual objects (spectra) to known classes. A class is defined by the similarity of the selected spectral features. Objects belonging to one class should be most similar with respect to the selected features, whereas objects belonging to different classes should show the largest differences. Classification methods can be divided into methods for class discovery (supervised) and methods for class prediction (nonsupervised) (Chapter 53.1). Supervised classification is based on a training set of previously labeled spectra, that is, spectra of known origin. Unsupervised classification requires no a priori information. Various classification algorithms are in use. Some do not yield confidence or class

probabilities; others first apply unsupervised classification and attempt to label each of the classes afterwards.

Image processing is the final step that visualizes the classified spectra. Commonly different colors are assigned to the classified spectra. The latter are subsequently reassembled into a false color image. Methods of rendering can be used to eliminate noise and to highlight areas of equal or similar features. Pattern recognition techniques may be used to visualize particular features in spectral images.

An example of the work flow of multivariate data processing is given for a thin tissue section of a mouse tumor sample (Figure 5.18). A stained thin section of the tissue was visually diagnosed by a histologist. Identified tumor areas are surrounded by a dotted line (Figure 5.18a). The adjacent thin section was imaged under the FT-IR microscope. A randomly selected subset of the raw spectra is shown in Figure 5.18b. Some are typically affected by distortions such as scattering (spectrum in the upper left part) or noise (spectrum in the upper right part). The spectroscopic image in Figure 5.18c was calculated from the raw spectra by integrating the absorbance values between 950 and 1800 cm^{-1}. The contrast in the image is deteriorated by one prominent outlier spectrum. The corresponding red dot is indicated by arrows in the lower right part of Figure 5.18c. All outlier spectra, which contain little or no information about the sample, were subsequently eliminated, the accepted spectra were scattering corrected, and background removed (Figure 5.18d). Figure 5.18e shows the spectroscopic image after elimination of outlier spectra. Normal and tumor tissue cannot be distinguished yet. Finally, a fuzzy *k*-means cluster analysis (nonsupervised multivariate data analysis; cf. Table 53.10) was carried out. Normalization to the area was performed in order to compensate for variation in the thickness of the tissue section. The five centroid spectra of the resulting clusters (Figure 5.18f) indicate different types of tissue. Figure 5.18g reveals the lateral distribution of the cluster spectra of Figure 5.18f. The clusters can be assigned to the following tissue types: red and green tumor tissue, blue and brown normal tissue. These areas correspond very well with the hematoxylin–eosin (HE)-stained histological microscopic image in Figure 5.18a.

For a more detailed description of the data analysis techniques the reader is referred to Chapter 53.1 and to the relevant literature.

Figure 5.18 Multivariate analysis of a 128×128 spectroscopic image of a tumor. (a) Microscopic image of the tissue section after histological HE staining. The tumor area is surrounded by a dotted line. (b) A subset of 100 accidentally selected raw spectra. (c) Spectroscopic image of the raw spectra. The integrated absorbance between 950 and 1800 cm^{-1} is shown by color codes. (d) The spectra subset after elimination of 24 outlier spectra and data preprocessing. (e) Spectroscopic image using the preprocessed spectra. The integrated absorbance between 950 and 1800 cm^{-1} is again shown by color codes. (f) The four centroid spectra obtained by fuzzy *k*-means cluster analysis. The centroid spectra can be assigned to the following tissue types: red and green tumor tissue, blue and brown normal tissue. (g) The lateral distribution of the clusters (color code as in (f)) corresponds very well with the histological image above and clearly reveals the diseased tissue region.

6.1

Mid-Infrared (MIR) Spectroscopy

In the mid-infrared (MIR) spectral region, we are dealing with transitions between various vibrational energy levels of molecules. Gaseous samples are a special case, because rotational fine-splitting of spectral bands can be observed. Fine-splitting is caused by simultaneous excitation of rotational and vibrational transitions.

The MIR spectral range extends from 4000 to 400 cm^{-1}. Transitions can be observed by absorption or emission measurements. For analytical purposes, absorption measurements are usually preferred. The decision about an optimal sampling technique is very much dependent on the aggregate state of the sample under investigation.

6.1.1

Sample Preparation and Measurement

According to the Beer–Lambert law, the density of the analyte (or concentration of it in case of mixtures or solutions) and the infrared (IR) pathlength in the sample are crucial. These parameters have to be chosen in such a way that good measurable optical signals are obtained in contemporary spectrometers between 20% and 60%T for band maxima. In order to minimize the background in the spectrum, care should be taken about the homogeneity of the sample, the level of impurities, and about absorptions in the solvent. The quality of spectral data acquired depends very much on the sampling technique chosen. Detailed descriptions of sampling techniques can be found in [1–3]. A summary of common sampling techniques is given in Figure 6.1.

6.1.1.1 **Gases**

Gas cells are essentially gas-tight containers fitted with IR transparent windows to enable the radiation to enter and exit the container. Gas cells should be equipped with inlets for introducing, pressurizing, and evacuating the gas. Cell sizes vary from a cylinder of a few centimeter pathlength, typically 10–20 cm and constructed

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

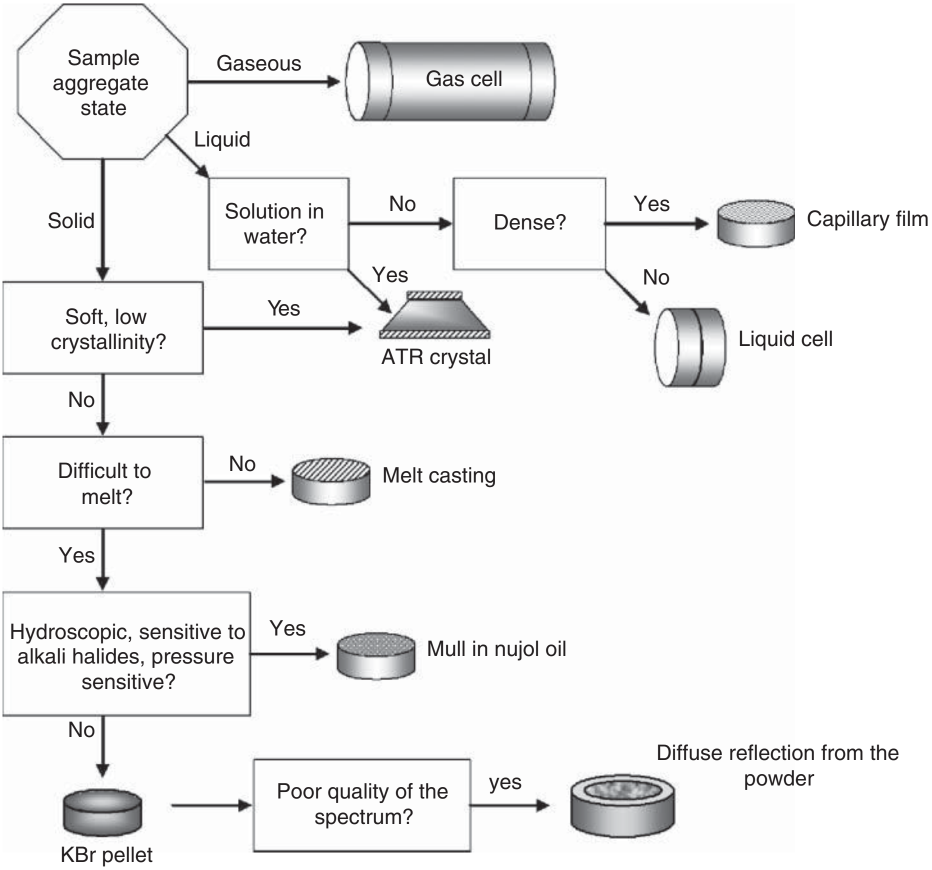

Figure 6.1 Summary of common IR sampling techniques.

from glass or stainless steel, with windows at each end, to compact long-pathlength cells, which have internal gold mirrors (multipass gas cells) in order to provide effective pathlength of many meters within the gas sample. At a pressure up to 50 Torr, many gases yield useful spectra in a standard 10 cm pathlength cell. Unfortunately, many molecular species have much lower saturated vapor pressure at room temperature, that is, a longer pathlength is required for meaningful measurements.

A sketch of a gas cell with multipass optics in the so-called White arrangement is given in Figure 6.2. It comprises three spherical mirrors, which can be adjusted for the desired number of passes. Four passes (as shown in Figure 6.2a) is the minimal number of passes in such an arrangement. The achievable maximum number of passes depends on the reflectivity of the mirrors and on the quality of the incoming beam. The latter is partly defined by the size of the IR source. Commercial cells with White optics have an outer length of about 30–100 cm and provide a folded optical with total path of up to 100 m. Measurements with the multipass gas cells

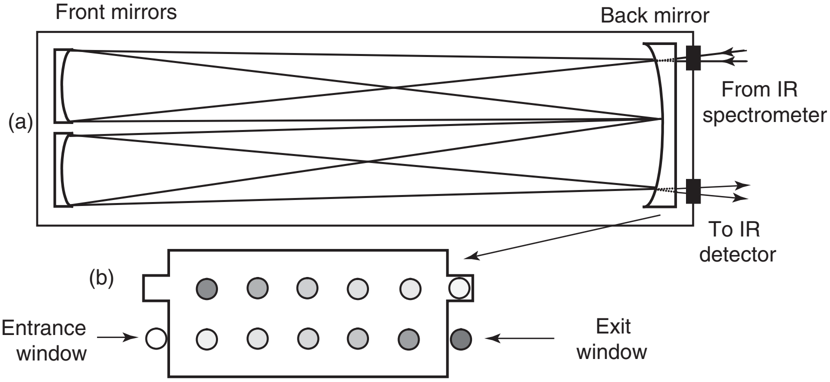

Figure 6.2 Multipass gas cell with White optics. (a) Ray diagram for four optical passes and (b) front view of the back mirror with images of the IR source on it in case of 24 passes.

should be carried out in a single beam mode. A restriction of multipass gas cells concerns cooling. It is very difficult to ensure stable alignment and prevention of atmospheric water condensation on the windows in low temperature experiments with such type of a cell.

High-resolution MIR spectrometers are required in order to resolve the rotational fine structure of vibrational bands. MIR instruments providing resolution down to 0.001 cm^{-1} are commercially available. The width of rotational spectral lines of a gaseous analyte depends not only on its partial pressure, but is a function of total pressure and temperature as well. Molecular collisions will broaden the rotational spectral lines, a phenomenon known as *pressure broadening*. The statistical distribution of velocities of the molecules causes the so-called Doppler broadening of the rotational lines. This broadening effect can be partly eliminated by cooling the gaseous sample.

Spectra of compounds with vapor pressure down to 0.001 Torr can be obtained using multipass gas cells. This technique proved very useful for the detection of atmospheric impurities or trace components in waste and combustion gases.

6.1.1.2 **Solutions and Neat Liquids**

Every solvent has its own absorption bands in the MIR region. For this reason, the most appropriate solvent for the given situation has to be chosen from a whole selection. Unfortunately this selection does not include water and alcohols, which exhibit broad and strong bands in their MIR spectra. Moreover, many optical materials used as MIR windows for liquid cells (alkali halides, such as KBr) are soluble in water and alcohol. The solvents with the largest absorption free areas in the MIR are carbon tetrachloride and carbon disulfide. As both solvents are quite toxic, they must be handled carefully. A list of most common MIR solvents is given in Chapter 5. A comprehensive review of the spectral transmission of all solvents is found in [1].

Windows for liquid cells typically consist in case of nonaqueous samples of NaCl or KBr or in case of aqueous solutions of CaF_2. A list of common MIR window material is given in Chapter 5.

For the selection of optical windows – besides such parameters as useful spectral range, mechanical resistance, and solubility – the refractive index has to be taken into account as well. The refractive index of the windows should match that of the liquid sample in order to minimize reflection losses, stray light, and distortions of band shapes (Christiansen effect). NaCl and KBr are very well suited for organic analytes. Inorganic analytes may have much higher refractive indices. The higher the refractive index, the greater the reflection losses result for the incident IR radiation.

For solutions, the typical thickness of liquid cells is in the 0.05–1 mm range, which is provided by a Teflon gasket placed between the two windows. Both fixed thickness and variable thickness liquid cells are available commercially. Typically, solutions of 0.05–10% in concentration are handled in IR cells. In double beam spectrometers, a reference cell is filled with pure solvent and placed in the reference beam in order to compensate for solvent bands and other background effects. In single beam instruments, solvent bands and background effects are usually removed by computing the difference of sample and solvent spectra. Both cell thickness and analyte concentration can be calculated from the measurements with high accuracy. This renders MIR spectroscopy well suited for quantitative measurements.

Neat liquids require a film thickness in the 10 μm range. As it would be difficult to fill a cell of such low thickness and even more difficult to clean it, capillary films of such samples are usually formed by squeezing few drops of compound between two windows.

In case of relatively low-melting solids, it is also possible to prepare a thin film by melting and squeezing the sample between two windows. Thin films of nonvolatile liquids or solids can be deposited on the window by solvent evaporation. The sample is first dissolved in a volatile solvent. A few drops of the solution are placed on the window. After evaporation of the solvent, a thin film of sample on the window is obtained. Windows can usually be cleaned using carefully dried methylene chloride or acetone. Preparing a thin film from solution or solidification from the melt are methods well suited to examine amorphous materials, such as waxes or soft resins.

6.1.1.3 **Pellets and Mulls**

Pellets are used for solid samples that are difficult to melt or dissolve in any suitable solvent, or which have to be measured in their native solid state. The sample is finely ground and mixed with dry potassium bromide (or other alkali halide) powder. The usual analyte/KBr ratio is approximately 1 : 100. An agate mortar and pestle or a vibrating mill can be used for grinding and mixing. The mixture then is pressed into a transparent disk in an evacuable die for 2 min at a pressure of 0.6 GPa (6 tons cm^{-2}). Without evacuation (e.g., when moist air is present during pressing) it is impossible to obtain highly transparent pellets. The ground particles should not exceed 2 μm in diameter, otherwise scattering losses may result. IR spectra

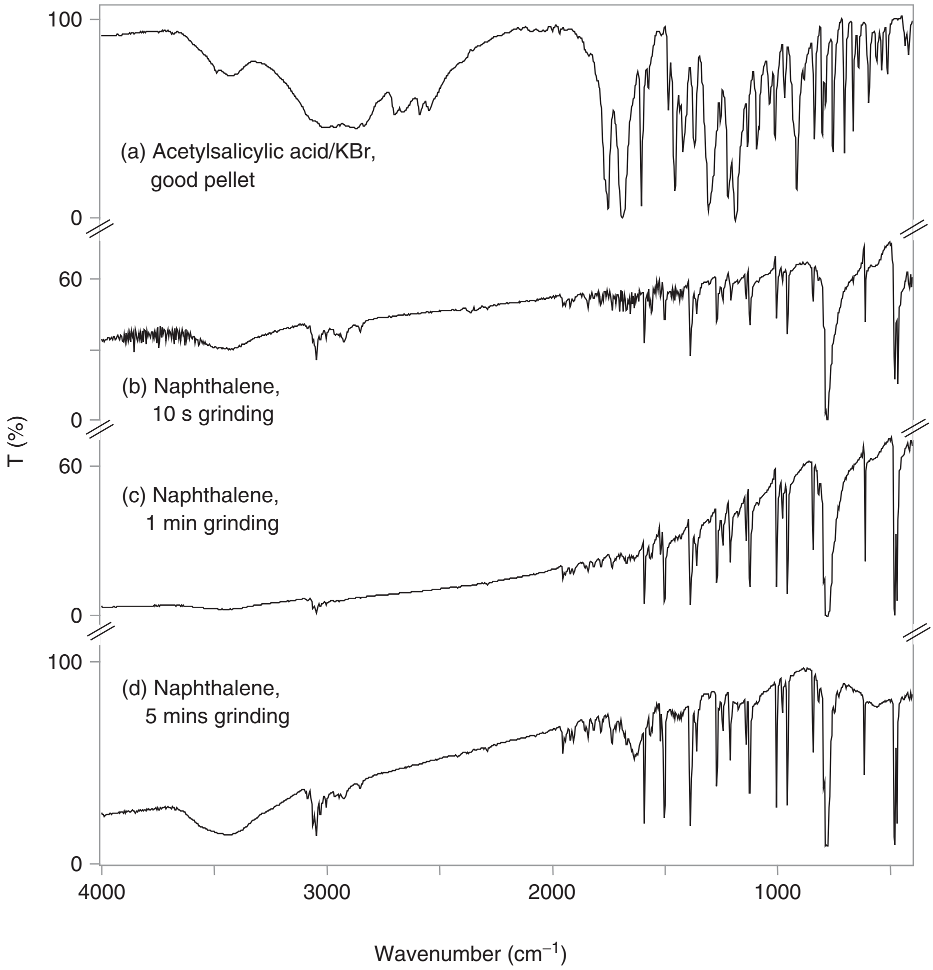

Figure 6.3 Examples of possible errors in the KBr pellet technique: (a) good spectrum of acetylsalicylic acid in a KBr pellet; (b) insufficient grinding results in light scattering (background slope) and small absorption bands; (c) longer, but still insufficient grinding improves size and shape of absorption bands; and (d) too long grinding results in good size and shape of absorption bands but causes adsorption of larger amounts of water in the pellet (broad band at 3450 cm^{-1}).

obtained by the pellet technique often exhibit bands at 3450 and 1640 cm^{-1} because of adsorbed moisture. Without internal standard added, the pellet technique is not suitable for quantitative measurements because the thickness is not precisely reproducible and the size of IR bands depends on dispersion of the sample (see Figure 6.3).

Mulls are used as alternatives for pellets. The sample (1–5 mg) is carefully ground into a suspension using a couple of drops of a mulling agent. This mull is pressed between two IR transmitting windows to form a thin film. Common mulling agents are Nujol (liquid paraffin), Fluorolube (a chlorofluorocarbon polymer), and hexachlorobutadiene. To obtain a complete IR spectrum that is free of mulling agent bands, experiments with various mulls are generally required. The mull technique is recommended for water-sensitive samples and for samples that interact with alkali halides.

A detailed description of all techniques can be found in [1].

6.1.1.4 **Neat Solid Samples**

Pellet or mull techniques cannot usually be applied to polymeric samples because of their softness. Samples of thermoplastic polymers can be prepared by using a so-called press tool for melt films. This tool consists of two heatable metal plates, which can be placed in a hydraulic press. The thickness of the squeezed film is defined by the thickness of a metal spacer placed between the heated plates. Metal plates may be wrapped by aluminum foil in order to prevent adhesion of the sample to the plates. The foils can be easily removed by dissolution in dilute HCl.

If the compound under investigation is both insoluble and nonmeltable, it can be cut into slices of appropriate thickness using a microtome. Conventional sampling techniques require sample areas of a few square centimeters, which might hardly be achievable for slices between 20 and 50 μm thickness. Samples of smaller area may advantageously be investigated by micro-attenuated total reflectance (microATR) (see below).

6.1.1.5 **Reflection–Absorption Sampling Technique**

This technique is used to study thin (down to submonolayer) films adsorbed on reflective substrates such as metals. Experimentally it involves measuring the change in the reflectance spectrum of the substrate that accompanies thin film formation. Various acronyms for the technique are used – infrared reflection–absorption spectroscopy (IRRAS, IRAS) and reflection–absorption infrared spectroscopy (RAIRS). Basics of IRRA spectra are described in Section 5.2.2.

According to theory, the maximum sensitivity in reflection–absorption measurements should be achieved at grazing incidence angle (between 65° and 85°). Various accessories are available, either with fixed angle of incidence or variable angle of incidence. It is necessary to record the reflectance spectrum of the substrate with a high signal-to-noise ratio both before and after formation of the thin film. The IRRA spectrum is then computed as a ratio of both former spectra. The range of incidence angles that can be effectively utilized is rather limited. The experiment has to be designed carefully, particularly in terms of source and detector types.

The depth of penetration of the electrical field from the surface of the metal substrate into the adsorbed sample is between 5 and 500 nm. This enables investigation of submonolayers. IRRA spectra differ from conventional transmission spectra of bulk compounds, because only vibrations with transition dipole moments perpendicular to the surface will be excited. As the evanescent field decays rapidly, vibrating groups closer to the surface yield larger absorption bands. Moreover, the polarization status of incident radiation is crucial – only p-polarized light will interact.

Another practical consideration is film thickness. In case of IRRAS of thick films, one observes a superposition of two spectra – a spectrum caused by molecules close to the surface (with some enhanced spectral bands) and a spectrum caused by the bulk sample (conventional transmission spectrum). In case of very thick samples, the bulk spectrum dominates and the angle of incidence is not so important. In case of thickness between 0.1 and 1 μm, both types of the spectra have to be taken into consideration.

Compared to other sampling technique for surface investigations, a great advantage of IRRAS results from propagation of the probe photon in a nonvacuum environment. This enables the spectrometer to be set up outside a ultra-high vacuum chamber, which considerably simplifies operation.

6.1.1.6 **Sampling by ATR**

ATR accessories are especially useful for obtaining IR spectra of samples that cannot be readily examined by common transmission methods. Such accessories are suitable for studying thick or highly absorbing solid and liquid samples, including films, coatings, powders, threads, adhesives, polymers, and aqueous samples. ATR requires only little sample preparation for most samples. It is one of the most versatile sampling techniques.

The basics of ATR have been described in Section 5.2.3. The sample has to be brought into good optical contact to the ATR crystal as shown in Figure 6.4. The IR beam is directed toward the bevel edge of the ATR crystal and undergoes single or multiple internal reflections. ATR multireflection crystals may be trapezoidal or rod-shaped. The number of reflections as well as the penetration depth decreases with increasing angle of incidence. The resulting IR-ATR spectrum is similar to a conventional IR spectrum, but the intensities of bands at longer wavelengths are higher because of the larger penetration depth at longer wavelengths. ATR accessories fit easily into the sample compartment of any grating or FT-IR spectrometer, but high-quality spectra can only be obtained by FT-IR spectrometers because of the energy limited condition.

ATR is a surface and interface investigation method. The penetration depth is in the order of a few tenths of the wavelength of investigation, in the IR between 0.5 and 10 μm (cf. Eq. (10) in Section 5.2.3). A variety of ATR accessories including various kinds of liquid cells or even horizontal units for cell-less investigation of liquids is available. Heatable ATR cells are commercially available as well. A special

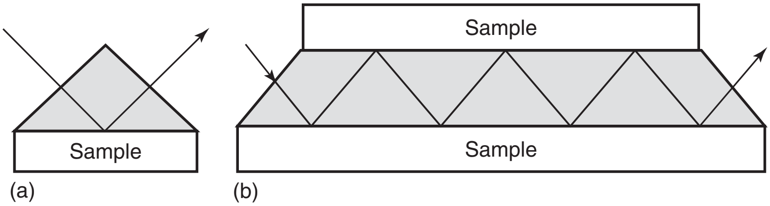

Figure 6.4 ATR sampling technique. (a) ATR crystal for single reflection measurement and (b) ATR crystal for multi reflection measurements.

and meanwhile widespread ATR variety uses a single reflection diamond. The fields of application of ATR are metals, polymers, lacquers, rubbers, coatings, laminates, papers, textiles, fibers, jelly-like samples, and interfaces of liquids and solids.

6.1.1.7 **Thin Samples**

Parts of the incident beam are reflected at each optical boundary (air-sample boundary in case of a free-standing thin sample or air-window/window-sample boundaries in case of a liquid cell), even at normal incidence. Of particular importance is that part of radiation, which undergoes multiple reflections at the two opposite surfaces of a plan-parallel sample. The double-reflected beam can interfere with the original beam, which results in sinus type periodical features in the background of the spectrum (Figure 6.5). Such features usually cause difficulties during evaluation of spectra. On the other hand, the interference provides access to the effective thickness of the sample as well as optical quality of its boundaries (deviations from plan-parallelity cause reduced amplitudes of interference fringes). The effective sample thickness can be calculated according to

$$d = \frac{N \times 10\,000}{2 \times n_\mathrm{D} \times (\tilde{\nu}_1 - \tilde{\nu}_2)}\ (\mu\mathrm{m})$$

where N is the number of interference fringes between $\tilde{\nu}_1$ and $\tilde{\nu}_2$, n_D is the refractive index of medium inside of the cell ($n_\mathrm{D} = 1$ in case of empty cell), 10 000 is the conversion factor between wavenumber (cm^{-1}) and thickness (μm). Usually, pathlengths of liquid cells of thickness up to 1 mm are determined by evaluation of their interference fringes (cf. Figure 6.5).

6.1.1.8 **Diffuse Reflection Sampling Technique**

There is a large group of solid samples (such as powders, pastes, pellets with rough and scattering sample surface) that do not give good-quality spectra by any of the above described sampling techniques. In these cases, measurement of the diffuse reflection may be an alternative. Diffuse reflection means scattering of a large part of radiation in all directions. The penetration depth of incident IR radiation into

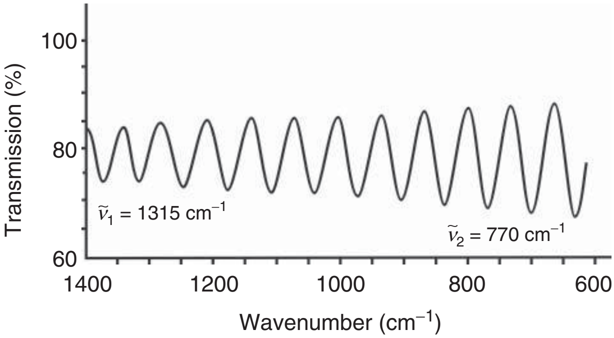

Figure 6.5 Interference fringes in an IR spectrum of an empty KBr cell. Eight fringes between 1315 and 770 cm^{-1} correspond to a cell thickness of 73 μm.

the scattering sample is usually between 10 and 500 μm. Even in case of rough surfaces, a small contribution of specularly reflected radiation always persists. Specularly reflected IR radiation does not contain much information about the sample (very short path within the sample); it mainly deteriorates the accuracy of the quantitative measurement and increases detector noise.

Diffuse reflection accessories are commercially available. They collect the diffusely scattered IR radiation by means of large ellipsoid mirrors. Even the largest mirrors only permit the collection of a part of the scattered radiation; therefore, the use of diffuse reflection accessories is restricted to FT-IR spectrometers (diffuse reflection in infrared by Fourier Transform spectrometer – DRIFT). The Kubelka–Munk transformation has to be performed in order to linearize the ordinate of the obtained spectra. Integrating spheres (the so-called Ulbricht spheres) are not any longer used in MIR because of the lack of nonabsorbing and uniformly high-scattering coatings for the inside of the sphere.

DRIFT spectra depend on both the scattering and the absorbing properties of the sample (Kubelka–Munk theory). DRIFT spectra are considerably complex. They are influenced by particle size, crystallite orientation, sample homogeneity, and analyte concentration. The bigger the particle size, the larger the contribution of specular reflection and absorption. Both contributions have to be minimized for quantitative evaluation. The ideal particle size is between 2 and 10 μm. Bigger particles have to be ground before measurement. Low absorbance is achieved by dilution in a nonabsorbing matrix, usually KBr powder in a ratio from 1 : 3 to 1 : 100. A special variation for compact materials is the abrasion technique. Nickel–diamond abrasive pads are used to rub off a part of the sample, for example, a varnish. The pad is then inserted into the DRIFT accessory and directly measured.

An excellent description of all aspects of diffuse reflectance can be found in [4].

6.1.1.9 **Sampling by Photoacoustic Detection**

The basics of photoacoustic spectroscopy (PAS) are described in Section 5.4. PAS is useful for examining highly absorbing samples that are difficult to analyze by other IR techniques. Minor or even no sample preparation is required here. Size and shape of the sample are not critical. PA spectra can be obtained from a wide variety of samples such as powders, polymer pellets, viscous glues, single crystals, and single fibers.

PA spectra are generally similar to conventional IR spectra except that strong spectral bands will often be saturated (truncated). However, the presence of such truncated bands does not much limit the practical use of PAS. Depth resolved measurements are an important feature of the FT-IR PAS technique. Depth resolution can be varied from 1 to 20 μm simply be changing the velocity of the moving mirror inside the interferometer. Multilayer samples such as polymer composites can easily be studied by PA spectroscopy.

6.1.1.10 **Microsampling**

Microsampling techniques have to be applied when either small amounts or small sizes of analytes have to be investigated. Microsampling techniques may be derived from conventional techniques by miniaturization. For all such miniaturized sampling techniques, a beam condenser (micro illuminator) is needed. Standard beam condensers are made of a pair of ellipsoidal mirrors. Micropellets for solids have a diameter of 0.5 and 1.5 mm with sample amounts of 5–10 μg in 4 mg KBr. For liquids and solutions, microcells with volume down to 0.3 μl are commercially available. A special case of microsampling is the so-called diamond anvil cell, where a tiny drop of liquid analyte is squeezed between two diamond crystals. Even solidification of the sample between the diamonds can be achieved by applying pressure up to 100 bar. Usual dimensions of the diamond surfaces are below 1 mm. This technique is very useful for conformational analysis.

Nowadays, microsampling is performed by using IR microscopes (see also Section 5.5). They permit easy access to spectra from small sample areas down to about 10 μm × 10 μm. This size limit results from the basic diffraction theory. Spectral information from smaller areas can be obtained only by investigating wavelengths closer to near infrared (NIR) spectral range. IR microscopes equipped with a x,x-motorized stage permit the 2D mapping of chemical properties with good lateral resolution (e.g., distribution of impurities). Several years ago, MIR instrument with array detectors became commercially available. Such instruments permit the collection of IR images in only a few seconds by direct imaging.

All microsampling techniques require very thorough sample preparation. For obtaining meaningful results in either transmission or reflection mode of an IR microscope, sufficient skills in microscopic sample preparation are required.

A wide range of compounds can be investigated by IR microscopy. The broad scale of sampling accessories for IR microspectroscopy includes even objectives for ATR or grazing angle measurements.

6.1.2
Structural Analysis

Every chemical compound has its own characteristic IR spectrum. The IR spectrum contains the entire information about the molecular structure of the investigated sample. The main problem is the assignment of experimental spectral bands. In addition to fundamental vibration bands, very often the so-called combination and overtone bands are present. Fermi resonance can cause intensity changes and frequency shifts of the bands involved. Intermolecular interactions (such as hydrogen bonding) can cause additional bands. Furthermore, influences of solvents, temperature, and pressure have to be considered. There are two different approaches for the assignment of vibrational bands.

The most convenient tool for identification of molecules from their vibrational spectrum are spectral databases (cf. Chapter 53). The matching process gets very much accelerated by computerized search programs. If an exact match cannot be found, these programs usually list the reference compounds that numerically match the unknown spectrum much closely. Attention: close proximity in a search hitlist does not guarantee close similarity of molecular structures.

A more chemical approach is the evaluation of characteristic or group frequencies. Some chemical groups exhibit highly characteristic bands no matter in what kind of molecule they are included. The group frequency approach is very useful for structural analysis. From frequencies and intensities of some spectral bands, it is possible to predict what kind of chemical groups are present in the molecule, how they are connected to other groups and, finally, the structure of the molecule under investigation may be guessed.

According to the theory of molecular vibrations in any N-atomic molecule, there are $3N - 6$ ($3N - 5$ in case of linear molecules) fundamental vibrations. By the group frequency approach, one takes into account only movements of atoms with largest amplitude but neglects atoms with much smaller vibration amplitude. Vibrations can be subdivided in two groups – stretching vibrations (when bond lengths are

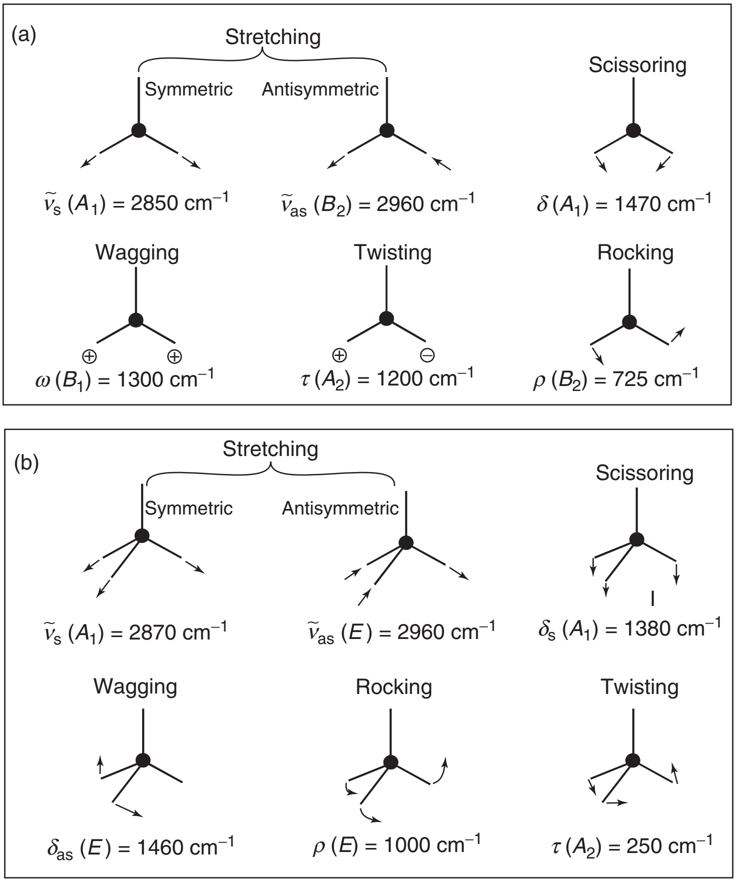

Figure 6.6 Group frequencies of (a) CH_2 and (b) CH_3 groups. The name of each type of vibration (abbreviated by a Greek letter) reflects the kind of movement. The italic letters given in parenthesis are used to fully describe the symmetry properties of the oscillator.

changing during vibration, also called *valence vibrations*) and deformation vibrations (when bond angles are changing). Deformation vibrations are subdivided further into scissoring, wagging, rocking, and twisting modes. Vibrations of CH_2 and CH_3 groups are summarized in Figure 6.6.

Each normal vibration has particular symmetry properties, described by symmetry elements of the point group to which the molecule under investigation belongs. Symmetry considerations are very useful for the assignment of the spectral bands. The so-called character tables may be used to derive the symmetry of each normal vibration and to deduce the IR and Raman activity of a given vibration. A vibration is IR active, if the total molecular dipole moment changes during vibration. It is Raman active, if the molecular polarizability changes during vibration. It can be deduced from symmetry considerations, whether dipole moment or polarizability changes occur during vibration. IR or Raman activity merely indicates the appearance of a particular band in the spectrum. In order to further predict the intensity of vibrational bands, detailed information about the magnitude of the transition moment is needed.

Not all vibrations exhibit characteristic frequencies. For instance, vibrational frequencies of the various C–C bonds in the carbon backbone of aliphatic molecules are very much coupled between each other (the so-called skeleton modes), and they depend very much on chemical groups connected to this aliphatic chain. This behavior can also be used for spectrum interpretation. A short list of group frequencies of some chemical groups is given in Table 6.1 and Table 6.2. A more comprehensive list of characteristic bands can be found in spectral correlation tables and charts, for example, in [4, 5].

For practical evaluation, the IR spectrum is often divided into three regions: (i) from 4000 to 1400 cm^{-1}, (ii) from 1400 to 900 cm^{-1}, and (iii) from 900 to 400 cm^{-1}.

6.1.2.1 **The Region from 4000 to 1400 cm^{-1}**

This region comprises stretching vibrations involving movements of light atoms (molar mass below 20 g mol^{-1}). O–H and N–H stretching bands are located in the region from 3700 to 2500 cm^{-1}. These groups very often participate in the formation of hydrogen bond complexes. The formation of such complexes results in red shifted and very broad spectral bands. C–H stretching bands are found in the 3300–2800 cm^{-1} spectral range. Bands in the 2700–1850 cm^{-1} spectral region usually belong to C≡C, C≡N, N≡N, or some groups containing hydrogen and a heavier atom (S–H, P–H, and Si–H). The 1950–1450 cm^{-1} region exhibits IR absorption from a wide variety of double-bonded chemical groups, in particular C=O. This region is of particular importance for investigations of biological molecules. Conjugation, ring size, hydrogen bonding, steric and electronic effects often result in significant shifts in absorption frequencies.

6.1.2.2 **The Region from 1400 to 900 cm^{-1}**

This is called the *fingerprint region*. Many chemical groups with single bonds have group frequencies in this region. These vibrations usually couple very strongly, that is, particular bands in this region can hardly be attributed to a single chemical

Table 6.1 Selection of characteristic group frequencies of organic compounds.

Spectral range (cm^{-1})	Chemical group	Group vibration
3700–3200	−OH	OH stretching
3400–3330	$-NH_2$	Antisymmetric stretching
3300–3250	$-NH_2$	Symmetric stretching
3065–3050	$-C-H_{aromat}$	C−H stretching
3020–2950	$-CH_3$	Antisymmetric stretching
2960–2910	$-CH_2$	Antisymmetric stretching
2970–2860	$-CH_3$	Symmetric stretching
2860–2840	$-CH_2$	Symmetric stretching
2590–2560	−SH	S−H stretching
2600–2350	−B−H	B−H stretching
2450–2275	−P−H	P−H stretching
2300–2230	$-C{\equiv}C-$	$C{\equiv}C-$ stretching
2260–2230	$-C{\equiv}N$	$C{\equiv}N$ stretching
2250–2100	−Si−H	Si−H stretching
2250–2100	−C−D	CD, CD_2, CD_3 stretching
1760–1720	−C=O	In organic acids
1740–1700	N−C=O	In ketones
1660–1650	−C=O	In amides
1660–1640	−C=N	Stretching
1700–1625	−C=O	Amide I
1660–1640	$-C{=}C^-$	Stretching
1600–1595	$-COO^-$	Antisymmetric $-COO^-$ stretching
1600–1450	−N=O	N=O stretching in organic nitrates
1470–1440	$-CH_3$	Antisymmetric deformation
1470–1440	$-CH_2$	Symmetric and antisymmetric deformation
1430–1420	−CO−OH	CO stretching in organic acids
1410–1390	$-COO^-$	Symmetric $-COO^-$ stretching
1400–1310	$-S{=}O_2^{\ -}$	Antisymmetric stretching
1390–1370	$-CH_3$	Symmetric deformation
1380–1300	$-CF_3$	Stretching
1340–1250	−CO−NH	Amide III
1330–1250	−CH	Deformation
1265–1250	−CO−OH	CO−OH deformation in organic acids
1280–1250		Oxirane, breathing of the ring
1300–1140	−P=O	Stretching
1300–1120	$-CF_2$	Stretching
1200–1120	$-S{=}O_2^{\ -}$	Symmetric stretching
1120–1060	−C−F	Stretching
1300–1100	−C−O−	Stretching
1150–950	−C−C−	Stretching
1070–1040	−S=O	Stretching

1100–1000	Phosphates PO_4^-, HPO_4^-, $H_2PO_4^-$	PO stretching
1100–900	Silicates	SiO stretching
880–860	Carbonates CO_3^-	OCO bending
840–815	Nitrates NO_3^-	ONO bending
840–800	Nitrites NO_2^-	ONO bending
680 to 610	Sulfates SO_4^-	OSO bending

bond or group. On the other hand, bands caused by complex interacting vibrations constitute a unique fingerprint for each compound. If two spectra exhibit identical fingerprint patterns in this region, the corresponding samples are generally considered to be identical.

6.1.2.3 The Region from 900 to 400 cm^{-1}

Some characteristic bands of aromatics occur in this region. These bands are due to aromatic C–H out-of-plane bending vibrations. The absence of absorption bands in the 900–650 cm^{-1} region usually indicates the absence of aromatic rings in the molecule under investigation. Some organic molecules containing halogen atoms can also contribute in this region. In the case of inorganic molecules, the bands due to bending vibrations of the molecular fragments OXO type, where X = C, N, or S are present in this region.

On the basis of extensive experience, the following scheme for interpretation of IR spectra based on group frequencies was worked out. No systematic procedure of general validity exists, and a reasonable way to proceed is as follows:

1. Carbon backbone:	Evaluation of C−H str, C−H def, C−C str Presence of aromatics −C−C−, −C=C−, −C≡C− groups Compare with NMR data!
2. O-containing compounds:	Evaluation of C=O str, O−H str Interactions with −C−H− str, −N−H− str, −O−H str
3. N-containing compounds:	Evaluation of N−H str, C≡N str Compare with MS data!
4. S-, P-, Hal-containing compounds:	Evaluation of S−H str, S=O str, $-SO_2$ str, P=O str, C−Hal str Compare with chemical analysis and MS data!

It should always be remembered that the aim of structural analysis based on characteristic IR frequencies is to identify structural groups, not to ascertain the total molecular structure of the analyte. Even the identification of structural groups should be based on different chemical and physical data, not just on a single IR spectrum. In general, it is impossible to deduce the total molecular structure solely by interpretation of IR spectra by means of correlation tables. Sometimes, the absence of a particular absorption may be more informative than its presence.

A very general approach is the comparison of experimental spectra with calculated spectra. For small molecules (up to 40–60 atoms), it is possible to predict their structure and IR and Raman spectra with reasonable precision by quantum chemical (*ab initio*) methods. By comparing theoretical and experimental spectra, the bands can be assigned. If calculated and the experimental spectra fit each other, the structure used for calculation should be the correct one.

Nowadays, the spectra of polymers and other large molecules can only be computed by semiempirical or molecular mechanics calculations. Such calculations allow one to predict the molecular structures, but do not give (or give too little) information about the vibrational frequencies and cannot be used for the interpretation of spectra.

6.1.3
Special Applications

Various modern accessories (ATR crystals, acoustic detectors, IR microscopes, polarization modulation technique) as well as hyphenation techniques substantially expanded the field of applications of IR spectroscopy. Applications of IR spectroscopy to surface investigations (characterization of the surface, physisorption and chemisorption studies, catalytic properties) are reviewed in [6–8]. Applications of hyphenated techniques, in particular combinations with chromatography, are given in [7].

IR spectroscopy retains its importance in the field of *industrial applications*, Raman spectroscopy regains attraction. A detailed summary of applications can be found in [9]. The industrial environment requires special conditions for the instruments such as rapid measurements, the high degree of automation and reliability, robustness, and special software. Of importance are the sampling methods, the data transfer to computer networks, and the software for quantitative analysis. A major field is quality assurance, for example, in the pharmaceutical and semiconductor industry. A very new field is the use of IR for industrial combinatorial chemistry. The most rapidly growing area is the on- and in-line process control in almost all industrial applications. For the investigation of inorganic substances and coordination and organometallic compounds, IR techniques also are suitable. An excellent survey of the experimental aspects and the applications with many examples is given in [10].

In recent years, the use of IR spectroscopy for *medical applications* such as in the analysis of human tissues and body fluids such as blood has substantially increased. In such kinds of measurements, all modern spectroscopic methods such as mapping and ATR microscopy, the data need to be evaluated by statistical and multivariate analysis. IR spectroscopy is very sensitive to structure and concentration changes of biological macromolecules such as nucleic acids, proteins, and lipids. A summary of this field is given in [11]. Examples of successful applications of IR are the monitoring of cellular metabolism and the identification of tumors. PAS applications in life sciences studies as well as on solids, liquids, and gases are described in [12]. A new method for applications in biology, medicine, and industry (semiconductors) is IR imaging spectroscopy, a combination of IR microscopy with a focal plane array detector. Another new method is 2D spectroscopy where the spectral intensity is obtained as a function of two independent spectral variables. A short description of the method is given in [13] and the literature cited therein.

The *analysis of polymers* is one of the most important application fields for IR spectroscopy. This kind of spectroscopy can be successfully used for the determination of chemical structures such as stereoregularity, chain conformation, orientation, and crystallinity, for the identification of complex polymeric systems, for monitoring the reaction processes, and for the study of dynamic properties such as diffusion. All these applications are discussed in [14].

For *forensic analysis*, IR spectroscopy is a commonly used method. A description of all application fields with many samples is described in [15]. Specific analyses are the analysis of paints, paper, inks, gemstones, polymers, fibers, food, and the analysis of physiological samples, and environmental samples. The main methods of investigation are the ATR diamond cell and all reflectance techniques as well as the GC-IR technique.

An excellent summary about the use of the IR spectroscopy in the *study of works of art* is given by Edwards [8]. So it is possible to investigate plastics, glass, faience, biomaterials, paintings, medieval manuscripts, and wall paintings to determine the origin and the age of all these art objects (see Reference Data Table 6.1).

Techniques yielding similar information: Raman spectroscopy.

Typical features of attached computers: computers (not built-in) are part of modern MIR spectrometer. The supplied software manages data acquisition and analysis. Additional software for chemometric evaluation is available.

Typical application (*as demonstrated in chapter*): qualitative and quantitative analysis, *in situ* measurements, process control.

Preferable samples: solutions in percent concentration.

Problematic samples: water as solvent, weakly absorbing samples.

6.1.4
Infrared and Raman Spectroscopic Imaging

Applications of IR and Raman spectroscopic imaging are nowadays found in all areas from bioanalytical chemistry of cells and tissue via food and polymers to homeland security [16].

The identification of relevant molecular processes and the distribution of biochemical features now provide the potential for an early detection of diseases and

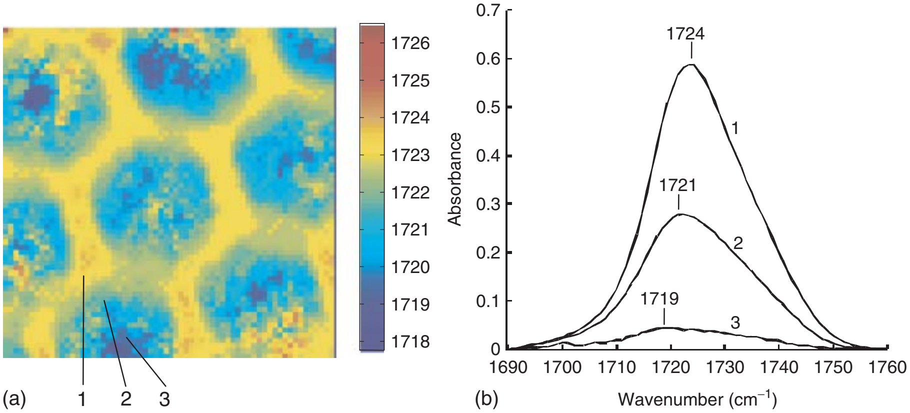

Figure 6.7 (a) Color-coded image, indicating the distribution of PMMA molecules in a microstructured 350 nm thick PMMA layer on gold substrate. Intensity and position of ν(C=O) infrared spectral band is taken as an indicator of concentration and type of adsorption of PMMA. (b) ν(C=O) bands that represent web region (1), pore wall (2), and pore center (3).

their optimized treatment. Therefore, the majority of the FTIR imaging activities are aimed at biochemical and medical questions. Most of these applications have been performed on thin tissue sections with the use of an IR microscope. The characterization of polymer samples based on FTIR imaging has emerged rapidly during the past 5 years. Chemical image of poly(methyl methacrylate) (PMMA) microstructured layer on gold substrate obtained by means of IR spectroscopic imaging is presented in Figure 6.7.

Other applications are focused on the identification and visualization of components in polymer blends and copolymers. The chemical images allow to identify the spatial distribution of polymers, the crystallinity, or the degree of orientation. Relatively new applications of FTIR imaging are the forensic analysis and the chemical monitoring of finger marks. Another growing field of spectroscopic imaging covers investigations of plant tissue (Figure 6.8). IR spectroscopic imaging is also an ideal tool for the high-throughput analysis.

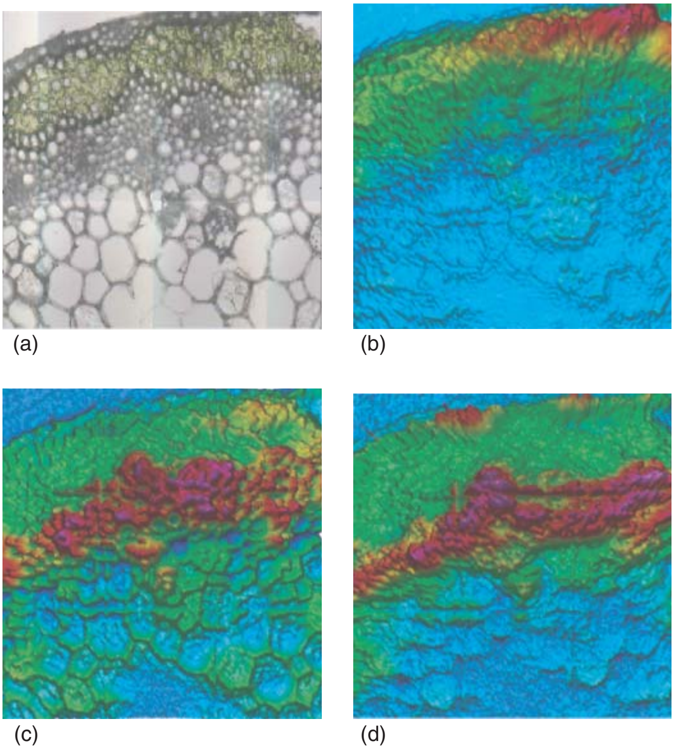

Figure 6.8 (a) Microscopic video image of a thin section of wheat stalk. The dimension of the image is approximately 500 µm × 500 µm. (b–d) The false color images representing the distribution of the three main components. The contrast is calculated from the intensity of the absorption in representative spectral ranges: proteins 1480–1710 cm^{-1}, carbon hydrates 900–1140 cm^{-1}, and lipids 1700–1770 cm^{-1}.

6.2
Near Infrared Spectroscopy

The NIR spans the range from 12 500 to 4000 cm^{-1} (800–2500 nm) and is dominated by overtones and combinations of O–H, N–H, C–H, and C=O vibrations. Overtone and combination bands are rather weak. Band intensities usually drop by a factor between 10 and 100 from excitation level to excitation level. The low absorbance of overtones and combinations restricts the application range of NIR spectroscopy usually to liquids and solids. Absorption regions for some important groups and vibrations are given in Table 6.3. In addition, the short wavelength NIR range covers lowest-energy electronic transitions. Fermi and other resonances occur in the region as well [17].

NIR is increasingly used in process and environmental analysis, food industry, agriculture, pharmaceutical industry, and polymer analysis. In-line measurement with fiber optics and rapid multicomponent quantification are the most important advantages of NIR spectroscopy. In comparison to MIR, NIR analysis is much faster and more versatile. Most samples are analyzed in 1 min or less. Often chemometric methods must be applied to determine the parameter of interest.

6.2.1
Sample Preparation and Measurement

One of the greatest advantages of NIR spectroscopy is the ease of sample handling. Often, common transmission and reflection techniques can be used for nondestructive analysis. Thus, NIR analysis eliminates the sampling errors caused by manual handling and reagent or solvent contamination.

Table 6.3 NIR absorption regions of important groups and vibrations.

Group	Type of vibration (ν, stretching, δ, bending)	Wavenumber (cm^{-1})	Wavelength (nm)
Free OH	3ν (second overtone)	10 400–10 200	960–980
Bound OH	3ν (second overtone)	10 000–8 850	1000–1130
C–H (CH_3, CH_2)	3ν (second overtone) and	8 700–8 200	1150–1220
	combination $2\nu + 2\delta$	7 350–7 200	1360–1390
Free OH	2ν (first overtone)	7 140–7 040	1400–1420
C–H (CH_3, CH_2)	Combination $2\nu + \delta$	7 090–6 900	1410–1450
Hydrogen-bonded OH	2ν (first overtone)	7 140–6 170	1420–1620
Free NH	2ν (first overtone)	6 710–6 500	1490–1540
Hydrogen-bonded NH	2ν (first overtone)	6 620–6 250	1510–1600
S–H	2ν (first overtone)	5 780–5 710	1730–1750
CH_3 and CH_2	2ν (first overtone)	6 020–5 550	1660–1800
C=O	3ν (second overtone)	5 230–5 130	1910–1950
Free OH	Combination $\nu + 2\delta$ and 3δ	5 210–5 050	1920–1980
C–H (CH_3, CH_2)	Combination $\nu + \delta$	4 440–4 200	2250–2380

For liquids, quartz cells similar to those used in UV/vis can be used. Because of the weak absorption coefficients, most samples need not be diluted, and cell of large pathlength up to some centimeters are possible. NIR spectra of some common solvents are shown in Figure 6.9. Tetrachloromethane is well suitable because all C–Cl vibrations occur far away from the NIR range. In contrast, water and ethanol are not suitable because of their strong O–H absorption bands. For the same reason, drying may be necessary for native samples (agriculture and food analysis) (Table 6.4).

Weakly scattering solids can be investigated by transmission techniques. For strongly scattering samples, diffuse reflection accessories must be used.

Slight temperature variations may lead to a shift of band positions and to changes in absorbance. This is of particular importance for quantitative evaluation of NIR spectra. The NIR spectra of water at several temperatures, shown in Figure 6.10, reveal band shifts toward shorter wavelengths, which arise from changes in average size of molecular clusters and from weakening of strongly H-bonded states [18]. Temperature effects of this size in aqueous samples can easily overlap weak absorption signals from weakly concentrated analyte.

The availability of low-cost, highly transmitting NIR fibers led to wide spread application of NIR fiber sensors. Fibers may simply be used as light guide between the NIR spectrometer and the measuring point, or they may serve as sensor by using the evanescent field of light totally reflected inside the fiber. NIR fiber optic sensors combined with statistical data evaluation are increasingly used for in-line monitoring of chemical compounds or reactions.

6.2.2
Application of NIR Spectroscopy

Fiber optic sensors provide access to real-time reaction profiles and to careful controlling of reactions. The need to measure product quality during the production process has driven the development of NIR fiber optic sensors. Gas, liquid, and solid material can be analyzed. An important field is *environmental monitoring*. NIR in combination with fiber optics is applied to acquire information about volatile organic compounds in water and waste water, sediments, mud, and solid samples. The polymer cladding (e.g., silicone) of optical fibers may act as a hydrophobic membrane that enriches nonpolar compounds in water. Chlorinated hydrocarbons and aromatic substances in water can be detected by using the evanescent field absorption of fiber guided light up to the subparts per million concentration range [17].

NIR spectroscopy has been used for more than 30 years in the *food industry and agriculture*. Main applications are in the determination of moisture and characterization of other compounds, for example, protein content in grain and milk products. Usually, diffuse reflection is measured, because samples need not be prepared extensively. Compared to wet chemical analysis or other instrumental methods of analysis, NIR in particular allows rapid detection even under field conditions. Some basic characteristic wavelengths are listed in Table 6.3.

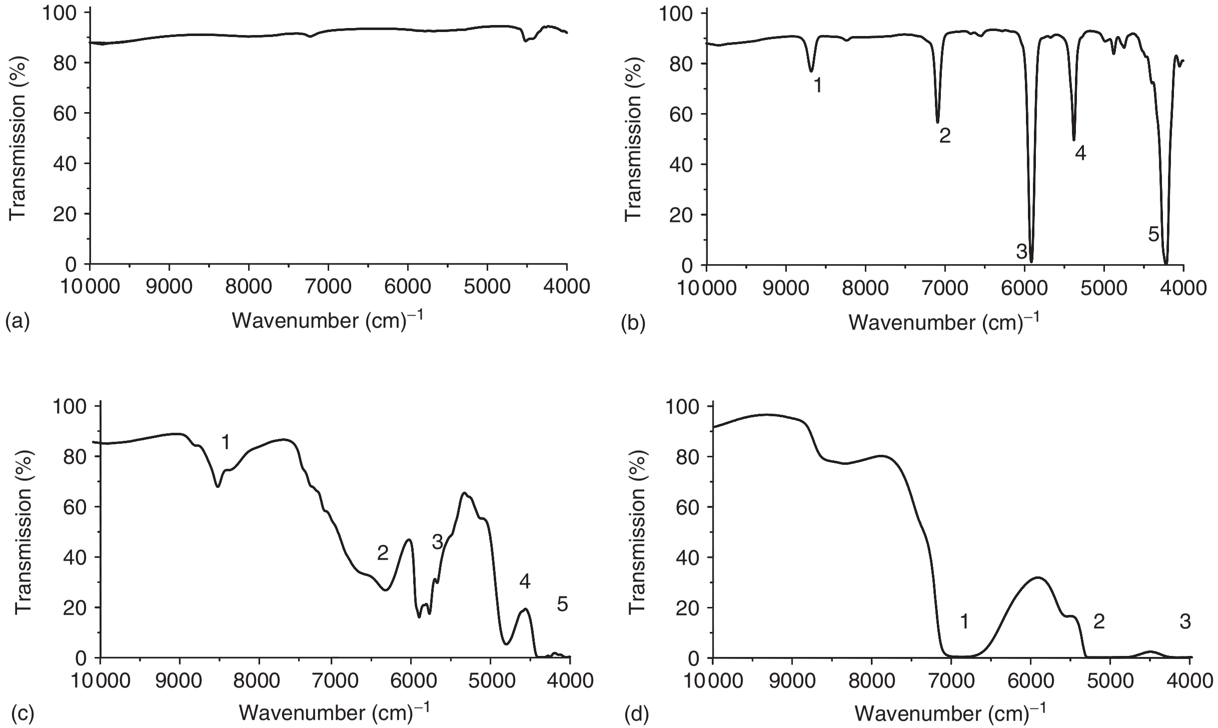

Figure 6.9 NIR spectra of some typical solvents such as (a) tetrachloromethane, (b) trichloromethane, (c) ethanol, and (d) water, recorded in 2 mm quartz cells. For band assignments see Table 6.4.

Table 6.4 Assignments of the most pronounced NIR absorption bands of solvents shown in Figure 6.9.

Water		Ethanol		Trichloromethane	
#		#		#	
1	2ν O–H	1	Second overtone ν C–H, combination C–H	1	Second overtone ν C–H
2	Combination	2	First overtone ν O–H, combination CH_2/CH_3	2	Combination C–H
3	ν O–H	3	First overtone ν C–H	3	First overtone ν C–H
		4	Combination O–H, ν C–O fourth overtone	4	Combination C–H
		5	Combination CH_2/CH_3, νO–H	5	Combination C–H

Bands are numbered as in the figure.

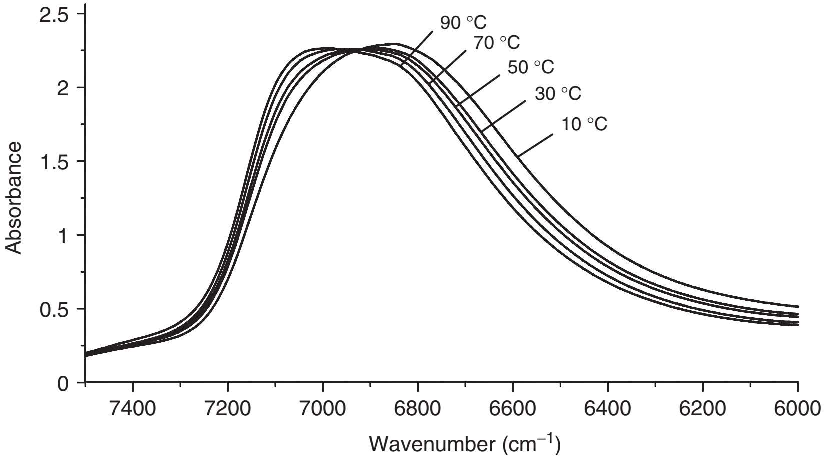

Figure 6.10 NIR spectra of water at different temperatures, recorded in a 2 mm quartz cell.

Table 6.5 Typical wavelengths for characterizing of food by NIR measurements [19].

Wavenumber (cm^{-1})	Compound
4400	Lignin
4330	Oil
4280	Cellulose
4590	Protein
4760	Carbohydrate
5150	Moisture

Moisture and hydroxyl number are important parameters, which are determined by measuring either the first overtone at 6890 cm^{-1} or the combination band at 5180 cm^{-1}. A few details about chemical structure are accessibly by interpretation of these bands. Changes in hydrogen bonding lead to changes in band shape and band location. Difference spectra or second derivatives must be calculated in order to detect minor chemical interactions of OH with other molecular species in the sample. The content of double bounds is another important parameter to describe properties of fats and oils, for example, their degree of unsaturation.

NIR spectroscopy can also be used to identify different makes or different charges of the same product. Chemometric evaluation even of very similar looking spectra provides access to the parameter of interest or to distinguish between similar samples. Spectra of different edible oils are shown in Figure 6.11. Despite the similarity of their spectra, samples can be well discriminated by statistical data analysis.

In the food industry, NIR spectroscopy is the most common in-line method to monitor moisture, oil, fat, and analyze grains, feeds, meat dairy, and other products for protein content. Metabolites in the leaves of spice plants can be determined by using NIR reflection measurements [20]. Accuracy and precision achieved are better than ±0.2% [21]. On-line measurements are also made in diverse snack food products.

NIR spectroscopy is applied in the *pharmaceutical industry* to analyze raw material, drugs, and to identify packing materials. The effect of drugs – among other things – depends on the crystalline form in which the drug exists. While structural information is available in MIR, secondary interactions between several groups are often seen in NIR. Thus, polymorphism of drugs as well as isomeric purity of optically active substances can be monitored by NIR.

In *polymer industry*, packing material, laminates including multilayer films, pellets, or molded products can be analyzed by NIR. Even polymer latex particles with up to 99% water content may be analyzed. NIR provides information about reaction mechanism, polymerization, crystallinity, orientation, water content, and hydrogen bonding, even during the process of polymers manufacturing. For example, the disappearance of the double bonds in polyethylene and polypropylene can be monitored. In their NIR spectrum, C=C bonds lead to a combination band at about

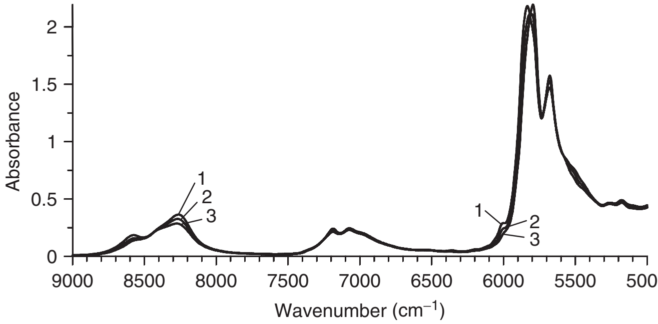

Figure 6.11 NIR spectra of three different edible oils: (1) flax oil, (2) sunflower oil, and (3) olive oil. The spectra are dominated by C–H and O–H bands.

$4740\,\mathrm{cm}^{-1}$ and a first overtone at about $6170\,\mathrm{cm}^{-1}$. NIR spectroscopy is applied to characterize ester-, nitrile-, or amide-based acrylic and methacrylic polymers. Other examples are the identification of poly(vinyl chloride), poly(vinyl alcohol), and poly(vinyl acetate) or the analysis of polymerization in epoxy and phenolic resins.

NIR is applied in many areas of *medicine*, *biology*, and *biotechnology*. Optical fibers for the NIR and new fiber optic compact process spectrometer as well as NIR light emitting diodes (LEDs) permit new applications in medical diagnosis [22]. Proteins [23], blood glucose [24], cholesterol, and fatty acids have been subjected to the investigations. Although *in vivo* NIR is connected with many problems such as high water absorbance in tissue, light scattering, band shift caused by temperature changes, and band overlap, the advantages of NIR are evident in the application in living tissues and cells [25]. Optical tomography systems use NIR spectroscopy to image the cerebral cortex and the level of oxygenated blood in the tissue [26]. In biotechnology, NIR spectroscopy is mainly used to monitor fermentation processes and to measure biomass, nutrient products, or the concentration of byproducts in real time.

NIR spectroscopy is an important method for rapid on-line monitoring of oil *and petrol production* processes. It has become an essential component in hydrocarbon processing. NIR reflection spectrometers are also used to analyze oil sand in petrol industry. NIR spectroscopy is used for *in situ* quantification of liquid natural gas. Feed streams can be monitored as well. Finally, NIR reflection spectroscopy is also used to determine pollution and contamination of oil and other petrol chemical products in sand and earth [27] (see Reference Data Table 6.2).

6.3
Raman Spectroscopy

Raman spectroscopy is a technique, which is complementary to IR spectroscopy. It offers particular advantages over MIR and NIR spectroscopy. As water is a weak scatter medium in the vis range, no special accessories are needed for measuring aqueous solutions. Furthermore, atmospheric gases are very weak scatterers, and therefore purging of the Raman instrument is not needed. Ordinary glass is transparent in visible and NIR spectral regions, where Raman spectra are excited, hence inexpensive liquid sample cells made from glass can be used in most Raman measurements. For remote analysis, glass fiber optics can be used. The standard Raman spectral range extends down to $10\,\mathrm{cm}^{-1}$, the technique is ideal for both organic and inorganic samples.

Limitations of Raman spectroscopy in comparison to IR are sensitivity and undesired fluorescence. Relatively expensive and sophisticated instrumentation also should be taken into account.

6.3.1
Sample Preparation and Measurements

The alignment of optics used for delivering the laser beam to the sample and for collecting Raman scattered radiation toward the spectrometer entrance slit is very important for the effective application of Raman spectroscopy, as Raman scattering is very weak. In conventional Raman instruments, this procedure is rather tedious and requires some experience. In FT-Raman instruments, this is more a routine task, because the alignment is based on the observation of the Raman interferogram. Various setups can be used to collect Raman scattering. The most common ones are 90° collection and 180° collection (back scattering) geometries (Figure 6.12). Zero degree scattering geometry is also possible but rarely used.

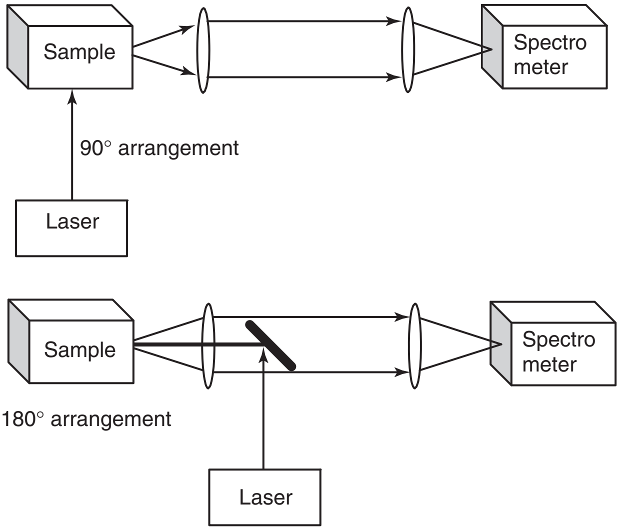

Figure 6.12 Most common sampling geometrics in Raman spectroscopy.

6.3.1.1 Sample Illumination and Light Collection

Sample illumination and methods for collecting Raman scattered light can be subdivided into three groups: by the use of conventional optics such as lenses and mirrors, by the use of fiber optics, and by optical microscopes.

A comprehensive overview of cells and sample illumination methods in Raman spectroscopy is given in [3]. Rectangular cells, spherical cells, NMR tubes, or light pipes may be used. Most popular arrangements for sample illumination are shown in Figure 6.13.

Optical fibers are increasingly used for remote Raman probing, for example, to monitor chemical processes in-line or inside a reactor. The laser beam is guided to the probe head by an excitation fiber, and the Raman signal is returned to the detector by a collection fiber. Probe heads usually work in the 180° arrangement. There are two different types of fiber probes for common use in Raman spectroscopy: the concentric unfiltered fiber bundle and the filtered probe. The fiber bundle is less expensive, while the filtered probe offers better signal-to-background ratio in certain applications.

Usually, fiber bundles consist of fibers of 100 μm core diameter. The fibers are cemented into a cylindrical holder and then polished. The central fiber (excitation fiber) delivers laser light to the sample, while the surrounding fibers collect Raman radiation. The laser beam is focused into the excitation fiber by a microscope objective. For coupling to the entrance slit of dispersive spectrometer, the output

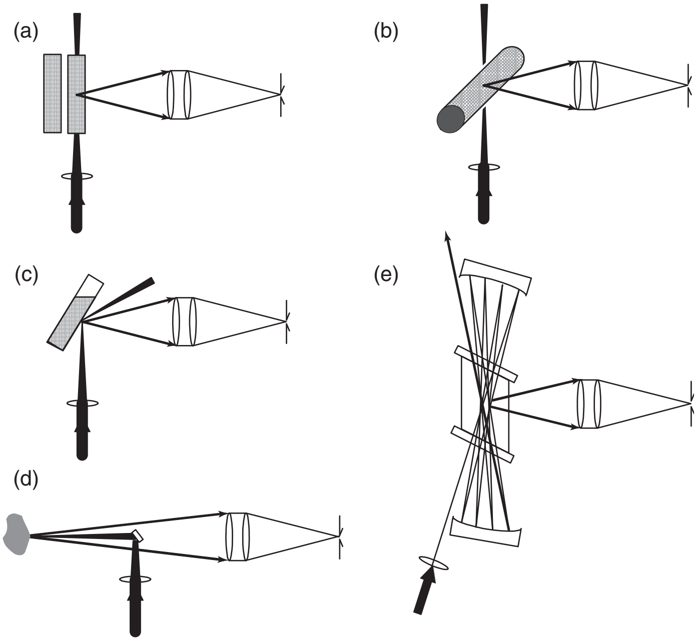

Figure 6.13 Sample illumination in Raman spectroscopy: (a,b) liquid sample; (c) liquid or solid sample; (d) solid sample; and (e) gaseous sample by multipath excitation.

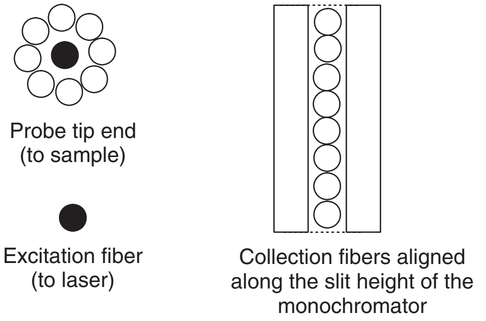

Figure 6.14 Sketch of an eight-around-one fiber probe, showing both ends of the fiber probe.

ends of the collection fibers are arranged in a row, as shown in Figure 6.14. Matching optics are only needed in case of a difference in f/numbers between fiber and spectrometer. The fiber bundle can be immersed into liquid samples or held at a short distance from the surface of a solid sample. Fibers are usually made from silica, which itself generates Raman as well as fluorescence signals. In most cases, fiber signals can be eliminated, but some noise may be introduced and weak Raman signals may be obscured. These problems are avoided by filtered probes. The basic diagram of such a probe is given in Figure 6.15. Light emerging from the excitation fiber is collimated and diffracted by a transmission grating. All signals except the laser light are blocked by the pin hole. Afterward, the laser light is reflected from the first filter of the notch filter pair toward the sample. The excited Raman and Rayleigh scattering as well as reflected laser light are passed back to the notch filters. These filters remove reflected laser light in order to avoid any fiber background generation as the collected Raman light travels to the spectrometer. The use of lenses allows efficient delivery and collection with single fiber. The advantage of such an arrangement is that once the coupling between the fibers, the laser, and the spectrometer has been optimized, the fiber probe will permit

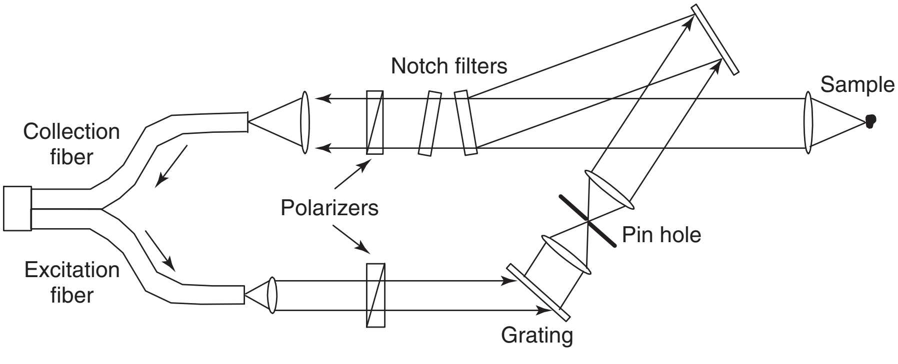

Figure 6.15 Basic diagram of a filtered Raman fiber probe.

spectral acquisition from a variety of liquid or solid samples without any optical realignment. Advanced fiber optics are available in particular in the NIR region.

A sampling technique of distinctly growing importance is the Raman microprobe by using a microscope. It permits the collection of Raman images by mapping or imaging. These techniques allow investigation of samples or sample regions at 1 µm in lateral resolution and 2 µm depth resolution. Depth resolution usually depends on the sample, and in the case of transparent samples, it is worse than the lateral resolution. Depth resolution can be enhanced by decreasing the depth of the focus by using a confocal Raman microscope (cf. Section 5.5.2).

The lateral step size in Raman mapping experiments can be as small as 100 nm. In case of imaging, the Raman signal from the observed sample area is directed by the microscope to a charge-coupled device (CCD) array detector. The wavelength range for investigation has to be selected by a tunable or a set of changeable filters.

6.3.1.2 Polarization Measurements

The depolarization ratio ρ is usually measured in 90° geometry. The experimental setup for Raman polarization measurements is shown in Figure 6.16. Four different spectra can be measured: I_{VV}, I_{VH}, I_{HV}, and I_{HH}, with the first index denoting the polarization of laser radiation and second one the polarization of the Raman scattered light. Actually, the last three polarized Raman spectra contain the same information ($I_{VH} = I_{HV} = I_{HH}$) and the depolarization ratio is defined as $\rho = I_{VH}/I_{VV}$ (cf. Eq. (14) in Section 3.3). These two spectra are usually measured one after the other with the corresponding positions of the analyzer. Polarization measurements have significant value for chemical analysis. They can give important information about the molecular symmetry of an unknown (symmetry of molecular packing in the crystal cell in case of monocrystalline samples) or give additional arguments for assignment of Raman bands.

In the case of highly symmetrical molecules (e.g., molecules with symmetry axes higher than second order), the depolarization factor ρ is equal to zero for total symmetric normal vibrations. In case of molecules of low symmetry, ρ can vary between 0 and ¾ for the corresponding Raman bands. For non-fully symmetric

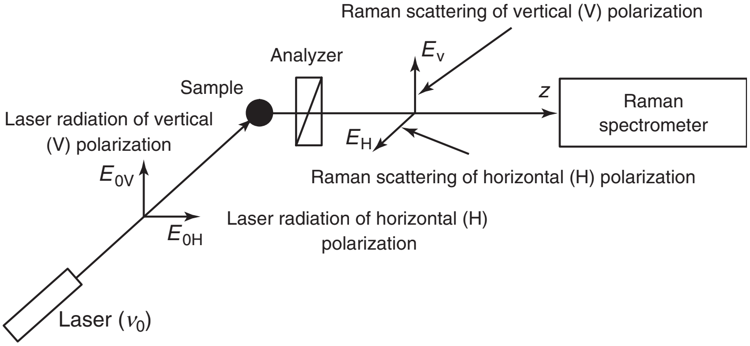

Figure 6.16 Setup for measuring depolarization ratios of Raman bands in 90° geometry.

vibrations of any molecule, ρ is equal to ¾ (or to 6/7 in case of excitation with nonpolarized light). This polarization rule is valid for liquids and gases, that is, for samples with chaotically oriented molecules. In solids, the situation is more complex. The spectral intensities I_{VV} and I_{VH} of crystalline samples depend on the orientation of the crystal axis with respect to the polarization of the incident light. In polycrystalline samples consisting of many small crystallites of different orientation, the scattered light undergoes multireflection at the crystallites, and the polarization information of Raman bands is lost.

In any anisotropic system, the depolarization factor may be used as a valuable source of information about the orientation of molecules, for example, about the orientation of polymer chains in fibers or the orientation of adsorbed molecules on surfaces.

6.3.1.3 **Enhanced Raman Scattering**

The quantum yield of the classical (or so-called linear) Raman effect is rather poor. Only a fraction of 10^{-6} to 10^{-8} of the exciting photons are converted into Raman photons. This excludes low concentrated analytes from being detected. Moreover, Owing to the very high quantum yield of fluorescence, even traces of fluorescent impurities may mask the Raman signal by their fluorescence. Therefore, there are many scientific efforts in developing Raman based methods, which allows one to overcome the problem. Such methods are resonance Raman scattering (RRS) and surface enhanced Raman scattering (SERS).

6.3.1.3.1 **Resonance Raman Scattering (RRS)** In linear Raman spectroscopy, the energy of the exciting photon is assumed to be much smaller than the energy of the lowest electronic transition. If the energy of the exciting photon approaches the energy of the electronic transition, the intensity of some Raman spectral bands increases by a factor of 10^2–10^4 because of resonance between electronic and vibrational excitation. The selection rules RRS are completely different from those in linear Raman scattering. Overtones of normal vibrations with $\Delta\nu = 1, 2, 3, 4, \ldots$ can be observed in RRS spectra. Figure 6.17 shows the RRS of I_2, whose spontaneous Raman spectrum has only one spectral band at 211 cm^{-1} with a low intensity of about 100 photon counts per second.

There are two physical reasons for the enhancement in RRS, the Franck–Condon (FC) enhancement and the vibronic enhancement. Both mechanisms are complicated, a detailed description of which is given in [28]. An application of RRS is the investigation of biological molecules such as metalloporphyrins and carotenoids. These molecules have very strong electronic transitions in the vis. The vibrations of the chromophoric part become resonance enhanced, whereas the vibrations of the surrounding protein matrix do not. This allows observation of the chromophoric site without spectral interference from the surrounding protein. RRS is suitable for molecules with strong vis absorptions such as fullerenes or polydiacetylenes. RRS can also be exploited in the UV, where many molecules absorb. However, the high costs of the equipment (lasers, optics, spectrometers) have limited the use of UV-RRS spectroscopy to a small number of specialists.

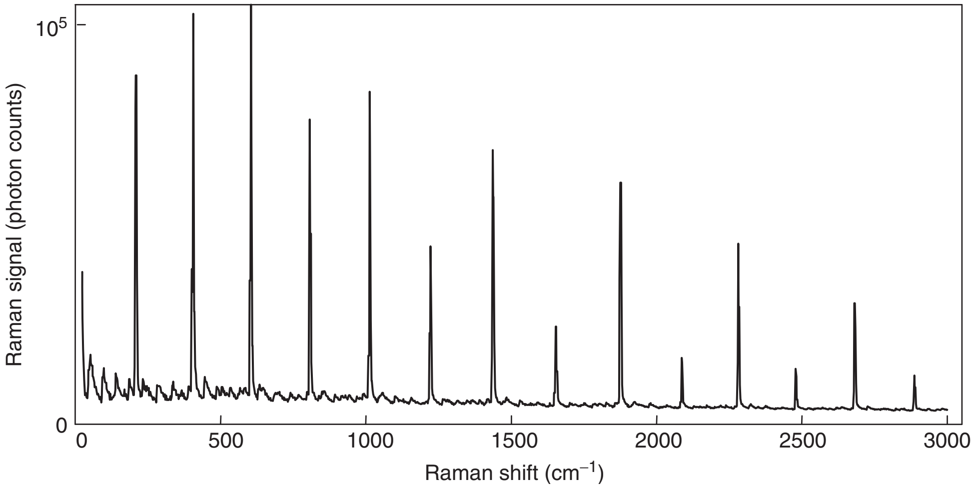

Figure 6.17 Resonance Raman spectrum of gaseous iodine. The argon ion laser line at $\lambda = 514.5$ nm was used for excitation.

6.3.1.3.2 **Surface Enhanced Raman Scattering (SERS)** This effect gives rise to an enhancement of the Raman signal up to six (or even more) orders of magnitude. As yet there is no complete theoretical understanding of this type of enhancement. Two mechanisms are taken into account to explain the SERS effect.

The first is an enhanced electromagnetic field formed at the surface of the metal. Molecules adsorbed on the metal surface experience a large increase in electromagnetic field strength compared to the strength of the incident radiation. The extent of the electromagnetic enhancement depends on a number of factors, including the electric properties of the metal, the distance of the molecule from the surface, the orientation of the molecule with respect to the normal of the surface, the energy of the incident radiation, the morphology of the surface, size, and geometry of surface roughness. Of particular importance is the surface roughness, which can be tailored electrochemically or by the use of solid or island films. The best morphologies are small particles of less than 100 nm in size or atomic rough surfaces. Only particular metals such as silver, copper, or gold can be used as substrate in SERS technology.

The second mechanism of SERS enhancement consists in the formation of a charge-transfer complex between the metal surface and the molecule. Molecules with lone pair electrons or π clouds such as aromatic amines or phenols show the strongest SERS effect. The effect can also be seen in other electron-rich compounds such as carboxylic acids.

The selection rules for SERS are essentially the same as those for the linear Raman effect. However, because of the fact that the local electrical field at the surface is highest in the direction normal to the surface, only vibrations perpendicular to the surface are strongly enhanced. In order to optimize the surface enhancement effect, the laser frequency has to match the frequency of a plasma resonance.

A large variety of SERS substrates is reported in the literature. The most common substrates are electrodes, colloids, metal films, and silver island metal films.

Because of the huge signal enhancement, SERS is particularly useful for trace analysis as well as for *in situ* investigations of various interfacial processes or of monolayers adsorbed on metals. However, sample preparation is a rather tedious procedure. For this reason, SERS is still more an academic tool rather than a routine analytical instrument. Some applications of SERS are given in [29].

6.3.1.4 Applications of Nonlinear Spectroscopic Techniques

Sum frequency generation (SFG) spectroscopy (cf. Section 3.3 and Section 4.8.2) is a technique very well suited for the investigation of surfaces. The method can be applied under normal conditions, at high pressure, on electrodes of electrochemical systems and at interfaces between solid and liquid phases. Various combinations of polarizations and incidence angles of laser beams can be used. SFG spectra contain information about orientation of molecules at the surface, about their conformations, about composition and structure of the surface layer [30]. Some applications of SFG spectroscopy are described below.

Self-assembled monolayers are perfect objects for SFG spectroscopy – the intensity of the SFG signal usually depends on the degree of ordering of the surface layer. Monolayers can be studied not only on metal surfaces, but also on dielectrics, semiconductors, and even on liquids. A typical SFG study is the investigation of an octadecanethiol (ODT) $SH{-}(CH_2)_{17}{-}CH_3$ monolayer on a gold surface. The CH stretching region of a SFG spectrum of ODT is shown in Figure 6.18. The most intense spectral bands are 2880 cm^{-1} ($\nu_s CH_3$), 2932 cm^{-1} (Fermi resonance duplet), and 2963 cm^{-1} ($\nu_{as} CH_3$). The CH_2 vibrations are inactive in SFG spectra because of the symmetry of the $(CH_2)_{17}$ chain.

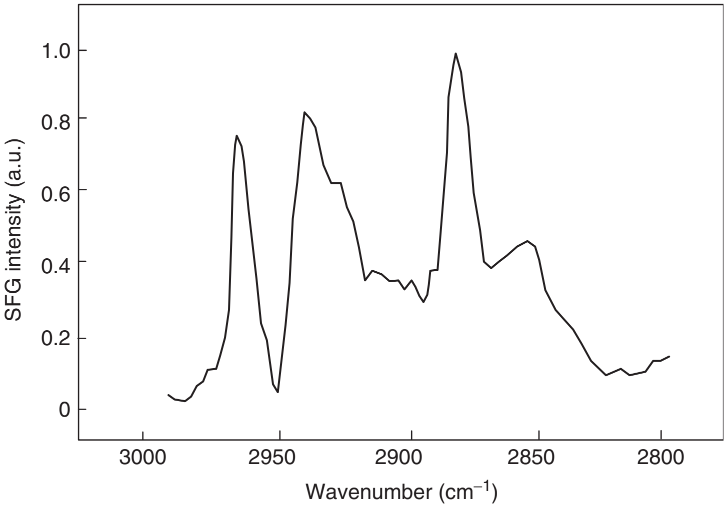

Figure 6.18 SFG spectrum of an octadecanethiol monolayer on gold.

SFG spectroscopy enables the study of *in situ modified polymer surfaces*. SFG was already applied to such technically important polymers as polyethylene, polyimide, poly(ethylene glycol). It was also applied to polymers chemically tuned to be biocompatible such as polymethacrylate and electricity conducting polymers such as polyaniline [3, 30].

Liquid surfaces are very important for processes such as biological functions, electrochemical reactions, wetting chemistry. The asymmetry of the surface layer causes properties of the surface which differ from those in the bulk phase. Investigations by conventional spectroscopic techniques are usually hampered by overlapping of spectral signals from the surface and from the bulk phase. SFG does not suffer from this problem because of the fact that signals from the centrosymmetric bulk phase are usually very weak. An SFG spectrum of a liquid surface is shown in Figure 6.19. The SFG spectrum of methanol consists of intense spectral band of the CH_3 symmetrical stretch at 2832 cm^{-1} and two less intense bands at 2925 and 1951 cm^{-1} because of Fermi resonance between the CH_3 symmetrical stretch and the overtone $2\rho(CH_3)$. This spectrum reveals that the methanol molecules are oriented at the surface with alkyl groups sticking out of the surface.

For Raman studies of biomolecules, which are often not available in large amounts, nonlinear techniques such as stimulated Raman spectroscopy (SRS) and coherent anti-Stokes Raman spectroscopy (CARS) (cf. Section 3.3 and Section 4.8.3) can be used. The particular advantage of CARS is its intense signal in the anti-Stokes spectral region, which enables investigations of fluorescent and luminescent samples. A wide application field for nonlinear Raman techniques is the study of gases and their temperature dependence. Applications of nonlinear Raman techniques (hyper-Raman spectroscopy, SRS, CARS) are described in [31, 32].

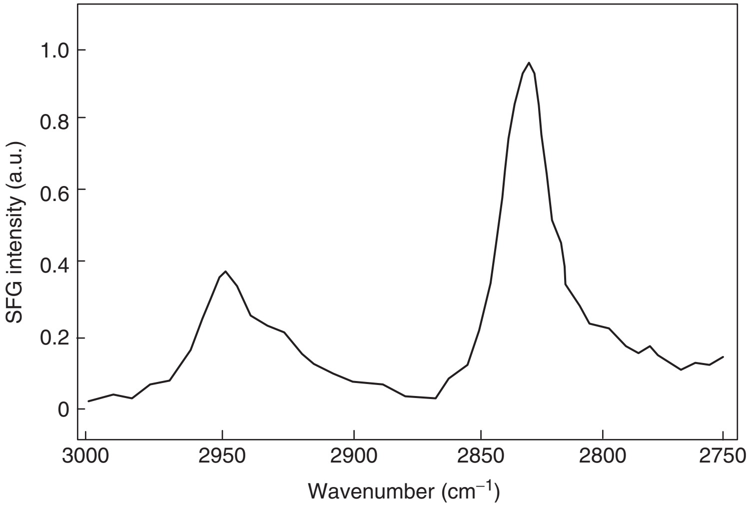

Figure 6.19 SFG spectrum of methanol.

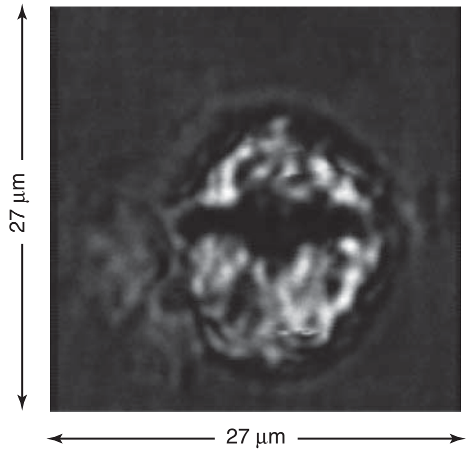

Figure 6.20 CARS image of the nucleus of a T lymphocyte from human blood. The image was obtained by mapping. The CARS microscope was tuned to the CH_2 stretching band at $2850\,cm^{-1}$. Light areas denote higher concentrations of chromatan.

All nonlinear Raman techniques as well as linear Raman enhancement techniques such as RRS and SERS have very high importance in Raman imaging. Owing to the fact that only one Raman spectrum from a very small area of the sample (defined by the size of the focused laser beam) can be captured at a time using a Raman microscope, Raman images of larger sample areas can only be obtained by the mapping technique. In order to ensure a reasonably low measuring time (in the range of minutes) for a mapping experiment at a reasonable lateral resolution, the Raman spectrum of one mapping point should be captured in a couple of milliseconds. This is only possible using one of the enhancement methods for the Raman signal. An example is the CARS image in Figure 6.20. It was obtained by using a Nd:YAG laser at 1.065 µm and an optical parametric oscillator with tunable wavelength for the excitation. The lateral resolution in the image is 0.4 µm. It consists of 270 × 270 mapping points. This CARS image was captured in 5 min (4 ms for one mapping point). A comprehensive review of various Raman imaging applications is given in [33].

6.3.2
Special Applications

The traditional application field of Raman spectroscopy as a complementary method to IR spectroscopy is structural analysis. In the case of molecules featuring a center of inversion, the combined evaluation of Raman and IR spectra is vital because of the so-called mutual exclusion rule: in such molecules, while one part of fundamental vibrations is IR active, the other part is Raman active only. The basics of structural analysis are described in Section 6.1.2 and will not be repeated here.

In a number of experimental situations, Raman spectroscopy is superior to IR spectroscopy, that is, the vibrational fingerprints obtained by Raman spectroscopy are more informative:

1) A Raman spectrum from 4000 to 10 cm^{-1} can be acquired in one scan, unlike the IR experiment.
2) In the case of hydrogen-bonded or wet samples, IR bands are often diffuse and broad, whereas Raman equivalents are sharp.

A survey of the advantages and special applications of FT-Raman spectroscopy is given in [34]. FT-Raman has widespread applications in biology, medicine, pharmacy, art, forensic science, inorganic materials, geology, and polymers.

Water is an ideal solvent for Raman studies; and this is reflected in the large volume of published work on organic and inorganic compounds in *aqueous solutions*. Both identification of species present and evaluation of their concentration are feasible, thus providing information on chemical processes in aqueous solution and their rate constants, often as a function of temperature and pressure. Raman spectroscopy is an appropriate method to analyze hydrogen bonding in aqueous solutions. Intramolecular interactions caused by hydrogen bond formation, or very weak intermolecular forces indicated by very low frequency vibrations (down to 10 cm^{-1}) can be investigated directly.

Rapid advances in *semiconductor technology*, including thin film formation by deposition, interface preparation, or microstructuring, demand characterization techniques that provide understanding of the fundamental processes involved, including information on structural order–disorder and spatial inhomogeneity. Raman spectroscopy is used both in process control and quality assessment [35]. Typical examples for semiconductor applications are composition determination, analysis of crystal structure, surface and interface analysis, phase determination, doping, point defects, temperature influence, and mechanical stress.

The most commonly used material in semiconductor industry is silicon. The Raman spectra of crystalline and amorphous silicon differ quite markedly in the region $\Delta\nu = 600\text{–}100\,\mathrm{cm}^{-1}$ (region of the phonon bands), the two phases can well be characterized. For other semiconductors, this difference is smaller. One should keep in mind that Raman bands from polycrystalline sample areas are similar to those from monocrystalline areas. The effect of strain can also be assessed, local stress can be studied via a Raman microscope. Silicon–metal interfaces are amenable to examination. For instance, it is possible to identify the PtSi layer, estimate its thickness and describe its crystallographic order. Zinc blende type semiconductors, particularly gallium arsenide (GaAs) and related materials such as GaAlAs, can be studied. Concentrations of free carrier may be determined, together with the width of the space charge layer. The effect of an amorphous phosphorous overlayer on n-type GaAs can be studied. The spectroscopic information usefully complements what has been deducted from the electric properties of the material. Alloy semiconductors can effectively be studied by Raman spectroscopy, for example, in a system like $\mathrm{Ga}_{1-x}\mathrm{Al}_x\mathrm{As}$, the value of x can be determined. As with the zinc blende type semiconductors, it is possible to determine carrier concentrations and assess the effect of ion implantation and annealing. Similarly, in the case of $Hg_{1-x}Cd_xTe$, the value of x may be determined.

Important targets for *biochemical and biomedical investigations* are proteins, nucleic acids, and biomembranes. It is also possible to investigate the dynamics of biological systems such as living cells or to study biological interfaces. Tissue differentiation has a great potential for clinical usage in the near future. The most promising medical areas for Raman applications are angiology, lithiasis, orthopedics, dentistry, ophthalmology, dermatology, and pathology.

Spectra obtained with a Raman microscope can be used to investigate nerve cells containing a one-layer membrane composed mainly of proteins and long-chain phospholipids. A field, where Raman microscopy may make major contributions, is characterization of tumors. The Raman spectra of carcinomas are dissimilar from those of the surrounding normal tissue.

Raman spectra of molecules with a solubility even lower than 5×10^{-4} g per 100 g H_2O can be obtained by means of SERS. In the case of biopolymers with chromophoric groups, Raman bands are both resonance and surface enhanced and high-resolution Raman spectra from very dilute solutions down to $10^{-8}\,\text{mol}\,\text{l}^{-1}$ can be measured. Summaries about biochemical and biomedical applications of Raman spectroscopy are given in [3, 34]. A review of pharmaceutical applications of Raman spectroscopy is given in [8].

When using the SERS technique for large molecules, one has to keep in mind that SERS activity decays very fast with increasing distance from the surface. In small molecules of an approximate size of 0.6 nm (benzene), all vibrations are enhanced. In large biomolecules with approximate size around 5 nm (hemoglobin protein), only groups which are attached directly to the surface will yield surface enhancement. Native DNA in solution exhibits some 30–40 Raman bands. The most intense bands are caused by vibrations of the base residues, adenine, guanine, cytosine, and thymine. DNA consists of a double-stranded helix with weak Raman scattering groups (sugar–phosphate groups) at the outside of the helix and strong Raman scattering groups (nucleic basis) located at the center of the helix. The distance from the center of DNA to the phosphate group is about 1 nm. These building blocks of DNA, when adsorbed on a silver surface, exhibit strong SERS bands. The interaction of DNA with other molecules, for example, antitumor anthracyclines, can also be investigated by means of SERS.

There are many Raman applications in the *pharmaceutical industry* varying from structural testing to chemical imaging. The ability to analyze samples without sample preparation leads to fast and specific identification tests for raw materials, finished products, package components, and packaged products. In the *food industry*, the degree of hydrogenation of fats (number of C=C bonds in the skeletal backbone of fat molecules) can be measured in seconds. No sample preparation is needed, in contrast to the chromatographic techniques still employed for this type of analysis.

Raman spectroscopy can be useful in the synthesis and characterization of *catalytic materials*, and in examining adsorbates and their reactivity on metals, metal oxide surfaces, and zeolites. Thin films can be characterized using the waveguide technique. SERS in combination with RRS and microRaman spectroscopy offer the possibility of detecting amounts of substance in the nanogram range. The sensitivity can reach detection limits at the level of highly sensitive fluorescence spectroscopy, maintaining the high structural sensitivity of Raman spectroscopy. Small metallic particles with a diameter of 10 nm, for example, Raney nickel or platinum black, can be used for Raman enhancement. Silica- and alumina-supported particles, consisting of 10 nm particles covered with 3 nm diameter metallic islands, can be used as well. An enhancement of 10^3–10^4 was observed for molecules such as CO, C_2H_4, and C_6H_6. The spectra consist of a series of sharp lines of the excited vibrational modes of the adsorbed molecules superimposed on a broad, enhanced background. Ethylene has been used to study the formation of intermediates on catalytic surfaces. Ethylene is chemisorbed dissociatively as acetylene at room temperature. This is revealed by the appearance of the C=C stretching vibration at 1204 cm^{-1} and was confirmed by inelastic electron loss spectroscopy applied to acetylene chemisorbed on Ni(111) surfaces. The strongest line in the spectrum of benzene chemisorbed at room temperature is the totally symmetric ring-breathing mode at 990 cm^{-1}. All molecules with ring systems exhibit this characteristic band, as it is the most strongly enhanced mode.

One important catalytic reaction cycle which starts from a primary gas mixture of carbon monoxide and hydrogen is the Fischer–Tropsch synthesis. Depending on the reaction parameters (temperature of the catalytic surface, gas pressure, and composition of the gas mixture), a great variety of aliphatic, aromatic, and even oxygen-containing compounds can be obtained. The understanding of reaction mechanisms in terms of the appearance of intermediates on the surface, their structure and symmetry, is of fundamental interest for the development of well-defined reaction pathways. The frequency of the C–H stretching Raman band is a measure for the state of hybridization of the adsorbed molecule.

The fact that Raman measurements can usually be made through glass and plastic packaging, eliminating the need to prepare samples prior to analysis, makes it very attractive for *forensic science*. The availability of commercial portable instrumentation and extended fiber optic probes makes Raman suitable for on-site forensic use, minimizing the risk of investigating personnel to potentially hazardous chemicals. For identification of explosives, SERS method has proved to be very useful. A tiny amount of explosive, diluted in colloid solution with silver particles, is enough to produce a SERS spectrum sufficient for analysis.

Raman spectra of drugs are full of information and are unique to each substance. Very similar chemicals, for example, amphetamine × HCl and amphetamine sulfate or heroin and morphine, yield very different spectra. Usually such samples consist of many constituents; hence, multivariate analysis (cf. Chapter 53) should be used to obtain quantitative models of drug concentrations in solid mixtures. The ability to correctly identify unknowns also depends on the availability of high-quality reference spectra.

Raman spectroscopy has proven useful also in areas such as identification of *gems and artworks*. A summary of the use of Raman spectroscopy for studies of artworks is given in [36]. Investigations of paintings, medieval manuscripts, and wall paintings of glass, pottery, plastics, biomaterials are working fields of Raman spectroscopy. The origin and the age of such objects can be determined.

Polymer science is an area, where Raman methods have found their widest application. Progress has been reported across the field from synthetic thermoplastics through elastomers, including vulcanizates and biopolymers. Virtually any polymer, degraded or loaded with filter, will give a superb Raman spectra. Liquid crystalline polymers change their structure as they are heated, which in turn gives rise to changes in their Raman spectra. A review of Raman applications in polymer science is given in [9]. Applications include polymer identification, multivariate quantitative analysis of composition, analysis of polymer microstructure such as isomers, chain sequence, and endgroups, analysis of morphology such as conformation, crystallinity, and molecular orientation. Furthermore, it is possible to investigate curing and degradation. Polymeric reactions (kinetics and degree of polymerization) can even be characterized in-line.

Sulfur or sulfur-containing organic compounds produce particularly intense Raman bands. This fact is employed in monitoring the reaction occurring during mastication of elastomers with vulcanization agents (sulfur, ZnO, and accelerators). Isomerization frequently occurs during vulcanization. As cis–trans and vinylic moieties of C=C groups oscillate at distinctly different frequencies, they can conveniently be kept apart by Raman spectroscopy. A serious limitation for Raman investigations of polymeric samples is set by carbon black. Already 1% content of carbon black renders Raman spectroscopy impossible. If it is attempted, the sample starts burning because of strong absorption of laser light and no spectra are obtained.

Further *industrial applications* of Raman spectroscopy include identification, quality assurance, reaction monitoring and on-line process control, and the analysis of gases. These applications require special conditions for the instruments such as rapid measurements, high degree of automation, reliability, and robustness. Raman spectrometers equipped with multiple-fiber optics can simultaneously record data collected at several remote locations, even in chemically hazardous environment for on-site monitoring in chemical plants. Advantages and disadvantages of Raman applications for industrial use are described in [32] (see Reference Data Table 6.3).

Techniques yielding similar information: IR spectroscopy.
Typical features of attached computers: computers (not built-in) are part of modern Raman spectrometers. The supplied software manages data acquisition and analysis. Additional software for chemometric evaluation is available.
Typical application (*as demonstrated in chapter*): qualitative and quantitative analysis, *in situ* and *in vivo* measurements, process control, stand-off measurements.
Preferable samples: neat liquids and solids.
Problematic samples: fluorescent and totally absorbing (black or umbra) compounds.

6.4
UV/vis Spectroscopy

Absorptions in UV/vis are caused by electronic transitions from the ground level to an excited state. The strongest transitions are $\sigma \rightarrow \sigma^*$, they are observed below 200 nm (vacuum UV). Typical examples are C–C and C–H bonds. Because all molecules include σ electrons, $\sigma \rightarrow \sigma^*$ transitions constitute the short wavelength cutoff of the routine UV/vis range. Saturated compound with pairs of free electrons exhibit $\mathrm{n} \rightarrow \sigma^*$ transitions in a wavelength range from 150 to 250 nm, their absorption coefficients do not exceed $1000\,\mathrm{l\,cm^{-1}\,mol^{-1}}$. Most UV/vis investigations are based on $\mathrm{n} \rightarrow \pi^*$ or $\pi \rightarrow \pi^*$ transitions, which occur across the UV/vis range and result from unsaturated groups. Typical absorption coefficients of $\mathrm{n} \rightarrow \pi^*$ transitions are below $100\,\mathrm{l\,cm^{-1}\,mol^{-1}}$, while absorption coefficients of $\pi \rightarrow \pi^*$ transitions exceed $1000\,\mathrm{l\,cm^{-1}\,mol^{-1}}$. Absorptions of transition metal ions are caused by their 3d and 4d electrons, whereas 4f and 5f electrons are excited in lanthanide and actinide ions. Absorption bands of d and f electrons are sharper than those of most chromophores because inner orbitals are largely shielded from external influences. Transitions of donor electrons to an acceptor orbital (charge-transfer complexes) originate in inorganic as well as organic compounds, their absorptions coefficients usually exceed $10\,000\,\mathrm{l\,cm^{-1}\,mol^{-1}}$. Band transitions in solids lead to UV/vis absorptions as well. Such transition may occur between valence and conduction bands or between a band and a localized energy level in the forbidden zone. Such condition may occur for instance in case of lattice defects or point defects.

A number of historic terms are still used in UV/vis spectroscopy:

Chromophore: system which is responsible for the absorption.
Auxochrome: substituent which leads to shift of the absorption maximum.
Bathochromic effect: red-shift (toward longer wavelength) of an absorption maximum.
Hypsochromic effect: blue-shift (toward shorter wavelength) of an absorption maximum.

Hyperchromic effect: increasing absorption intensity.
Hypochromic effect: decreasing absorption intensity.

6.4.1
Sample Preparation

Samples are prepared as described in the preceding chapters, mostly by dilution with a suitable solvent. The application range of solvents is given by their short wavelength cutoff (Table 6.6).

Water and ethanol are good solvents for most samples. Both are cheap and transparent down to about 210 nm. Hexane and other hydrocarbons are more suitable for less polar samples. The latter solvents interact only weakly with the solute, so that the fine structure of the absorption band may be revealed much better.

All solvents influence the position of absorption bands. $n \rightarrow \pi^*$ absorption bands are shifted toward shorter wavelengths on increasing solvent polarity, whereas $\pi \rightarrow \pi^*$ transitions become red shifted on increasing solvent polarity. Forces between the solvent and the sample lead to a lower energy level of both the excited and unexcited levels. The effect also influences $n \rightarrow \pi^*$ transitions but the stronger blue-shift resulting from solvation of lone pairs may cover the weaker red-shift (Figure 6.21).

6.4.2
Structural Analysis

Locations of the typical UV absorption bands of representative chromophores are listed in Table 6.7. Substitution leads to a bathochromic shift of the band maximum. Conjugation of π electrons leads to lower π^* energy levels. As the

Table 6.6 Cutoff wavelengths of common solvents.

Solvent	Cutoff wavelength (nm)

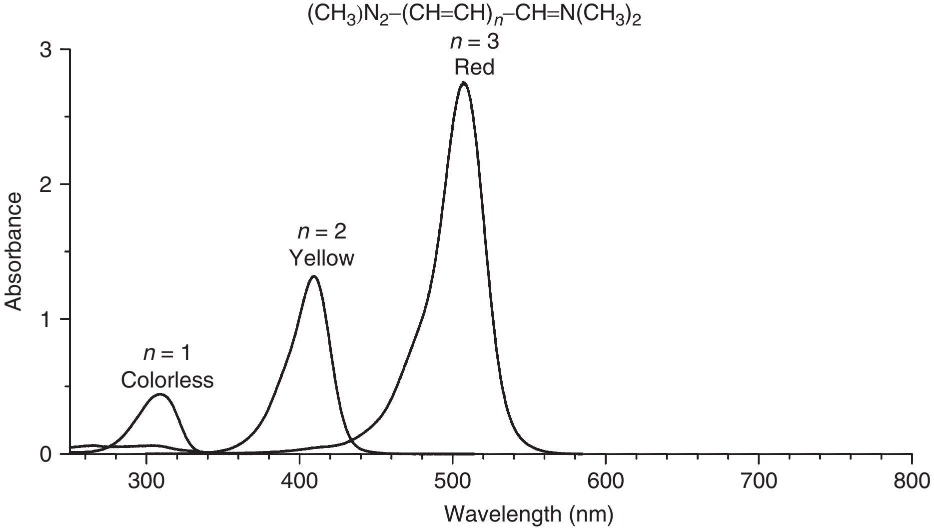

Figure 6.22 UV/vis spectra of polymethines. The absorption maximum shifts toward longer wavelengths and the absorbance increases because of the increasing number of double bonds.

number of double bonds in conjugation increases, the absorption maximum will shift toward longer wavelengths. In coincidence with the spectral shift also, the absorption coefficient will increase (Figure 6.22). Besides the number of double bonds in long-chain polyenes, changes from cis- to trans-configuration may lead to red-shift and increasing absorbance as well.

The Woodward rules provide values for estimation of positions of absorption bands for dienes. The calculation is based on typical parent compounds and takes into account the red-shift increments by additional conjugated double bonds and by further auxochromes:

Parent diene:	Acyclic	217 nm
	Heteroannular	214 nm
	Homoannular	253 nm
	α, β unsaturated carbonyl	222 nm
Additions for each substituent:	Double bond extending the conjugation	30 nm
	Exocyclic double bond	5 nm
	Each alkyl group or ring residue	5 nm
	$-OR$	6 nm
	$-SR$	30 nm
	$-NR_2$	60 nm
	$-Cl$, $-Br$	5 nm

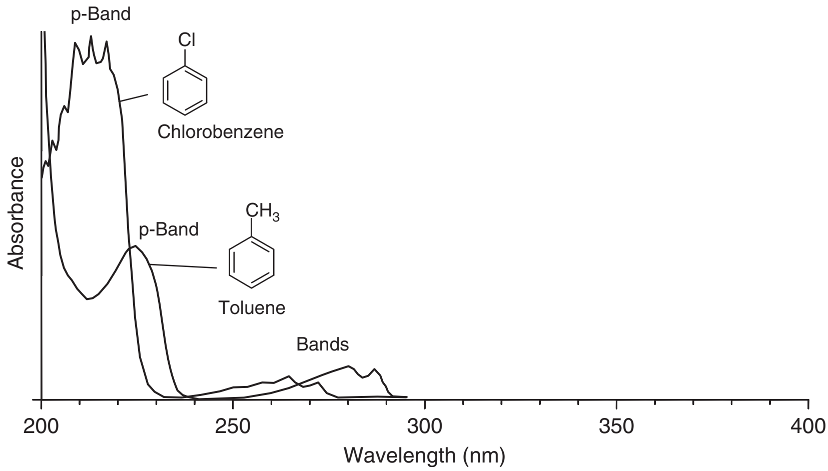

Figure 6.23 UV/vis absorption spectra of chlorobenzene and toluene. Both p- and α-bands show vibrational fine structure. Toluene was fivefold less concentrated than chlorobenzene. Solvent: *n*-hexane.

A weak band in the 275–300 nm range is an indicator of a ketone or aldehyde carbonyl group. Substituents such as OH, NH_2, NHR, or halogen shift the $n \rightarrow \pi^*$ transition toward shorter wavelengths. Conjugation of a C=O group with C=C bonds shifts the $\pi \rightarrow \pi^*$ transition toward the vis range.

The $\pi \rightarrow \pi^*$ transitions in *benzene* and *benzene derivates* lead to absorption bands in the range 160–270 nm. Although four transition $\pi_{2/3} \rightarrow \pi_{4/5}{}^*$ are expected in benzene, only three bands can be observed because of a degenerate state. The band at 250 nm shows vibrational fine structure (Figure 6.23).

In *disubstituted benzenes*, p-substitution causes red-shift of main absorption bands, whereas o- or m-substitution does bands not much shift (Figure 6.24).

Spectra of *polycyclic aromatic hydrocarbons* may be used as fingerprints for identification of the compounds. Highest and lowest orbitals are not degenerate so that four transitions may occur. On increasing annulation, bands shift toward longer wavelengths. *Heteroaromatic compounds* show roughly the same effects as their corresponding hydrocarbons. Spectroscopic effects caused by the heteroatom depend on the electronic properties and on the orientation of the substituent.

Proteins show typical absorptions in the 190–350 nm range. Peptide bonds have an intense $\pi \rightarrow \pi^*$ transition between 190 and 210 nm. The $n \rightarrow \pi^*$ transition at 210–220 nm is weak as it is forbidden and forms a shoulder on the $\pi \rightarrow \pi^*$ absorption band.

Aromatic amino acids have bands between 210 and 280 nm. These bands are commonly used to determine the total protein concentration in solutions. Proteins may have colored prosthetic groups, such as heme, Cu complexes, and covalently bound coenzymes. Some proteins show absorption because of changes of the pH. For example, the chromophore of tyrosine is the phenolic group. On decreasing pH, the maximum absorption is shifted from 275 to 295 nm. Proteins show a slight

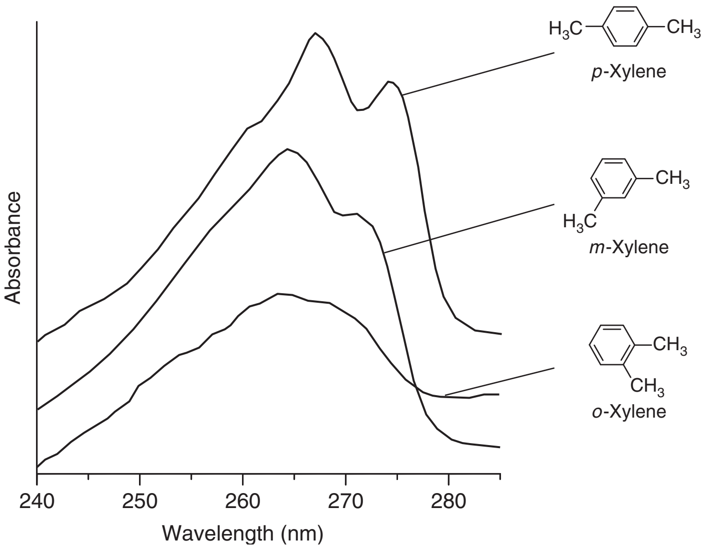

Figure 6.24 UV/vis spectra of xylenes. The red-shift increases from o- via m- to p-substitution.

sensitivity to the polarity of the environment; they arise from the aromatic side chains and indicate their interaction with polar groups. An increase in nonpolar constituents leads to a red-shift of the absorption maximum. Especially tyrosine and tryptophan show such environmental sensitivity which can be used to detect conformational differences in different states of a protein (Table 6.8).

The aromatic L-amino-acids tryptophan, tyrosine, and phenylalanine are responsible for protein absorption in the UV. The aromatic side chains of amino acids have often characteristic spectra. UV/vis spectroscopy offers the advantages of being nondegrading to the sample.

6.4.3
Metal Complexes and Semiconductors

The color appearance of *metal complexes* is basically controlled by three kinds of transition: charge-transfer, $\pi \rightarrow \pi^*$, and $n \rightarrow \pi^*$ transitions in complexes with organic ligands, d–d transitions within the metal ion. The latter are usually weaker than the former two, nevertheless the color of aqueous solutions of transition metals is caused by d–d transitions. Owing to splitting of d-orbitals in ligand field or crystal field (Figure 6.25), absorptions at longer wavelengths may occur. UV/vis spectra of Ti ions with and without ligand field splitting are shown in Figure 6.26.

The degree of splitting depends on several factors: the charge on the metal, the size of the metal, and the nature of the ligand. It is possible to correlate empirically the various ligands in a sequence according to their ability to split the orbital. The

Table 6.8 Absorption maxima of some amino acids.

Phenylalanine		190, 205, 255

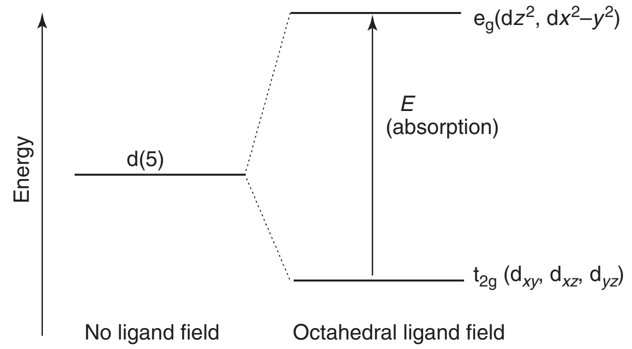

Figure 6.25 The octahedral ligand field splits the d orbital into two levels, which give rise to a new absorption band.

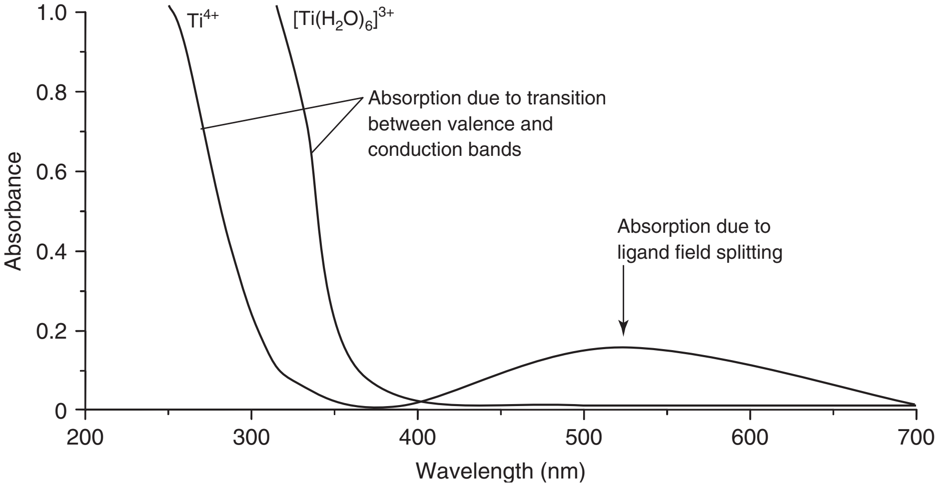

Figure 6.26 UV/vis spectra of Ti^{4+} and Ti^{3+} complexes. Ti^{3+} has an octahedral ligand field where the d-level is split into two levels. Transitions between the latter cause an additional absorption band at 510 nm. The absorption edges around 300 nm arise from transition between valence and conduction band.

cyanide anion has the strongest ligand field in the so-called spectrochemical series:

$$\text{halides} < OH^- < H_2O < NCS^- < NO_2{}^- < CO, CN^-$$

Metal complexes with organic ligands show different spectroscopic effects, dependent whether the metal–ligand bonds are covalent or ionic. If the metal–ligand bond is essentially ionic, only small changes occur. The spectrum of the complex is similar to that of the protonated ligand. On the other hand, the spectrum gets significantly changed for complexes with strong covalent metal–ligand bonds, and such complexes are highly colored.

Charge-transfer transitions may occur in case of covalently bound ligand orbitals and empty or antibonding metal orbitals. Organic ligands forming charged transfer complexes are often used in the analysis of ions such as Fe, Cu, Cd, or Zn.

The porphyrin dyes hemoglobin and chlorophyll are biologically important. Both belong to octahedral metal complexes, as proteins are bound to the central atom. In the hemoglobin molecule are five ligand positions occupied by histidine.

In most *semiconductors*, the gap between valence and conduction bands gives rise to a transition in the UV/vis range. Such transitions produce an UV/vis absorption edge (Figure 6.27).

The absorption edge λ_{gap} may be expressed by

$$\lambda_{\text{gap}} = \frac{h}{W_0} c$$

where W_0 is the binding energy, h is the Planck constant, and c is the speed of light in vacuum. If $W_0 > 3.1$ eV, the semiconductor is transparent whereas crystals with $W_0 < 1.5$ eV are absorbing across the whole UV/vis range and look like metals. Gap

PbS	0.29	4274
InSb	0.23	5390

transition energies and corresponding wavelengths for a range of semiconductors are given in Table 6.9.

In UV/vis spectra of semiconductors with an indirect band transition (photon–phonon excitation), the absorption band edge may indicate a higher binding energy W_0. Additional energy levels may occur in imperfect semiconductor crystals. These energy levels are often placed between valence and conduction band and lead to absorption at greater wavelengths. Other processes such as electronic interaction between excited electron and hole may lead to intrinsic band changes. A well-known example is the absorption band edge of CuO where additional narrow absorption bands occur.

Band structure details of *insulators* can be determined by their UV/vis spectra. Defects in the crystal produce electronic levels within the gap between conduction and valence bands. Spectroscopic measurements at low temperature allow the investigation of the phonon structure of a crystal. Owing to lattice or point defects, absorptions can be used to describe the optical and electronic properties of the insulator. For example, Cr in Al_2O_3 crystals introduces an intensive color change of the crystal. Many so-called *color centers* are based on lattice defects caused by intercalation of atoms in the crystal lattice.

Techniques yielding similar information:
Typical features of built-in computers: built-in computers are not part of modern UV/vis spectrometer. The supplied software manages data acquisition and analysis.
Typical application (*as demonstrated in chapter*): characterization of organic compounds, biological samples, semiconductors, quantitative analysis.
Preferable samples: molar till micro molar solutions.
Problematic samples: gaseous samples, highly absorbing samples, scattering samples.

6.4.4
UV/vis Spectroscopic Imaging

UV/vis spectroscopic imaging is a technique which combines spectroscopy, high-resolution CCD imaging, and computing. The key to achieving high sensitivity in the UV/vis spectral range (0.2–0.8 µm) is the use of silicon based low-light-level CCD cameras. Commercial systems are either filter-wheel multiple exposure systems, or full spectral capture systems based on interferometers. The advantages of the filter multiplex system are high sensitive measurements at the selected wavelengths and a robust optical system. Typical systems are available in a turnkey format completed with up to eight interchangeable filters. The CCD camera has more than 4 MP. Images can be recorded continuously at one wavelength or at different wavelengths (changing filters) with frame rates of 1 s.

The principle of full spectral systems is the simultaneous recording of an entire spectrum for each pixel of the CCD camera. Spectral imaging systems are used to obtain brightfield images, or imaging data sets of fluorescence, absorption, transmission, or reflection spectra. Acquisition times range from few seconds to several minutes. A Sagnac interferometer mounted on a rotatable disk provides a spectral resolution as good as 2 nm at short wavelengths increasing to approximately

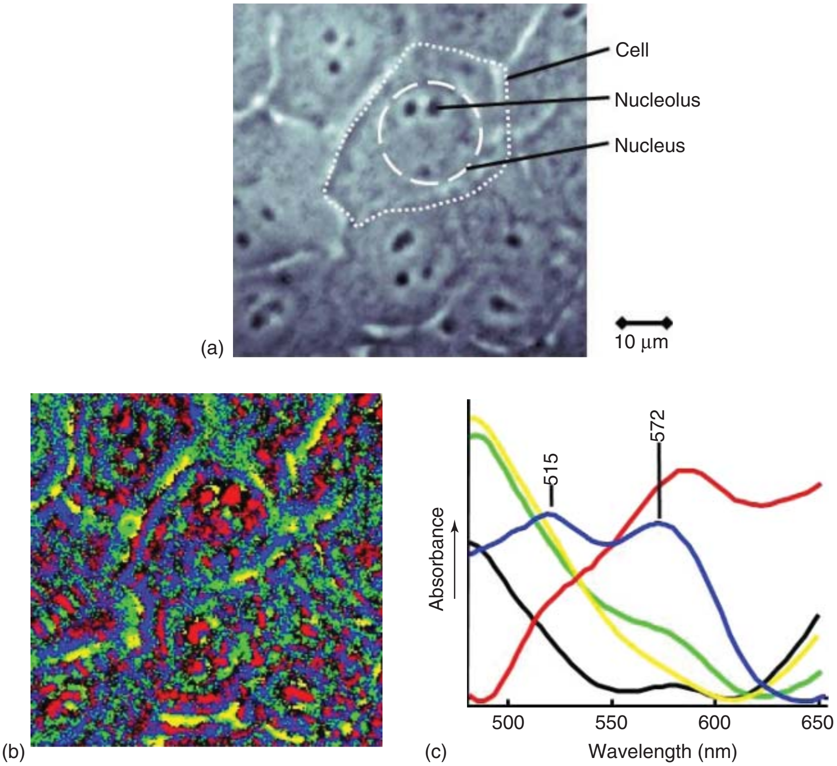

Figure 6.28 Vis spectroscopic image of retinal ganglion cells. (a) Microscopic image; (b) spectroscopic image evaluated with *k*-means cluster analysis; and (c) cluster centroid spectra.

25 nm toward the NIR range. Figure 6.28 shows the spectroscopic image of retinal ganglion cells. Contrast in the unstained cells in the brightfield image (a) is mainly based on light scattering on the cell membrane and on nucleoli. Each pixel of the spectroscopic image contains an entire vis spectrum. The spectral data set is analyzed by *k*-means cluster analysis and reassembled to the image (b). The corresponding cluster centroid spectra are shown in (c). Red and black pixels indicate mainly nuclei and nucleoli. Green and yellow pixels can be assigned to membrane structures. Blue pixels indicate cytochrome *c*. The two spectral bands at 515 and 572 nm are assigned to the β-band and to the α-band, respectively.

6.4.5
Metal Nanoparticles

Some recent applications involve the characterization of *metal nanoparticles*. Because of their unique chemical, electronic, and optical properties, metal nanoparticles are of interest for a variety of applications in chemistry, material science,

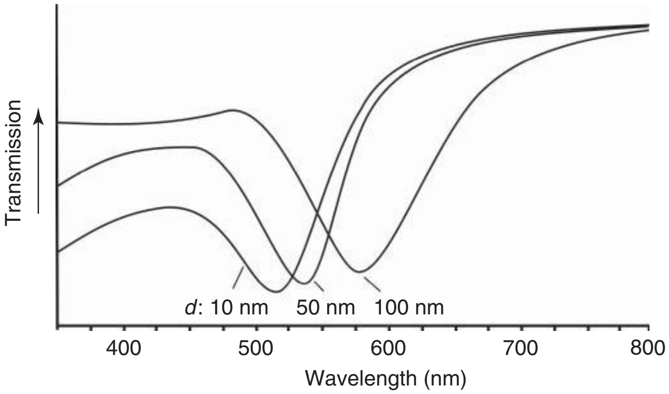

Figure 6.29 Calculated plasmon resonance spectra for single gold nanoparticles of spherical shape at different diameters (*d*).

medicine, biology, and environmental science. Typical sizes and shapes of the nanoparticles range from spheres with few nanometers in diameter up to nanorods with more than 1000 nm in length. Such small particles are known to act as strong light scatterers, if the wavelength of the incoming light and the particle's plasmon resonance are in the same range. This may happen in the visible spectral region. Plasmon resonance causes an intense absorption. Position, shape, and intensity of the absorption band give information about size, shape, and chemical nature of the nanoparticles as well as about their interactions with the surrounding medium. A detailed description is given in [39, 40]. Figure 6.29 illustrates the effect of the size of nanoparticles on the spectral position of the plasmon resonance for gold nanoparticles deposited on a glass slide.

Fluorescent nanoparticles, called *quantum dots* (*QDs*), emit up to 3000 times brighter light than conventional nanoparticles. QDs are very small semiconductor crystals between 1 and 5 nm in size that generate light when stimulated by electrons or photons. Owing to the small dimension of QDs, electrical charges within the dots are confined in all directions. Thus, behavior and properties of QDs are controlled by quantum mechanical effects. QDs are becoming increasingly popular in optical spectroscopy and biosensing. QDs are being used for cellular labeling because of their lower toxicity in addition to their brighter fluorescence.

6.5
Fluorescence Spectroscopy

After the appearance of the first book on fluorescence in 1951 [41], fluorescence spectroscopy became a widely used scientific tool in biochemistry, biophysics, as well as in material science. Within the last years, however, several new applications based on fluorescence have been developed, promoting fluorescence spectroscopy from a primarily scientific to a more routine method. The phenomena of fluorescence is, for example, exploited in simple analytical assays in environmental science and clinical chemistry, in cell identification and sorting in flow cytometry, and in imaging of single cells in medicine. The analyte, whose light emission is investigated, is often called a *dye*. Fluorescence measurements give information about the photophysical properties of the dye as well as about the chemical and physical nature of the surroundings of the dye.

6.5.1
Sample Preparation and Measurements

Beside the classical sampling techniques using different types of cuvettes, there are several advanced ways of detecting the fluorescence signal. The use of fiber optics allows for measuring fluorescence in whole organs *in vivo*. When looking to cells, one can use cell culture plates or flow cytometry. Selected spots within a cell can be monitored using classical, confocal, or multiphoton microscopy (cf. Section 5.5).

As each of the measurement techniques is providing different information based on different ways of detecting the fluorescence signal, the data evaluation is different for each method. Table 6.10 provides the references, dealing with the mathematical data treatment and evaluation of the basic fluorescence techniques. Some details of fluorescence data treatment are outlined in Chapter 53 "General Data Treatment."

6.5.1.1 Fluorescence Quantum Yield and Lifetime

In the gas phase or noninteracting solvents and in the absence of other photophysical processes (cf. Figure 6.30), the fluorescence intensity F detected over a certain emission wavelength range decays following a monoexponential decay law with an average lifetime τ. The rate constant of this fluorescence decay k $(=1/\tau)$ represents the sum of the emissive rate of the fluorophore k_0 $(=1/\tau_0)$ and the rate constants of the two radiationless processes, internal conversion, and intersystem crossing, k_{ic} and k_{isc}, respectively. The radiative lifetime τ_0 can be correlated to the transition

Table 6.10 References for fluorescence data evaluation.

dipole moment **M** by

$$\tau_0 \approx \frac{1}{k_{\text{ave}}^3 n^2 |\mathbf{M}|^2} \tag{6.1}$$

where n is the refractive index of the solvent and k_{ave} is the average wavenumber of the center of gravity of the fluorescence emission spectrum. The natural lifetime τ_0 can be considered as a photophysical constant of a chromophore surrounded by a defined solvent shell. In the case of planar aromatic systems, it appears to be temperature-independent [46]. As the internal conversion and intersystem crossing processes compete with fluorescence for deactivation of the lowest excited singlet-state, not all will return to the ground state by fluorescence (Figure 6.30). The fraction of excited molecules that do fluoresce is called the *quantum yield* ϕ. In terms of the above defined rate constants and lifetimes, ϕ is given by Eq. (6.2)

$$\phi = \frac{k_0}{k_0 + k_{\text{ic}} + k_{\text{isc}}} = \frac{\tau}{\tau_0} \tag{6.2}$$

The fluorescence lifetime τ can be determined directly by monitoring the decay curve of fluorescence intensity following a brief excitation pulse [47] or by detecting the emission delay of intensity modulated excitation light [48]. Using a standard

Not included are processes such as solvent relaxation, energy transfer, and photochemical reactions.

steady-state fluorometer, the quantum yield ϕ is determined, usually by comparison with standard compounds of known quantum yield [49].

6.5.1.2 Fluorescence Quencher

A fluorescence quencher is a compound, the presence of which leads to a decrease of the fluorescence quantum yield or lifetime of the examined chromophore. The quenching system can be molecules or ions added to the solution, which come into molecular contact with the chromophore introducing new or promoting already existing nonradiative pathways (solute quenching). Further possibilities are the self-quenching by other molecules of the same dye type and the quenching by solvent molecules. In any case, the quenching term k_Q [Q] has to be added to Eq. (6.2), yielding

$$\phi = \frac{k_0}{k_0 + k_{ic} + k_{isc} + k_Q[Q]} \tag{6.3}$$

where k_Q is the bimolecular quenching constant and [Q] is the concentration of the quencher.

6.5.1.2.1 Solute Quenching Solute quenching reactions are a very valuable tool for studies of proteins, membranes, and other supra- or macromolecular assemblies and can provide information about the location of fluorescent groups in the examined molecular structure. A fluorophore that is located on the surface of such a structure will be relatively accessible to a solute quencher (for a list of quenchers see Table 6.11). The quenching agent will quench a chromophore that is buried in the core of the molecular assembly to a lesser degree. Thus, the quenching experiment can be used to probe topographical features of the examined structure and to detect structural changes that may be caused by addition of external compounds or changed physical conditions. In usual quenching experiments, the

solute is added successively to the probe. The analysis of the dependence of the fluorescence intensity, F, quantum yield, Φ, or lifetime, τ, yields quantitative information about the accessibility of the chromophore within the macro- or supramolecular structure.

Depending on the chemical nature of the quenching agent as well as that of the chromophore, one has to distinguish between two forms of quenching, the dynamic and the static quenching. Static quenching results from the formation of a nonfluorescent complex between a quencher and a fluorophore already in the ground state. Characteristic of that type of quenching is that the increasing quencher concentration decreases the fluorescence intensity or quantum yield, but does not affect the fluorescence lifetime. A further characteristic feature of static quenching is its decrease with increasing temperature, as the stability of the complexes between the fluorophore in the electronic ground state and the quencher is generally lower at higher temperatures. If quenchers act by competing with the radiative process (see Eq. (6.3) and Figure 6.30), the ratio of the quantum yield in the absence, ϕ_a, and the presence, ϕ, of the quencher will be equal to the ratio of the corresponding lifetimes, τ_a/τ (see Eq. (6.2)). The concentration dependence of this so-called dynamic or collisional quenching is described by the Stern–Volmer equation, where the Stern–Volmer constant K_{SV} is equal to $k_Q \tau_a$

$$\frac{\phi_a}{\phi} = \frac{\tau_a}{\tau} = \frac{F_a}{F} = 1 + K_{SV}[Q] = 1 + k_Q \tau_a [Q] \tag{6.4}$$

Thus from the plot of one of those ratios versus the quencher concentration and by knowing τ_a separately, the bimolecular quenching constant, k_Q, can be determined. The magnitude of k_Q is given by the following factors

$$k_Q = 4\gamma \pi D r N' \tag{6.5}$$

where γ is the efficiency of the quenching reaction, D and r are the sum of the diffusion coefficients and molecular radii, respectively, for the quencher and chromophore, and $N' = 6.02 \times 10^{20}$. The diffusion coefficient for a single species i can be calculated by using the Stokes–Einstein relationship to be

$$D_i = \frac{bT}{6\pi \eta r_i} \tag{6.6}$$

where b is Boltzmann's constant and η is viscosity. Thus the quenching constant increases with increasing temperature T because of the diffusion control of dynamic quenching. The molecular mechanism of the fluorescence quenching depends on the chemical nature of the chromophore and solute. Quenchers that possess halogens or heavy atoms quench by increasing the intersystem crossing rate induced by spin orbital coupling mechanism. Acrylamide quenching of tryptophans in proteins is probably due to excited state electron transfer from the indole to acrylamide. Paramagnetic species are believed to quench aromatic fluorophores by an electron spin exchange process. In many instances, the fluorophore can be quenched both by dynamic and static quenching. The characteristic feature for mixed quenching is that the plot of the concentration dependence of the quantum yield or intensity ratios (see Eq. (6.4)) shows an upward curvature. In this case, the Stern–Volmer equation has to be modified resulting in an equation, which is second order in [Q]. More details on theory and applications of solute quenching can be found in [51]. Table 6.11 gives an overview of characterized fluorophore-quencher pairs [52–77].

6.5.1.2.2 **Example for Application of Solute Quenching in Protein Studies** One of the main aims in biophysical studies of the structure and function of proteins is to identify the protein domains, which are responsible for the interaction of the entire protein with physiologically relevant binding partners. Proteins usually contain several tryptophan residues, which might be distributed among the different protein domains. As each of these tryptophan residues is located in a distinct environment, each residue might exhibit different fluorescence lifetime profile as well as different accessibilities to quenching molecules. Using picosecond time-resolved fluorescence spectroscopy, the tryptophan fluorescence lifetime profile of proteins containing up to three tryptophan residues can be determined with high accuracy [56]. A picosecond tryptophan study of prothrombin fragment 1 (BF1), which is the 1–156 N-terminal peptide of prothrombin, a key blood coagulation protein, may serve as an example here. It is believed to be the region predominantly responsible for the metal ion and membrane binding properties of prothrombin. An important question has been as to what extent the conformation of the two protein domains, the so-called Gla and kringle domain, are altered by the interaction with calcium ions and negatively charged phospholipid surfaces (see Figure 6.31).

The analysis of the fluorescence decays of the three tryptophan residues (Trp42, Trp90, Trp126) in apo-BF1 resulted in a five exponential decay model, where the five fluorescence lifetimes are wavelength independent. As structural data show a huge difference in solvent accessibilities for the kringle tryptophans ($4 \times 10^{-20}\,\mathrm{m}^2$ for Trp90 and Trp126) and the Gla tryptophan ($133 \times 10^{-20}\,\mathrm{m}^2$ for Trp42), acrylamide quenching studies were performed to assign the five lifetimes to the two types

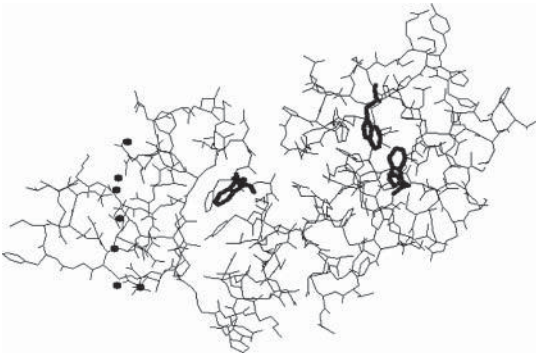

Figure 6.31 A depiction of the X-ray structure of Ca-BF1. The right part of the protein is the kringle domain, where the solvent inaccessible tryptophan residues Trp90 and Trp126 are located. The Gla domain is the left part of the protein, containing the solvent and quencher accessible Trp42 and seven calcium ions (dots).

of tryptophans. Acrylamide was added successively up to a concentration of 0.7 M. The Stern–Volmer analysis of the fluorescence decays showed that the five lifetimes are basically due to two different types of tryptophans characterized by two different k_Q values ($0.2 \pm 0.2 \times 10^9$ and $1.1 \pm 0.3 \times 10^9\,\mathrm{M}^{-1}\,\mathrm{s}^{-1}$ for the kringle and Gla tryptophan components, respectively). Note that the theoretical k_Q value for a fully exposed polypeptide-tryptophan is about $3 \times 10^9\,\mathrm{M}^{-1}\,\mathrm{s}^{-1}$. The resulting assignment of the lifetime compounds to the two types of tryptophans allowed for a separate investigation of conformational changes in the two protein domains without cleaving BF1 into the isolated Gla (containing Trp42) and kringle domains (containing Trp90 and Trp126) or modifying the protein by site-directed mutagenesis. On the basis of the assignment of the lifetimes to the two tryptophan types in BF1, further experiments led to the conclusion that the Gla domain is exclusively responsible for the interaction with calcium ions and negatively charged phospholipids. Moreover, the first experimental evidence for a lipid specific conformational change in the Gla domain of prothrombin was found, indicating an important role of this domain in the regulation of blood coagulation [78].

6.5.1.2.3 **Solvent Quenching** The influence of solvent molecules on the fluorescence characteristic of a dye is certainly one of the most complex issues in fluorescence measurement. Eventually, every chromophore shows some dependence of its quantum yield on the chemical structure of the surrounding solvent. This observation is to some extent due to fluorescence quenching by the solvent. One possibility is that the interaction of the chromophore with its solvent shell can promote nonradiative pathways, by changing the energy levels of the S_0, S_1, and T_1 states. The transition probabilities for the internal conversion and intersystem crossing processes are governed by the energy-gap law [79]. This law states that the rate constants k_{ic} or k_{isc} increase exponentially as the energy gaps between the S_1 and S_0 or S_1 and T_1 states, respectively, decrease [79]. Thus any change in those energy levels will strongly influence the fluorescence lifetime and quantum yield (see Eq. (6.2)). Some of the so-called hemicyanine dyes represent special cases for the promotion of nonradiative pathways by increasing solvent polarity [80]. These dyes undergo an intramolecular twist in the excited state. The intramolecular twist leads to an increase of the polarity and the twisted form of the S_1 states is very effectively deactivated by fast internal conversion. Increasing solvent polarity promotes the intramolecular twist and, therefore, the nonradiative deactivation by internal conversion [80]. Moreover, evidence has been accumulated that quenching by interaction with solvent molecules can proceed by a vibrational mechanism. It has been speculated that the collision between dye and solvent molecules results in vibrational coupling that favors efficient internal conversion [81]. In this connection, the solvent deuterium effect on the fluorescence lifetime, which has been observed for a variety of chromophores should be mentioned [82–84]. It has been found that the quantum yield is substantially increased when using D_2O instead of H_2O as the solvent. Interestingly, this effect appears to be independent of the chemical nature of the dye. It is conceivable that the different energies of the OH versus OD stretching vibrations (3657 and $2670\,\mathrm{cm}^{-1}$, respectively) are responsible for more effective solvent quenching by H_2O versus D_2O. Independent of the physical nature, this heavy atom effect in solvent quenching has been shown to be a smart tool for the characterization of water accessibilities in supra- and macromolecular assemblies [82].

6.5.1.2.4 **Self-Quenching**

Self-quenching is the quenching of one fluorophore by another. It is a widespread phenomenon in fluorescence, but it requires high loading concentrations or labeling densities. The general physical treatment of self-quenching processes involves a combination of trap-site formation and energy transfer among fluorophores, with the possibility of migration of trap-sites, which results in quenching. Trap-sites may be formal fluorophore complexes or aggregates, or may result from fluorophore proximity at sufficiently high concentrations. A mathematical modeling of such processes is given in [85]. Self-quenching experiments are frequently exploited, by simply monitoring the increase in the fluorescence intensity F because of decrease of local dye concentrations. One example represents a self-quenching assay for the characterization of leakage of aqueous contents from cells or vesicles as a result of lysis, fusion, or physiological permeability. This assay is based on the fact that carboxyfluorescein is $>95\%$ self-quenched at concentrations >100 mM [86]. Concentrated solutions of these water-soluble dyes are encapsulated in liposomes. On addition of a fusogen or other permeabilizing agent, dye release is accompanied by an increase in fluorescence. Other chromophores, the self-quenching properties of which are exploited in biochemical assays are NBD (derivatives of 7-nitrobenz-2-oxa-1,3-diazol-4-yl) [87, 88], Bodipy (derivatives of 4,4-difluoro-4-bora-3a,4a-diaza-s-indacene) [89], and DPH (derivatives of 1,6-diphenyl-1,3,5-hexatriene) [90].

6.5.1.2.5 **Trivial Quenching**

Trivial quenching arises from attenuation of the exciting beam and/or the inability of fluorescence photon to reach the detector. It occurs mainly when compounds are added that strongly absorb in the UV range. Although the added concentration may be small, they might block the excitation light completely. Turbidity of the sample can be another reason for trivial quenching. True and trivial quenching, however, are easily differentiated, as in trivial quenching lifetime and quantum yield remain constant.

6.5.1.3 Solvent Relaxation

Any electronic excitation from the ground state S_0 to the excited state S_1 is paralleled by a change in the dipole moment $\Delta\mu_c$ ($\Delta\mu_c = \mu(S_1) - \mu(S_0)$). As the timescale of the electronic transition is much shorter than that of nuclear motion, the excitation causes an ultrafast change of the probes charge distribution but does not affect the position or orientation of the surrounding solvent molecules. The solvent molecules are, thus, forced to adapt to the new situation, and start to reorient themselves in order to find an energetically favored position with respect to the excited dye. The dynamic process starting from the originally created nonequilibrium FC state and gradually establishing a new equilibrium in the excited state (R) is called *solvent relaxation* (SR). This relaxation red-shifts the probe's emission spectrum continuously from the emission maximum frequency of the FC state ($\upsilon(0)$ for $t = 0$) to the emission maximum of the fully relaxed R-state ($\upsilon(\infty)$ for $t = \infty$). As a more polar solvent leads typically to a stronger stabilization of the polar R-state, the overall shift $\Delta\upsilon$ ($\Delta\upsilon = \upsilon(0) - \upsilon(\infty)$) increases with increasing solvent polarity for a given change of the solute's dipole moment $\Delta\mu_c$. The accurate mathematical description of this relationship depends on the choice of the dielectric solvation theories [91–96]. The fundamental ''dielectric continuum solvation model'' [94–96] predicts a linear proportionality between $\Delta\upsilon$ and a dielectric measure of solvent polarity for a large variety of solvents [97]. According to this model, changes in $\Delta\upsilon$ directly reflect polarity changes in the dye environment, giving the first major information accessible by studies of the SR process. The second information obtainable from the investigation of SR processes is based on the fact that the SR kinetics is determined by the mobility of the dye environment. The response of solvent molecules to the electronic rearrangement of the dye is the fastest in the case of water: more than half of its overall solvation response occurs within 55 fs [98]. If the dye is located in a viscous medium, the SR takes place on the nanosecond (ns) timescale [99]. In vitrified solutions, on the other hand, the dye may fluoresce before SR toward the R-state is completed [100].

6.5.1.3.1 **Steady-State Spectra** Nonviscous solvents at ambient temperature respond with a fast inertial (vibrational) motion in the range between 50 and 500 fs to the ultrafast change in the dipole moment because of electronic excitation. After this initial period of solvation response, the diffusion of the solvent molecules, occurring on the pico- to subnanosecond timescale leads to further solvation energy relaxation toward the R-state [97, 98, 101, 102]. The fluorescence decay time τ of chromophores is usually 1 ns or longer. Thus, almost the entire fluorescence in a steady-state experiment occurs from the equilibrium state R. Considering the above described connections between $\Delta\upsilon$ and the dipole moments of the solute, $\Delta\mu_c$, and the polarity of the solvent, there are two basic consequences for the spectral position of the steady-state fluorescence spectrum: (i) increased solvent polarity leads generally to a red-shift of the emission spectrum. For illustration, the influence of the solvent on the emission maximum of Prodan (6-propionyl-2-(dimethylamino)-naphthalene) is depicted in Figure 6.32. (ii) The larger $\Delta\mu_c$, the more pronounced the effect of solvent polarity on the position of the emission spectrum. Moreover, as SR is much faster than fluorescence, the wavelength of the maximum emission and the fluorescence lifetimes are independent of the excitation wavelength.

If the dye is located in a viscous medium, the SR might take place on the nanosecond (ns) timescale. Thus, emission occurs to a substantial extent during SR, and the emission spectrum represents an average of the partially relaxed emission. In this case, the maximum of emission spectrum is no longer directly correlated with the polarity of the solvent. An increase of the temperature leads to a faster solvent reorientation process and, thus, to a red-shift of the maximum of the emission spectrum. Moreover, the wavelength of the emission band maximum of polar fluorophores in motionally restricted media, such as in very viscous solutions

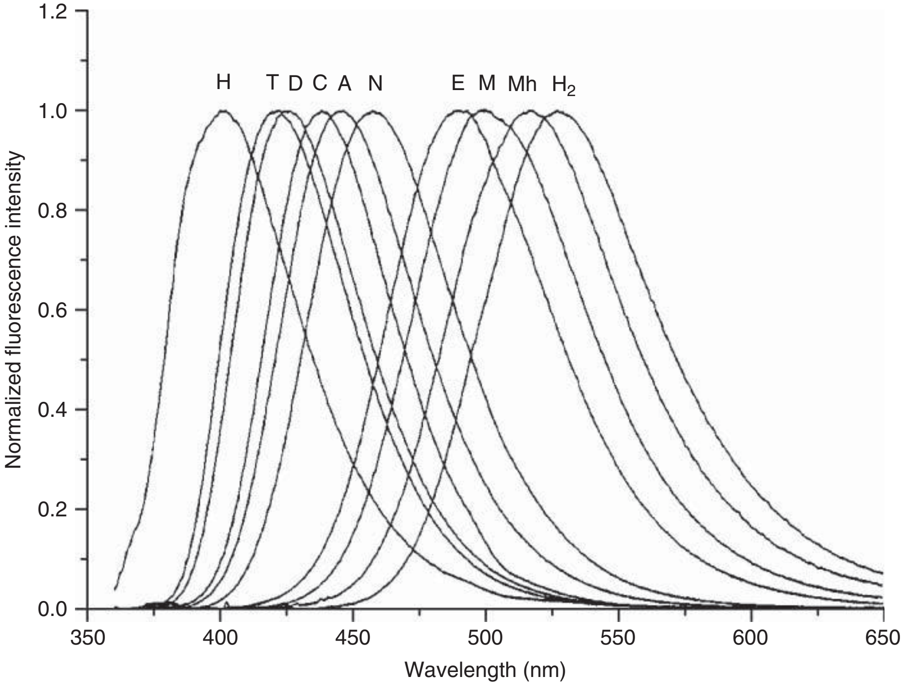

Figure 6.32 Fluorescence spectra of Prodan in different solvents at ambient temperature; $\lambda_{ex} = 337$ nm; H, heptane; T, toluene; D, dioxane; C, chloroform; A, acetone; N, acetonitrile; E, ethanol; M, methanol; Mh, methanol/water 1 : 1; H_2, water.

[103, 104] or membranes [99], shifts to longer wavelength by shifting the excitation wavelength toward the red-edge of the absorption band [105]. The observed shift should be maximal if the SR is much slower than the fluorescence, and it should be zero if SR is fast and independent of the excitation wavelength the entire fluorescence origins from the relaxed R-state. Thus, the red-edge excitation shift can serve as an indicator of the mobility of the probe surrounding [103, 104, 106]. Usually, red-edge excitation shift values range from several up to 40 nm depending on the chosen solute and solvent system. The red-edge excitation shift is especially useful when using dyes, the absorption and fluorescence maxima of which hold linear correlations with the polarity of low-viscosity solvents [100, 107], because then the probed polarity as well as the hypothetical emission maximum of the fully relaxed R-state can be estimated from the absorption maximum. In vitrified solutions such as sol–gel matrices [100], SR becomes much slower than fluorescence and it arises from states close to the FC state.

6.5.1.3.2 **Time-Resolved Emission Spectra** Although there have been several attempts to simplify the characterization of the SR process, the determination of time-resolved emission spectra (TRES) is certainly the most general and most precise way to quantitatively describe the solvent response. The TRES are usually

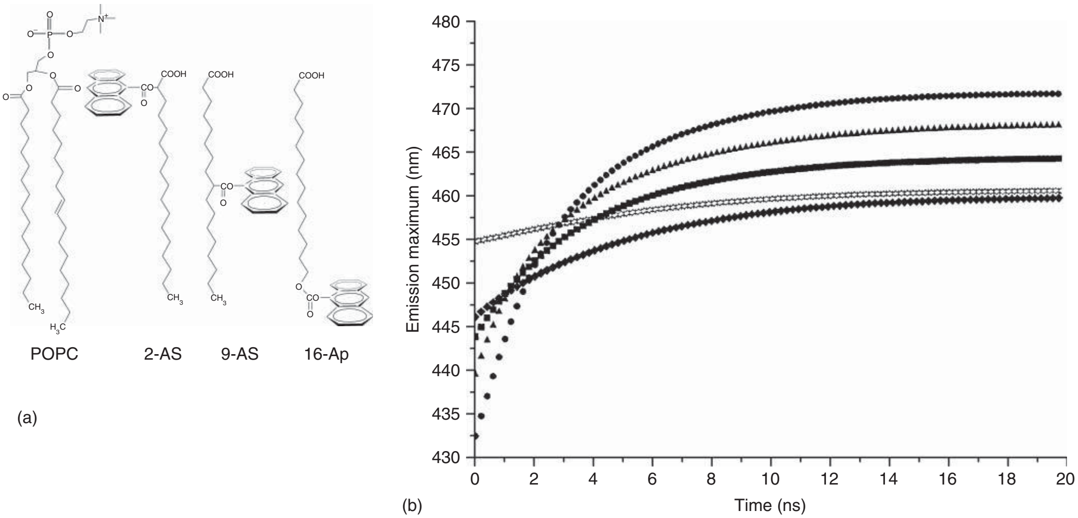

Figure 6.33 (a) Schematic structures of 2-AS, 9-AS, and 16-AP and their relative position within phospholipid bilayers with respect to a phospholipids molecule (1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine, POPC). (b) Time course of the emission maximum wavelength λ (in nanometer) as a function of time after excitation of the *n*-AS in PC-SUV at 25 °C. Circles, 2-AS; triangles, 6-AS; boxes, 9-AS; diamonds, 12-AS; asterisks, 16-AP recorded with a time resolution of approximately 200 ps. For a fully quantitative description of the solvent relaxation process of those *n*-AS dyes see [109].

determined by "spectral reconstruction" [97, 98, 107]. The TRES at a given time t is calculated from the wavelength dependent time-resolved decays by relative normalization to the steady-state spectrum [108]. By fitting the TRES at different times t by the empirical "log-normal" function, the emission maximum frequencies $\upsilon(t)$ (or emission maximum wavelengths $\lambda(t)$: see Figure 6.33b) and the total Stokes-shift $\Delta\upsilon$ (or $\Delta\lambda$) are usually derived [107]. As $\upsilon(t)$ contains both information about polarity ($\Delta\upsilon$) and viscosity of the reported environment, the spectral shift $\upsilon(t)$ may be normalized to the total shift $\Delta\upsilon$. The resulting "correlation functions" $C(t)$ (Eq. (6.7)) describe the time course of the solvent response and allow for comparison of the SR-kinetic and, thus, of relative microviscosities, reported from environments of different polarities [97, 98, 103, 109, 110].

$$C(t) = \frac{\upsilon(t) - \upsilon(\infty)}{\Delta\upsilon} \tag{6.7}$$

SR probes used for the characterization of microviscosities and polarities are listed in Table 6.12 [111–121]. They are characterized by a large change in the dipole moment $\Delta\mu_c$ on electronic excitation.

6.5.1.3.3 **Example for Using Solvent Relaxation for Probing Micropolarities** The benefit of the SR techniques in probing micropolarities might be demonstrated

by the TRES of the *n*-anthroyloxy fatty acids (*n*-AS) in small unilamellar vesicles (SUVs) [109]. These compounds constitute a unique set of fluorescent dyes with the advantage of using a common chromophore, which is covalently attached at different positions ($n = 2, 9, 16$) along the acyl chain of the fatty acid (stearic acid for $n = 2, 9$; palmitic acid for $n = 16$; see Figure 6.33a). The *n*-AS probes are believed to insert into the membrane with the stearoyl chains parallel to the phospholipid acyl chains. While the total Stokes-shifts $\Delta\upsilon$ in highly viscous, nonpolar solvents such as paraffin oil evoking from an intramolecular relaxation process are small and independent of the fluorophore position ($\Delta\lambda = 1630\,\text{cm}^{-1}$), the *n*-AS dyes show much larger $\Delta\upsilon$ values increasing within the series 16-AP < 9-AS < 2-AS (i.e., 2950, 2450, 2300 cm^{-1}, respectively), when incorporated in phosphatidylcholine small unilamellar vesicles (PC-SUVs). Apparently, 2-AS, which is located closest to the membrane/water interface probes the most hydrated, polar environment, while 16-AP residues in much more hydrophobic environment, although still seeing some water molecules. The presented trends illustrate the $\Delta\upsilon$/solvent polarity relationship and show that the SR is an excellent direct method for detecting externally induced polarity and fluidity changes within the bilayer and other self-organizing systems. Recent examples of the application of the SR technique in membrane science have been highlighted in publications [110, 116]. In both contributions, it is shown how the headgroup mobility and hydration in liposomes used in drug [116] and DNA [110] carrier systems are controlled by small variations in the composition of those liposomes.

6.5.1.4 **Polarized Fluorescence**

Excitation with linear polarized or to lesser extent even unpolarized light leads to an anisotropic spatial distribution of excited state molecules. As this selection persists also in emission, the emitted light is also polarized. The degree of fluorescence polarization is largest when linear polarized excitation is used and depends on how well the effect of photoselection has been kept in the emission. The polarization can be diminished by excitation energy transfer and by rotational diffusion of the excited molecule. The latter process depends on the viscosity of the dye environment and on the size of the diffusing species. This connection represents the basis for the applications of fluorescence polarization studies. The depolarization by excitation energy transfer [124] is usually an undesirable process. Resonance energy transfer, however, occurs only in concentrated solution where the average distance between the dyes is typically near 5 nm (see Section 6.5.1.5). Thus, this depolarization mechanism can be avoided by the use of dilute solutions.

The polarization is conventionally characterized with reference to a system of laboratory coordinates defined by the directions of linear polarized excitation ($E_{||}$) and of the fluorescence beam. It is customary to observe the fluorescence beam resolved in directions parallel ($F_{||}$) and perpendicular ($F_{\perp}$) to the direction of the excitation light ($E_{||}$). The degree of fluorescence polarization P is defined as

$$P = \frac{F_{||} - F_{\perp}}{F_{||} + F_{\perp}} \tag{6.8}$$

An equivalent parameter used for the description of polarization of fluorescence is the anisotropy a

$$a = \frac{F_{||} - F_{\perp}}{F_{||} + 2F_{\perp}} \tag{6.9}$$

Although both parameters are equivalent for the description of polarized light, anisotropy is usually preferred. Following pulse excitation, the anisotropy of spherical particles in homogeneous isotropic medium decays exponentially, given by

$$a = a_0 \exp\left(\frac{-t}{\tau_\mathrm{p}}\right) \tag{6.10}$$

where τ_p is the rotational correlation time of a sphere and a_0 is the anisotropy at $t = 0$. The initial value of the anisotropy a_0 is constant if the fluorophore is fixed in space. Thus, it can be experimentally determined by measuring the steady-state anisotropy of the dye in a rigid and homogeneous medium, such as a vitrified solution. It depends on the angle between the absorption and transition moment of the dye, β. As the orientations of absorption and transition moments are characteristic for the corresponding electronic transitions, the angle β is a constant for a pair of electronic transitions of a dye. Fluorescence usually arises from a single transition. Thus a_0 is supposed to be invariant to the emission wavelength. The presence of SR occurring on the nanosecond timescale, however, can result in a wavelength dependent change of the emitting S_1 state (see Section 6.5.1.3.1), and thus to a substantial decrease in anisotropy across the emission spectrum. As the excitation spectrum might be composed of several absorption bands corresponding to several transition moments, the polarization of fluorescence might change with the exciting light wavelength. Thus, polarization excitation spectra can be used to identify different overlapping electronic transitions. Using linear polarized light under one-photon excitation conditions (for multiphoton excitation see [125]) a_0 for a randomly orientated molecule is

$$a_0 = 0.6\ \cos^2\beta - 0.2 \tag{6.11}$$

For collinear transition dipole moment, the theoretical maximum value a_0 is equal 0.4.

6.5.1.4.1 **Steady-State Fluorescence Anisotropy**

In low-viscosity solvents, the rotational depolarization of low molecular weight compounds occurs on the picosecond timescale [126]. As in this case, the rotation is much faster than the fluorescence, the steady-state emission is nonpolarized. If the rotational motion of the fluorophore is on the same scale as the fluorescence, a steady-state polarization is observed. In the simplest case for a spherical rotor and single-exponential fluorescence intensity decay (τ), the measured anisotropy is given by

$$a = \frac{a_0}{1 + \tau/\tau_\mathrm{p}} \tag{6.12}$$

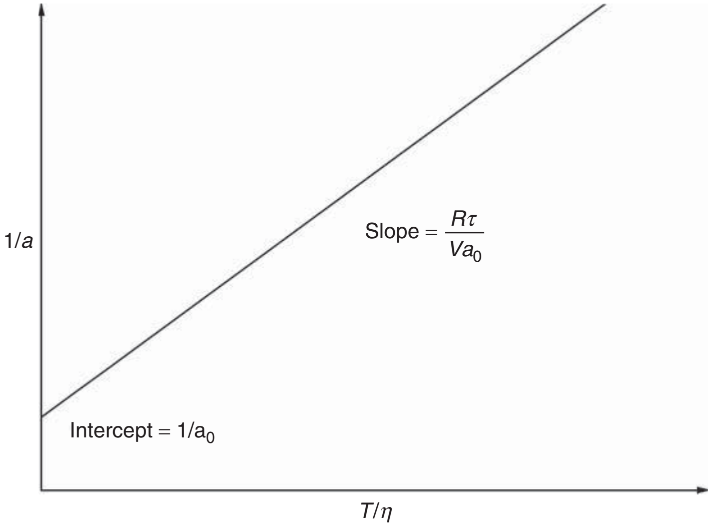

Figure 6.34 Illustration of a Perrin plot for the determination of the apparent hydrodynamic volume V by steady-state fluorescence anisotropy measurements.

The rotational correlation time of a sphere τ_p is given by

$$\tau_\mathrm{p} = \frac{\eta V}{RT} \tag{6.13}$$

where η is the viscosity, T the temperature, R the gas constant, and V the volume of the rotating unit. It is important to note that these connections hold only for spherically symmetrical molecules. A formal description of these connections for spherically unsymmetrical and ellipsoidal molecules can be found in the literature [124, 127–129]. By combining Eq. (6.12) and Eq. (6.13), it can be seen that a plot of $1/a$ versus T/η should be linear, with intercept equal to $1/a_0$ and with a slope/intercept that is directly proportional to τ and indirectly proportional to V (see Figure 6.34). If one of the latter two parameters is known, the other can be calculated from such data. The absence of viscosity dependence indicates that some other depolarizing process dominates. A nonlinear plot of $1/a$ versus T/η indicates the existence of more than one rotational mode.

Prior to the availability of time-resolved measurements, such so-called Perrin plots have been extensively used to determine the apparent hydrodynamic volume of proteins [130, 44, 131]. As protein association reactions usually affect the rotational correlation time of the protein label, such reactions have been characterized by steady-state anisotropy measurements [132, 133].

6.5.1.4.2 **Time-Resolved Fluorescence Polarization** As described by Eq. (6.10), the anisotropy of spherical particles in homogeneous isotropic medium decays exponentially. Anisotropy decays, however, can be more complex. The three most important origins for nonmonoexponential decays are described in the following:

1) *Nonspherical particles in homogeneous isotropic medium*
   The theory for rotational diffusion of nonspherical particles is complex. In theory, the anisotropy decay of such a molecule can be composed of a sum of up to five exponentials [134]. The ellipsoids of revolution represent a smooth and symmetrical figure, which is often used for the description of the hydrodynamic properties of proteins. They are three-dimensional bodies generated by rotating an ellipse about one of its characteristic axes. In this case, the anisotropy decay displays only three rotational correlation times, which are correlated to the rotational diffusion coefficients $D_{||}$ and $D_{\perp}$. In this case, the indices || and ⊥ denote the rotation around the main and side axis, respectively [129]. The preexponential factors of the three exponentials depend on the angle between the emission transition moment and the main axis of the rotational ellipsoid. In practice, owing to the limited time resolution, one rarely resolves more than two exponentials [129].
2) *Segmental mobility of the chromophore*
   A more important factor is that the chromophore is not rigidly fixed to the biopolymer and, thus, rotates about the bond linking it to the biopolymer. Consequently, the anisotropy decay kinetics is found to be double or triple exponential, because of the contributions from internal and global rotation of the macromolecule. The same concept applies for the rotational wobble of that portion of the biopolymer in proximity to the fluorophore or in the more defined case for the rotation of a molecular domain [45].
3) *Hindered rotors: fluorescent dyes in biological membranes.*
   If isotropic rotors are imbedded in an anisotropic environment, such as phospholipid bilayers, the decay of fluorescence anisotropy can be complex. Let us consider a dye, such as 1-(4-trimethylammonium-phenyl)-6-phenyl-1,3,5-hexatriene (TMA-DPH) or DPH, intercalated inside the bilayer. The polarization of its fluorescence depends on the resistance to its motion, exerted by its molecular environment. In the case of a fixed hindrance to rotational relaxation motion, the value of anisotropy decreases exponentially, not to zero, but to a finite value a_∞, yielding Eq. (6.14)

$$a = (a_0 - a_\infty)\exp\left(\frac{-t}{\tau_\mathrm{p}}\right) + a_\infty \tag{6.14}$$

Thus, the time-resolved measurement of such membrane probes contains information on the dynamics of the hindered probe rotation, often interpreted as the microviscosity, and about the hindrance of this rotation, usually interpreted as the static packing arrangement of the lipids or the so-called membrane order [135, 136]. Fluorescence polarization studies in membranes, however, exhibit some major limitations: the experimentally determined steady-state and time-resolved anisotropies characterize the motional restrictions of the ‘‘reporter’’ molecule itself and give therefore only *indirect* information about the dye environment, with the consequence that, if the probe is bound covalently to the lipid (TMA-DPH), this attachment may dominate the recorded depolarization behavior. The membrane order parameters obtained from freely mobile probes such as (DPH) result from a broad distribution of localizations within the hydrophobic interior, the detailed characterization of which reveals inherent ambiguities [137].

Among the fluorescence techniques employed, the determination of fluorescence anisotropy has certainly been the dominating fluorescence method in studies of biological systems. For a detailed description of the theory and several examples of its application, readers are referred to two review articles [129, 136].

6.5.1.5 **Förster Resonance Energy Transfer**

The Förster (often called *fluorescence*) resonance energy transfer (FRET) is a nonradiative transfer of the excitation energy from a donor to an acceptor chromophore. It is governed by a long-range interaction between the emission and absorption transition dipole moments of the donor and acceptor, respectively. The rate of energy transfer depends on the extent of the spectral overlap of the emission and absorption spectra of the donor and acceptor, respectively, on the quantum yield of the donor, the relative orientation of the transition dipole moments, and the distance between donor and acceptor molecules. The distance dependence has resulted in its widespread use to measure distances between donors and acceptors in macromolecular systems. The quality of a *donor/acceptor* pair is usually characterized by the parameter R_0, which is typically in the range between 2 and 9 nm. It is defined as the distance at which the rate of resonance energy transfer is equal to what would be the decay rate of the donor on the absence of an acceptor and can be estimated, as follows

$$R_0(\mathrm{nm}) = 979(\kappa^2 n^{-4} \phi_0 J)^{\frac{1}{6}} \tag{6.15}$$

where n is the refractive index of the medium, ϕ_0 is the fluorescence quantum yield of the donor, J the spectral overlap integral, and κ an orientation factor. The rate of energy transfer k_{ET} is given by

$$k_{\mathrm{ET}} = \frac{1}{\tau_{\mathrm{d}}} \left(\frac{R_0}{r} \right)^6 \tag{6.16}$$

where τ_{d} is the decay time of the donor in absence of the acceptor and r is the distance between donor and acceptor. Thus the rate depends strongly on distance, providing a spectroscopic ruler for determining distances in macromolecular assemblies.

The magnitude of k_{ET} can be determined from the efficiency of energy transfer, ET, via

$$k_{\mathrm{ET}} = \frac{1}{\tau_{\mathrm{d}}} \frac{\mathrm{ET}}{1 - \mathrm{ET}} \tag{6.17}$$

and ET, in turn, can be experimentally evaluated by the measurements of the decrease in the intensity F or lifetime τ of the donor in the presence of the acceptor

$$\mathrm{ET} = 1 - \frac{F}{F_{\mathrm{d}}} = 1 - \frac{\tau}{\tau_{\mathrm{d}}} \tag{6.18}$$

Thus, determining ET and knowing R_0, the separation distance r can be calculated. In such distance measurements, there is often a concern about the effects of the orientation factor κ^2, which depends on the relative orientation of the emission oscillator of the donor and the absorption oscillator of the acceptor. The value of κ^2 varies from 4 (parallel orientation of the oscillators) to 0 (perpendicular orientation). Often a value of $\kappa^2 = 2/3$ is assumed, which corresponds to the situation when there is rapid, isotropic rotation of the donor and acceptor molecules. Randomly oriented dipoles that remain fixed during the singlet lifetime give $\kappa^2 = 0.476$. When required, the range of values for κ^2 can be estimated by polarization measurements [138]. A comprehensive discussion on the theory and effects of the orientation factor is given in [139].

When assuming the simplest case of a monoexponentially decaying donor τ_{d}, a fixed distance r and a dynamically random orientation factor $\kappa^2 = 0.476$, k_{ET} will be added to Eq. (6.3) and thus the energy transfer will simply result in a shortened, monoexponential decay of the donor τ_{d}. In homogeneous solution, however, at low donor concentrations and without diffusion of the donor and acceptor within the fluorescence lifetime, the intensity decay is given by [140–143]

$$F = F_0 \exp\left(\frac{-t}{\tau_{\mathrm{d}}}\right) \exp\left[-\gamma\left(\frac{t}{\tau_{\mathrm{d}}}\right)^{\delta}\right]; \quad \delta = \frac{\mathrm{dim}}{6} \tag{6.19}$$

For randomly distributed donor and acceptor molecules the value for the dimension dim is equal 3 and γ is

$$\gamma = \frac{4}{3} g \pi^{\frac{3}{2}} c_{\mathrm{a}} R_0, \quad \text{where } g = \sqrt{\frac{3}{2}\kappa^2} \tag{6.20}$$

with c_{a} as the acceptor concentration. With knowledge of the acceptor concentration and on the condition that the donor fluorescence decays monoexponentially in the absence of the acceptor, the R_0 value and the dimension of the medium in which donor and acceptors are imbedded can be determined. Two-dimensional or the so-called fractal energy transfer is of interest, if the dye molecules are bound to phospholipid membranes [43, 144] or imbedded in silicate networks [145]. One-dimensional energy transfer has been considered for dyes bound to DNA [146].

FRET is widely used in biosciences as a molecular ruler to characterize the topography of macromolecules and supramolecular structures in cells and model systems [147–150]. The method is usually combined with microscopic imaging in case of living cells studies. A variety of experimental approaches exist for microscopic FRET studies [151]. The simplest approach is to perform two-color ratio imaging of donor and acceptor emission. Overlap of excitation and emission spectra of donor and acceptor can result in problems with cross-talk, making control experiments needed to establish the presence of FRET [148]. A more rigorous, although experimentally more complicated approach, is fluorescence lifetime imaging (FLIM) of the donor. This method is less prone to cross-talk artifacts and allows also the use of nonfluorescent acceptors [148]. Fluorescence anisotropy can be also used to measure FRET. This approach is convenient in cases where the mobility of the donor is strongly restricted and its fluorescence, thus, strongly anisotropic. If the transition moment of the acceptor is oriented randomly or differently than that of the donor, energy transfer results in depolarization of fluorescence of the sample. This method can easily detect the presence of FRET, however, it is not good for estimating the strength of the effect [148].

Studies of protein conformation and folding represent an important field of FRET applications [147, 152, 153]. Green fluorescent protein (GFP) and its analogs are the main tools of fluorescence spectroscopy in protein science and FRET assays are no exception. Cyan fluorescent peptide (CFP) as the donor and yellow one (yellow fluorescent peptide, YFP) as the acceptor are the most widely used FRET pair; other possible pairs include GFP or YFP as the donor and orange or red proteins like mCherry as the acceptor [148, 153]. Assays for the characterization of fusion of cells or vesicles represent another application field of FRET. Usually such membrane systems are labeled either by a donor or an acceptor molecule. Fusion leads to an intermixing of these membrane labels in the same bilayer, allowing resonance energy transfer to occur. Examples can be found in the literature [154–158]. Another membrane application of energy transfer has been the demonstration of lipid asymmetry in human red blood cells [159]. Moreover, energy transfer has been shown to be a very useful tool in elucidating the subunit structure of oligomeric assemblies in membranes. Examples are studies on the oligomerization of ATPase of sarcoplasmic reticulum in phospholipid vesicles [160], on gramicidin A transmembrane channels [161], and on the aggregation state of bacteriorhodopsin [162]. Finally, the combination of energy transfer with flow cytometry [163] and its use in immunoassays should be mentioned [164]. More detailed information on theory and applications of energy transfer can be found in [139, 165, 164].

6.5.1.6 **Excimer Fluorescence**

The term *excimer* is used when the excited dye forms a transient fluorescent dimeric complex with another fluorophore of the same kind. The excimer fluorescence is usually red shifted with respect to that of monomers (see Figure 6.35). The most widely used types of *excimer-forming probes* are pyrene (see Figure 6.35) and perylene and their derivatives. The ratio of the maxima of the excimer to the monomer spectra can be used to judge the efficiency of excimer formation. This (Ex/Mo)-ratio depends on the concentration of the dye and is controlled by the diffusion properties. When using pyrene or perylene labeled fatty acids or phospholipids (see Figure 6.35), it allows for the estimation of the probe's lateral diffusion coefficients in lipid bilayer membranes. Thus, membrane fluidity can be measured by monitoring the fluorescence spectra of such an excimer probe.

As increasing temperature leads to increased fluidity and thereby to a faster probe diffusion, pyrene lipids have been frequently used to study phase transition in membranes [166, 167]. Phospholipid phase separation increases the local concentration of dye labeled lipids and can be, therefore, investigated via the characterization of excimer formation. The binding of proteins or ions, however, might induce phase separation as well as decrease lateral lipid diffusion. As these two effects are opposing in terms of excimer formation, the binding of such proteins or ions cannot be studied by the (Ex/Mo)-ratio. The time-resolved analysis of the monomer fluorescence of the labeled lipid, however, allows for the separation of

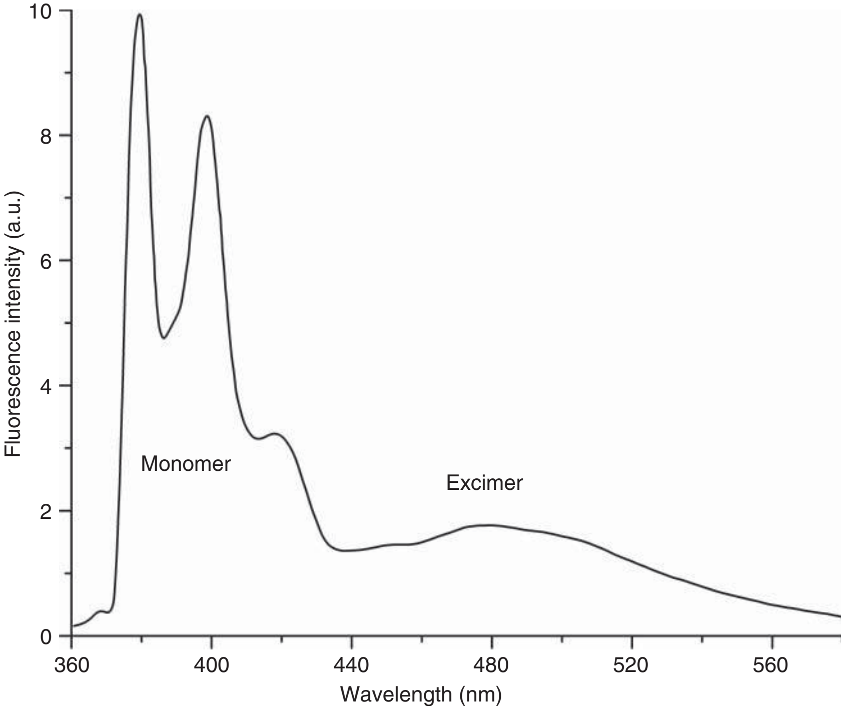

Figure 6.35 Fluorescence spectrum of pyrene-labeled phosphatidylglycerol (5 mol%) in phosphatidylcholine small unilamellar vesicles at ambient temperature; $\lambda_{ex} = 337$ nm.

both effects [168]. A comprehensive treatise of theory and application of excimer probes in membrane research can be found in [169, 170].

6.5.2
Special Applications

6.5.2.1 Fluorescence Recovery after Photobleaching (FRAP)

Fluorescence recovery after photobleaching (FRAP) was introduced as a method to measure the local mobility of fluorescently labeled particles bound to the plasma membrane of living cells [171–173]. It has been used to study transport phenomena in a wide variety of biological membrane-bound systems, as well as to probe the photobleaching properties of fluorescent molecules [174]. FRAP is based on the principle of observing the rate of recovery of fluorescence, because of the movement of a fluorescent marker into an area of the membrane which contains this same marker but which has been rendered nonfluorescent via an intense photobleaching pulse of laser light. The two-dimensional diffusion coefficient of the fluorophore is related to both its rate and extent of recovery. For a discussion of the photophysical mechanism of photobleaching see Ref. [175]. In order to create a finite observation area, both laser beams, the single short pulse with rather

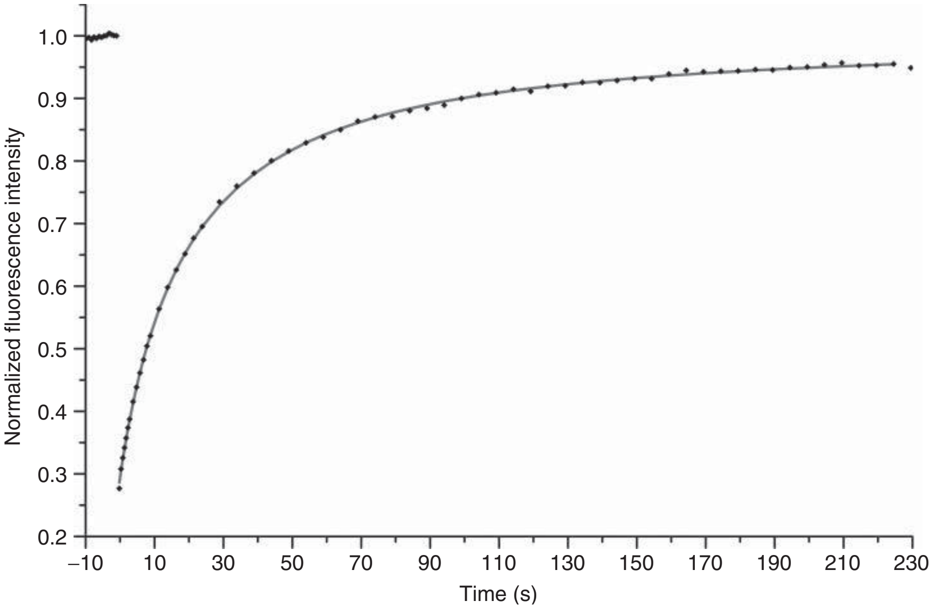

Figure 6.36 Representative TIR–FRAP curve for splicing regulator Brd2 tagged with GFP in the nucleoplasm of HeLa cells. Note that the fluorescence intensity does not recover fully. This effect is generally observed in photobleaching experiments and is one of the major drawbacks of this method. (Data courtesy of Dr David Staněk and Eva Šimková, Institute of Molecular Genetics of ASCR, Prague, Czech Republic.)

high intensity leading to photobleaching and the less intensive pulse monitoring the fluorescence recovery, are usually focused by an epifluorescence or confocal microscope. A very elegant variation is to combine FRAP with total internal reflection fluorescence (TIRF) [176]. Here, a laser beam totally internally reflects at a solid/liquid interface, creating an evanescent field, which penetrates only a fraction of the wavelength into the liquid domain. When using planar phospholipid bilayer and fluorescently labeled proteins, this method allows for the determination of adsorption/desorption rate constants and surface diffusion constants [177, 178]. Figure 6.36 shows a representative FRAP curve for splicing regulator Brd2 tagged with GFP in the nucleoplasm of HeLa cells. It should be mentioned that, similar to other applications of fluorescence microscopy, two and three photon excitation might be combined with FRAP as well [179].

6.5.2.2 **Fluorescence Correlation Spectroscopy (FCS)**

Since its first introduction in the early 1970s [180–183], the method has developed significantly and has become a standard tool in many scientific disciplines. The typical setup contains a laser with high temporal stability, a single photon detector with low noise (usually a single photon counting photomultiplier tube or a single photon avalanche diode), and a confocal or multiphoton fluorescence microscope with a high-quality objective [184, 185]. In such a setup, fluorescence emission is collected only from a very small volume of the sample, which is typically about 1 μm^3 or smaller. Its radius within the focal plane is diffraction limited and about 200–300 nm, while its characteristic dimension along the optical axis of the microscope is a few micrometers [184, 185]. The method is based on recording time traces of fluorescence intensity $I(t)$ with high temporal resolution and calculating their normalized autocorrelation function $G(\tau)$, which measures probability of detecting a photon at time $t+\tau$ if a photon was detected at time t

$$G(\tau) = \frac{\langle I(t)I(t+\tau)\rangle}{\langle I(t)\rangle^2} \tag{6.21}$$

where pointed brackets represent averaging over all values of t. The shape of the autocorrelation function reflects the timescale of fluorescence intensity fluctuations. On a nanosecond timescale, within the lifetime of fluorescence, it rises steeply from zero to a maximum. This effect, called *photon antibunching*, is related to the time delay between two consecutive photon emissions by a single fluorophore [184] and it can be used to determine the number of independent fluorophores per molecule or molecular complex [186]. Intensity fluctuations on a microsecond timescale result mainly from photophysical and photochemical processes such as intersystem crossing to nonfluorescent triplet state and, in case of polarized detection, rotational diffusion of molecules also contributes. On longer timescales, translational diffusion of molecules in and out of the detection volume dominates the autocorrelation function. In cases of reactions, where a product has much higher fluorescence quantum yield than the reactants, concentration fluctuations around equilibrium can be also detected and used to determine reaction kinetics [182]. If more processes happen on comparable timescale, it is difficult to distinguish their contributions to the autocorrelation function.

The detection volume is usually approximated by a three-dimensional Gaussian volume element [184]. The autocorrelation function $G(\tau)$ for a three-dimensional Brownian diffusion is then given by Eq. (6.22) [187]

$$G(\tau) = 1 + \frac{1}{N}\frac{1}{1+(\tau/\tau_\mathrm{D})}\left(\frac{1}{1+\left(\tau/\tau_\mathrm{D}\right)(\omega_0/\omega_\mathrm{z})}\right)^{\frac{1}{2}} \tag{6.22}$$

where ω_0 and ω_z are characteristic dimensions of the detection volume in the focal plane and along the optical axis respectively defined as distances at which the intensity drops by the factor e^{-2}. τ_D is the diffusion time and N is the particle number (number of fluorescent particles within the detection volume). The dimension of the detection volume can be determined by a measurement of diffusion of a molecule with known diffusion coefficient.

To account for intersystem crossing, an average fraction of fluorophores in triplet state T and intersystem crossing relaxation time τ_T need to be induced into

Eq. (6.22) [187]

$$G(\tau) = 1 + \left[1 - T + T\exp\left(\frac{-\tau}{\tau_T}\right)\right] \frac{1}{N(1-T)}\frac{1}{1+(\tau/\tau_D)}\left(\frac{1}{1+(\tau/\tau_D)(\omega_0/\omega_z)}\right)^{\frac{1}{2}} \tag{6.23}$$

If more fluorescent species are present in the sample, a multicomponent autocorrelation function (Eq. (6.24)) is used [187]

$$G_M(\tau) = 1 + \frac{\sum_{i=1}^{M}\left(\frac{Q_i}{Q_1}\right)^2 F_i g_i(\tau)}{N\left[\sum_{i=1}^{M}\frac{Q_i}{Q_1}F_i\right]^2},$$
$$g_i(\tau) = \frac{1}{1+(\tau/\tau_{Di})}\left(\frac{1}{1+(\tau/\tau_{Di})(\omega_0/\omega_z)}\right)^{\frac{1}{2}} \tag{6.24}$$

where Q_i is the detection efficiency of ith species and F_i its fraction. When the diffusion is confined only to two dimensions, as in the cases of supported phospholipid bilayers (SPBs) [188], giant unilamellar vesicles (GUVs) [189], or monolayers on air–water interfaces [188], Eq. (6.22) is reduced to the following form

$$G_{2D}(\tau) = 1 + \frac{1}{N}\frac{1}{1+(\tau/\tau_D)} \tag{6.25}$$

The physically relevant parameters τ_D and N can be, then, extracted from the experimentally obtained autocorrelation function $G(\tau)$ via nonlinear fitting with an appropriate theoretical model (Eq. (6.22), Eq. (6.23), Eq. (6.24), and Eq. (6.25)). Owing to the highly nonlinear connection between the physically relevant parameters and the measured autocorrelation function, it is very difficult to analyze the accuracy of their estimation. The standard deviation of the fit of the autocorrelation curve can be obtained using the method described by Wohland *et al.* [190]. Knowing the size of the detection volume, it is possible to easily calculate diffusion coefficient D and concentration c of the fluorescent molecule from the measured parameters τ_D and N respectively.

The signal-to-noise ratio is the highest when there is on average about one fluorescent molecule within the detection volume [188, 191], which means very low (nM) concentrations are optimal. For that reason, FCS (fluorescence correlation spectroscopy) is often included among *single molecule* techniques; it is based on detection of fluctuations caused by single molecules, but extracts from them ensemble-averaged kinetic data. High excitation intensities can lead to artifacts because of photobleaching and optical saturation, when an increased number of molecules within the detection volume are not in the ground state but in an excited or triplet state leading to loss of proportionality between excitation and fluorescence intensities [184, 185]. Other artifacts, which can influence the results of FCS, are caused by deviations of the real shape of the detection volume from the Gaussian one assumed in Eq. (6.22), Eq. (6.23), Eq. (6.24), and Eq. (6.25).

A detailed discussion of the artifacts of FCS can be found in the works of Enderlein and his group [184, 185, 192]. The most important source of artifacts in the case of two-dimensional systems is the problem with exact positioning of the sample along the optical axis of the microscope (z axis). There exist several methods to overcome this problem: two-focus scanning fluorescence correlation spectroscopy (SFCS) [193] or two-focus FCS with overlapping foci, which uses two alternatively pulsed polarized lasers [192] and a single-focus technique called *z-scan FCS*, which can be performed with most standard FCS setups [188].

z-Scan FCS is based on measuring fluorescence autocorrelation functions $G(\tau)$ at different positions of the sample along the z axis (with step size typically 200 nm), thus changing the distance Δz between the sample and the focus. Diffusion time τ_D and particle number N depend quadratically on Δz (Eq. (6.26)) [194]

$$\tau_D(\Delta z) = \frac{\omega_0^2}{4D}\left(1 + \frac{\lambda^2 \Delta z^2}{\pi^2 \omega_0^4}\right), \quad N(\Delta z) = \pi c_S \omega_0^2 \left(1 + \frac{\lambda^2 \Delta z^2}{\pi^2 \omega_0^4}\right) \tag{6.26}$$

where D is the lateral diffusion coefficient of the fluorescent molecule, c_S its surface concentration, ω_0 is the radius of the excitation beam in the plane of focus, and λ is the wavelength of the excitation light in the medium of the sample. Diffusion coefficients obtained by this method are independent of external calibration and free of most artifacts of standard FCS [192].

FCS is widely used in biological sciences to study diffusion of lipids and proteins in cellular membranes or their models. The high spatial resolution of FCS allows for the characterization of diffusion processes in different compartments of cell [195–199]. In many applications, the diffusion properties of two species with different molecular weight are analyzed. In case that the fluorescently labeled low molecular weight compound binds to the high molecular weight compound, titration of the latter allows for the determination of equilibrium binding constants. This principle can be used, for example, for the characterization of interactions between different proteins [200–203], proteins and membranes [204], xenobiotics and proteins [205], or polynucleotides and DNA [206]. Moreover, any chemical or biochemical reactions leading to a marked change of the molecular weight can be analyzed in real time [195, 196, 207]. However, when the change in molecular weight and, thus, diffusion coefficient is not a big one, as for example, in case of dimerization of relatively small molecules, FCS may not be able to resolve the contributions from the two populations. In some cases, photon counting histograms (PCHs) may be a useful tool to extract the concentrations of different components of the mixture using the difference in their molecular brightness ϵ defined as average number of photons per molecule per sampling time. The PCH of a mixture is the convolution of PCHs of the individual components [208].

Signals from two fluorophores of different emission wavelengths can be separated by means of optical filters and their diffusions measured independently by dual-color FCS. Cross-correlation of their signals reveals whether the two fluorophores move independently or not [209]. Cross-correlation dual-color FCS is also suitable to study kinetics in changes of FRET efficiency; for example, a CFP and YFP bound to different domains of a protein can provide information on internal protein dynamics [210]. Different lifetimes of fluorescence can also serve to identify signal from different fluorophores. The method called *lifetime FCS* may even separate signal coming from the same fluorophore located in different environments [211]; this approach has been applied successfully to elucidate the mechanism of DNA compaction by multivalent cations [212].

Determination by FCS of diffusion coefficient of very slowly diffusing molecules, such as proteins or protein complexes in cellular membranes, may require impractically long measurement times which are connected with an increased risk of artifacts caused by photobleaching and photoinduced degradation of the biological samples. For that reason, several variations of FCS have been developed, which are better suited for such range of applications. In SFCS, the microscope focus is constantly moving along a certain trajectory within the sample (a line or a circle usually). The exposure time of each individual point in the sample is, thus, considerably reduced [193, 123]. FCS measurements in a small number of individual points may not yield representative values of molecular diffusion in as inhomogeneous systems as cellular membranes and other biological structures. That issue is addressed by camera-based FCS, which probes diffusion in many points simultaneously providing a map of molecular mobility [214, 215]. Apart from the possibility of obtaining FCS data from each individual point of an image, whole images may be analyzed by image correlation spectroscopy (ICS), a variant of FCS in which spatial correlations between individual pixels of the image are calculated with interpixel distance playing the role of lag-time τ in standard FCS. Spatial correlations are employed, for example, in spatiotemporal image correlation spectroscopy (STICS), which is efficient in the characterization of directed flows and enables construction of complete transport maps of proteins within regions of cellular membrane [216]; similar information is provided by a related technique *k*-space image correlation spectroscopy (kICS), which uses transformation to the reciprocal space [217]. Raster image correlation spectroscopy (RICS) is based on spatial correlations of images recorded by laser scanning microscopes. Its main advantages include easy implementation using standard laser scanning microscopes as well as broad dynamic range provided by two distinct timescales of scanning (pixels in the same row and pixels in adjacent rows respectively) [218].

6.5.2.3 **Single Molecule Fluorescence**

Following the advances in ultrasensitive instrumentation, the number of works using single molecule experiments has grown rapidly in recent years and some of the techniques have already become well-established experimental procedures. Thanks to its high sensitivity, fluorescence spectroscopy using laser-induced fluorescence is a leading method of single molecule detection. Several optical methods have been used to study single molecule fluorescence; their principles and application can be found, for example, in the reviews [219, 220]. These methods are listed in Table 6.13 [221–241]. Almost any type standard fluorescence spectroscopic measurement can be performed at single molecule level, such as measurements of excitation spectra [242, 243], fluorescent lifetimes by time-correlated single photon counting (TCSPC) [228, 244], or correlation measurements of kinetics of fluorophore’s transition to

Table 6.13 Methods for studying single molecules using laser-induced fluorescence.

Method for studying single molecules	References

Wide-field epi-illumination	[238, 239]
Evanescent wave excitation	[240]

a dark state [245]. The photostability of the single fluorophores is in many cases a limiting factor [245] and for that reason QDs are sometimes used in single molecule studies. These luminescent nanocrystals have supreme brightness and photostability; however, their main drawbacks are larger size, which can interfere more with the investigated system, and their cytotoxicity [246].

One of the motivations for single molecule studies is the development of ultrasensitive analytical assays [220, 248]; a very perspective example is single molecule DNA sequencing [249]. But the most important motivation for single molecule experiments is undoubtedly the possibility of collecting detailed information, including complete statistical distributions, about processes on the level of individual molecules, which cannot be extracted from ensemble-averaged data provided by other techniques. This approach has yielded much deeper insight into several phenomena in many scientific disciplines, such as chemistry, molecular biology, molecular medicine, and material science. Single molecule excitation spectra of fluorophores embedded in crystals revealed, for example, time-dependent spectral shifts related to motions of surrounding molecules [242]. Single molecule fluorescence has also proved to be an efficient tool for gaining deeper insight into intracellular processes such as the mechanism of function of various enzymes. A well-known example is the elucidating of the step-wise movement of molecular motors and the importance of thermal fluctuations for their function [250].

6.5.2.3.1 **Single Particle Tracking** This is a well-established method for studying diffusion of molecules in cells, cellular membranes, and model systems [251–253]. The position of the fluorescently labeled molecule is recorded with a given time interval Δt and the mean square displacement (MSD) (Δt) of the molecule is calculated. Equation (6.27) relates the MSD (Δt) to the lateral diffusion coefficient D

$$\mathrm{MSD}(\Delta t) = \langle \boldsymbol{r}^2 \rangle = 4D\Delta t^{\alpha} \tag{6.27}$$

where $\boldsymbol{r}$ is the particle position and α is the scaling exponent. α equals 1 for free Brownian diffusion and $\alpha < 1$ for anomalous diffusion [253]. Concentration of fluorescent molecules is a crucial parameter in single particle tracking experiments; it has to be sufficiently low to minimize the probability of detecting two closely neighboring fluorophores, but high enough that the fraction of observed trajectories of fluorescent impurities is negligible [245]. More information on the single particle tracking experiments and their applications in investigations of cellular processes can be found, for example, in a recent review [254]. As the position of single molecules in tracking experiments is determined with precision from 10 to 30 nm [255], investigating movement of molecules confined to a certain structure, for example, cytoskeletal filaments, can determine the dimensions and morphology of the structure with a precision superior to imaging by confocal fluorescence microscope [251].

Other possibilities of reaching sub-diffraction-limited resolution in single molecule fluorescence microscopy are the use of near-field scanning optical microscope (NSOM) [228, 231] or tip-enhanced near-field optical spectroscopy, which is discussed in more detail in Chapter 23.

6.5.2.4 **Fluorescence Sensors**

Thanks to the high sensitivity, selectivity, and versatility of fluorescence spectroscopy, fluorescence based sensors are the most highly developed ones. They are not only very easy to use and cost-efficient, but usually also among the most sensitive methods for sensing given analytes and, thus, opening new possibilities in analytical chemistry. For example, FRET based sensors for metal ions have reached single ion sensitivity [256]. In many cases, the sensing probe is placed on a carrier material and the analyte can be either in gas phase or in solution. Interaction between the sensing probe and the analyte leads to a fluorescence change. The use of fiber optics allows one to perform fluorescence measurements on remote objects, which is especially useful in clinical applications. The required fluorescence change, monitoring, for example, the pH, O_2 pressure, or the concentration of ions in blood, can occur in the intensity, emission spectrum, anisotropy, or lifetime of the sensing probe. The mechanism for a change in the listed fluorescence parameters can be collisional quenching, resonance energy transfer, photoinduced electron transfer, or analyte induced change of the state of sensing chromophore. Table 6.14 gives some examples for analyte, sensing probe, and sensing mechanism [70, 257–263]. As intensity measurements are dependent on

Table 6.14 Examples of fluorescence sensing.

Analyte	Sensing dye	Sensing mechanism	References
Oxygen	Several Ru-complexes (e.g., $[Ru(Ph_2phen)_3]^{2+}$	Collisional quenching	[266]
Chloride	Sultons (betains) of quinolinium and acridinium ions	Collisional quenching	[24, 259]
Calcium	Blue and green fluorescent proteins	Resonance energy transfer	[260]
pH	Fluoresceins	pH-dependent ionization	[261, 263]
Glucose	Fluorescein and rhodamine	Resonance energy transfer	[267]

the concentration of the fluorophore, they are often not usable and they might be inaccurate if photobleaching occurs. Moreover, intensity-based systems suffer from other problems including turbidity, limited range of detection, low signal-to-noise ratios, and optical losses. Fluorescence lifetime-based sensing, on the other hand, does not suffer from these problems and are much more promising for the future. An overview of this topic is given in the chapter ''Fluorescence sensing'' in Ref. [264], and more information on the design of fluorescent sensors can be found in review [265].

Section III
Methods 2: NMR

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

Introduction

The nuclei of all elements possess mass and charge. One or more isotopes of most nuclei also have spin, that is, angular momentum. As spinning charge creates a magnetic field, there is a magnetic moment, μ, associated with the angular momentum. It is this property of matter that is exploited in nuclear magnetic resonance (NMR) spectroscopy. The magnetic moment, a vector quantity, can be aligned in the presence of an intense static magnetic field, B_0, then manipulated in space, that is, caused to evolve in time under the influence of specific interactions and, finally, observed. The detected response can provide information about (i) the specific nuclear isotope present, (ii) the local structure around the nucleus, and (iii) the motional dynamics of the matter containing the nuclei. As will be apparent in the following three chapters, the environment reported on by nuclear magnetization extends far beyond the immediate nuclear horizon, giving information on the bonding arrangement of neighboring nuclei, many angstroms removed. Each magnetic nucleus in a molecule reports on itself and on its relationship with its neighboring nuclei such that the sum of the overlapping connectivity information from all nuclei redundantly determines a unique structure for the molecule. The goal of much of the research activity in NMR over the past 25 years has been the development of multi-dimensional NMR techniques that makes it possible to extract the needed information from NMR spectra. With the current, routine solution state ^{1}H NMR capabilities it is possible to assign essentially every proton resonance in modest molecular weight proteins to a specific proton in a specific amino acid residue, determine the amino acid sequence, and determine the three-dimensional (3D) structure of the folded protein. Such a *tour de force* requires high static magnetic field strengths (today's state-of-the-art magnets have $B_0 = 21.15$ T, i.e., 900 MHz proton frequency) and modern multi-dimensional correlation pulse sequences replete with their editing, filtering, and solvent-suppression schemes. This stunning accomplishment represents one marker on the path of NMR progress that, 55 years after the birth of this spectroscopy, is still a healthy, burgeoning research that provides one of the most exciting areas of science to work in.

The quantum mechanical description of the NMR experiment tells us that the maximum observable component of the angular momentum is $Ih/2\pi$, where I is the nuclear spin quantum number, or simply, the spin, and h is Planck's constant. The magnetic moment is quantized along $2I + 1$ orientations with respect to the

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

static field. The magnitude of the moment vector is a measure of the strength of the nuclear magnet. It depends on the angular momentum and on the internal structure of the nucleus, that is, the distribution of protons and neutrons and their associated angular momenta, according to Eq. (1):

$$\mu = \gamma Ih/2\pi \tag{1}$$

where γ, the gyromagnetic ratio, is the proportionality factor between the magnetic moment and the angular momentum.

For $I = 1/2$ nuclei such as ^{1}H, ^{13}C, or ^{15}N, there are two orientations of the moment in the applied field, aligned parallel and anti-parallel to the field. The force exerted by the static field on the moments causes them to precess about the static field direction. This motion is analogous to that of a toy top: the top spins with its angular momentum along its spinning axis and wobbles (precesses) about the Earth's gravitational field. Nuclei with spin $I > 0$ have isotope-specific nuclear magnetic moments and field dependent addresses, ω_0 or ν_0, the precession frequency, given by the Larmor relation:

$$\omega_0 = \gamma B_0 \rightarrow \nu_0 = \frac{\gamma B_0}{2\pi} \tag{2}$$

For typical magnetic field strengths, the Larmor frequency is in the radio frequency region of the electromagnetic spectrum. For protons in an 18.8 T field, $\nu_0 = 800$ MHz; for ^{13}C in the same field $\nu_0 = 201.6$ MHz.

The NMR experiment consists of inducing transitions between the states of quantized magnetization. This is accomplished by irradiating the sample with radio frequency (RF) energy. The frequency of the RF must exactly match the precession frequency of the nuclei in order to cause the transition. This specificity is the resonance phenomenon, analogous to the tuned circuit in a radio receiver. The tuned receiver (the spin system composed of a specific nuclear isotope) is only capable of interacting with the broadcast signal whose frequency matches the Larmor frequency of the nuclei.

It is our good fortune that NMR has layers of complexity that are not explicitly revealed in Eqs. (1) and (2). Unraveling this complexity (shielding, coupling, and relaxation) has been the preoccupation of NMR spectroscopists for more than half a century, and is the topic of this section of the Handbook. Three chapters on NMR spectroscopy are assembled. They are authored by outstanding experimentalists working at the forefront of NMR research.

In Chapter 7, Leslie Butler (Louisiana State University) introduces the fundamental structure parameters in the NMR experiment through a discussion on solution state ^{1}H NMR. The shielding of nuclei by core and valence electrons, gives rise to those structure-pregnant numbers called *chemical shifts*, δ, that have been accrued and correlated since the earliest days of NMR. Scalar coupling, J, is the through-bond transmission of spin state orientation that historically has been the avenue through which chemists have established bonded atom relationships, configuration, and conformation in molecules. This section is followed by a discussion of properties commonly studied through solid state NMR, namely, chemical shift anisotropy (CSA), dipolar coupling, and quadrupolar interactions. A section on spin–lattice relaxation precedes a discussion of the use of NMR to measure the dynamics of molecular motion. A short introduction to NMR imaging follows to acquaint the reader with spin density mapping using linear gradients. The chapter ends with a description of a 3D NMR experiment used to establish atom connectivity and provides an appropriate segue into the next chapter.

Chapter 8 by Gary Martin, Chad Hadden, and David Russell (Pharmacia Corporation) begins with an exposition of the uses of scalar coupling in the context of one-dimensional (1D) experiments. Homonuclear decoupling experiments and nuclear Overhauser effect (NOE) difference spectroscopy are illustrated before moving on to heteronuclear coupling and the selective population transfer (SPT) experiment. SPT is the basis for enhanced signal intensity in the non-selective polarization transfer experiments, insensitive nuclei enhanced by polarization transfer (INEPT) and distortionless enhancement by polarization transfer (DEPT), J-modulated experiments that sort ^{13}C spectra into resonance subsets based on carbon multiplicity groups, for example, C, CH, CH_2, and CH_3 groups. The principles of two-dimensional (2D) NMR are introduced and illustrated in the context of 2D J-resolved spectroscopy in which the 2D spectrum correlates chemical shifts on one axis with scalar coupling on the second frequency axis. Homonuclear 2D NMR experiments in which both frequency axes are chemical shift and that reveal J-coupling partners (correlation spectroscopy (COSY), total correlation spectroscopy (TOCSY)) or NOE connected partners (nuclear Overhauser spectroscopy (NOESY), rotating-frame Overhauser spectroscopy (ROESY)) as off-diagonal elements are illustrated. The focus then shifts to heteronuclear chemical shift correlation and treats experiments based on one-bond coupling (heteronuclear multiple-quantum correlation (HMQC), heteronuclear single-quantum correlation (HSQC)). Heteronuclear chemical shift correlation via long-range coupling (heteronuclear multiple bond correlation (HMBC)) is described in turn along with multiplicity-edited versions of these experiments. In current practice, most 2D NMR experiments are implemented using pulsed field gradients (PFGs) to select coherence transfer pathways in lieu of using phase cycling routines, as originally conceived, to successively add desired magnetization components and cancel unwanted magnetization components. Thus, gradient correlation spectroscopy (GCOSY), gradient heteronuclear multiple-quantum correlation (GHMQC), and gradient heteronuclear multiple bond correlation (GHMBC), for example, are the modern experiments in use, giving the same experimental correlations, but with excellent artifact cancellation and time savings, in instances where sample size is not limiting. Pulse sequence modifications which optimize the HMBC experiment over a range of J-coupling amplitudes are discussed and end with a description of ^2J, ^3J HMBC, an experiment which makes possible the detection *and* differentiation of two-bond and three-bond proton couplings to protonated carbon and nitrogen centers. It is worth reflecting for a moment on the evolution in the use of three-bond coupling that has occurred since the early discovery of scalar coupling. Correlations of unambiguous ^3J with structure, that is, Karplus relations, dihedral angle dependence of three-bond coupling, were established in many molecular fragments. Karplus relationships have been used to make structural and conformational predictions in applicable systems, it being necessary to establish independently the correct designation of similar magnitude two- and three-bond long-range couplings. ^2J, ^3J HMBC now provides the long-range assignment capability, experimentally distinguishing ^2J from ^3J.

The chapter continues with an overview of inverse (proton-detected) ‘‘hyphenated’’ 2D NMR techniques which join together two correlation experiments. HSQC–TOCSY, for example, first labels protons with the chemical shift of the directly bound heteronuclide, ^{13}C say, in the HSQC part of the experiment, and after the magnetization is transferred back to the proton, homonuclear vicinal coupling is propagated between contiguous protons in the homonuclear TOCSY segment of the experiment. The proton magnetization ultimately acquired provides homonuclear correlated spin systems sorted by the chemical shift of the directly bound carbon(s) in question.

In cases in which just a select coupling or correlation is needed from a spectrum to complete an assignment or structure determination, a complete 2D analysis may not be required. There are 1D analogs of 2D NMR experiments which can provide the specific information in a more time-efficient manner than performing a full 2D NMR analysis. Examples of 1D analogs for NOESY and heteronuclear correlation experiment (HETCOR) experiments are described that use field gradients to select the resonance of interest.

The chapter concludes with a discussion of NMR sensitivity using probes designed for small samples. 2D NMR data are presented for a submicro inverse-detection gradient (SMIDG) probe that demonstrate the current performance (10s of micrograms) for sample limited NMR analysis. The future in the area of small sample NMR studies is in the development of cold metal NMR probes, that is, cryogenic probes, which have the potential to reduce analysis time by nearly one order of magnitude. A COSY spectrum on a 2.9 μg sample of Taxol and an HSQC spectrum of the aliphatic region of strychnine (40 μg), recorded in 45 min and <2 h, respectively, illustrate the state of the art in sensitivity using cryogenic probe technology.

A short description of DOSY and how NMR can be used to determine diffusion constants with the aid of pulsed field gradients is presented next.

For the structural analysis of molecules residual dipolar couplings have proved to be a powerful tool. Its determination and usage in gaining structural information makes up the last part of this chapter.

Chapter 9 the authors briefly introduce the concept of magic angle spinning and its ability to produce high resolution NMR spectra from suspensions and emulsions.

Chapter 10 by Lyndon Emsley and Steven Brown (EcoleNormaleSupériere de Lyon) begins with sketches of the major interactions that lead to spectral broadening in the solid state. The motionally averaged spectrum observed in solution NMR is replaced in the solid phase with a more complex spectrum reflecting the tensor character of the CSA, dipolar coupling (D), and quadrupolar coupling (C_q). Each of these anisotropic interactions can broaden the NMR resonance beyond the normal limits of the isotropic chemical shift distribution. This, in and of itself, does not prevent analysis of the spectrum. The theoretical description of the spectrum is well known for each interaction and the appropriate parameters can be extracted, in principle, by fitting the experimental and calculated spectrum. However, this method fails for materials where many resonances overlap.

In typical applications, say of organic solids by ^{13}C NMR, microcrystalline solids or amorphous samples are studied in which all orientations of molecules are present. Each ^{13}C in a molecule is represented by a distribution of resonances, a powder pattern, which reflects the orientation dependence of the chemical shift and ^{1}H$-$^{13}C dipolar interactions. The experimental spectrum is the sum of powder patterns from all the resonances in the spectrum, and as such usually presents a nearly featureless and uninterpretable solid state NMR spectrum. The authors present the principal line narrowing method used in solid state NMR, namely, magic angle spinning (MAS), in which the sample is mechanically spun along a unique axis, inclined at angle $\theta = 54.74^\circ$ with respect to the static field axis. This coherent motion narrows the orientation dependent CSA and D interactions by the factor $(1 - 3\cos^2\theta)$. At the magic angle, the chemical shift tensor reduces to the isotropic chemical shift and the dipolar interaction vanishes, yielding a high-resolution spectrum. In practice, the sample cannot be spun fast enough using current technology to completely remove the broadening from dipolar interactions. MAS is used in concert with high power decoupling (dipolar decoupling) to eliminate the dipolar broadening.

Having demonstrated the achievement of high-resolution solid state NMR capability, the authors describe experiments that combine the high-resolution aspect of MAS NMR with methods that retain the structure and/or dynamic information inherent in the anisotropic interactions. Rotational-echo double resonance (REDOR) allows the determination of D between isolated heteronuclear spin pairs. D is related simply and without approximation to internuclear separation. Hence, REDOR makes possible the unambiguous direct determination of internuclear distance between the labeled spin pair, independent of pair orientation, that is, in *amorphous* and/or *microcrystalline* solids, and extends our ability to quantitatively explore complex materials. It is also possible to extract internuclear distance from homonuclear dipolar coupled spin pairs, and these experiments are also reviewed.

As in solution state NMR, the extension of experiments into two or more dimensions is the path used to gain the resolution required to measure multiple, large anisotropic interactions (dipolar coupling, CSA) that are accessible in solids. Experiments that focus on homonuclear multi-dimensional experiments include J-mediated ^{13}C$-$^{13}C correlation and dipolar-mediated ^{1}H 2D double quantum (DQ) MAS spectroscopy. The authors give an example of the state of the art in solid state ^{1}H NMR line narrowing experiments using combined rotation and multiple pulse decoupling (CRAMPS), and indicate that the newest variants of this experiment have yielded line widths as low as 60 Hz for the aliphatic protons resonances of the amino acid L-alanine.

The correlations of anisotropic and isotropic interactions in 2D NMR are illustrated with experiments that measure the CSA of spin 1/2 nuclei. Results using the elegant magic angle turning (MAT) experiment are illustrated for the monoterpene verbenol that show the determination of the CSA tensor quantities for all carbons in this polymorphic substance. The usefulness of 2D NMR methods for characterizing chemical exchange processes is illustrated using static ^{2}H NMR and MAS ^{13}C NMR. In contrast to the rotor synchronized ^{1}H$-$^{1}H double quantum magic angle spinning (DQ-MAS) experiment referred to above, this experiment can also be performed using a large spectral width in the isotropic dimension, reintroducing the spinning sideband patterns in the spectrum. From their intensities, it is possible to calculate D directly and, hence, inter-proton distances. The applications of this experiment and others allow the measurement of proton–heteroatom distances position NMR as a powerful method to quantitatively study hydrogen bonding.

The focus of the chapter then shifts to heteronuclear 2D correlation (HETCOR) experiments. The evolution of single quantum coherence (SQC) of two different nuclei in these experiments with a coherence transfer step provides the basic formula for these correlations. In ^{1}H$-$^{13}C wide line separation (WISE), a wide dipolar broadened ^{1}H resonance is correlated with narrow ^{13}C resonances in the isotropic ^{13}C dimension. These experiments are used to distinguish rigid and mobile components of mixtures as the width of the ^{1}H dipolar coupling in the ^{1}H dimension is partially averaged by molecular motion. ^{1}H$-$^{13}C correlation with high resolution in both dimensions is useful for establishing one bond correlations using the dipolar coupling. In contrast to using D, experiments that use the isotropic J-coupling for the coherence transfer are complementary signal assignment methods that only detect intra-molecular contributions to the correlations.

Experiments that allow the measurement of multiple heteronuclear dipolar couplings in a single experiment and, hence, the simultaneous measurement of multiple internuclear distances, are reviewed. Variations of these experiments are also reported that allow the determination of bond angles, for example, the H–N–H bond angle in the NH_2 group, and torsion angles in fragments like $H^{N}-N-C^{\alpha}-H^{\alpha}$. The application of heteronuclear 2D correlation experiments using ^{15}N chemical shift and ^{15}N$-$^{1}H dipolar coupling in oriented samples, that is, uniformly ^{15}N-labeled membrane proteins in an oriented lipid bilayer, allows the determination of the tilt angle of a polypeptide helix with respect to the bilayer normal.

This chapter concludes with a section on measuring spectra of half-integer quadrupolar nuclei. For such nuclei, the central transition, $m_{\mathrm{I}} = +1/2 > \leftrightarrow m_{\mathrm{I}} = -1/2>$, is not broadened by the quadrupolar coupling to first order, and is observable. The resonance is broadened to second order by a fourth rank tensor contribution that is not removed by MAS. This broadening often confuses the recognition of chemically or crystallographically distinct sites. Mechanical methods to eliminate this broadening, that is, dynamic-angle spinning (DAS) and double rotation (DOR) are summarized. The 2D multiple quantum magic angle spinning (MQ/MAS) technique is an echo experiment that refocuses the second order quadrupolar broadening and yields 2D spectra from which both quadrupolar and chemical shift parameters can be extracted. The MQ/MAS experiment extends the effective domain of solid state NMR to dozens of half-integer quadrupolar nuclei using conventional MAS technology. This robust experiment has already proven itself capable of providing new insight into many inorganic systems.

It is an understatement to say that the manipulation of nuclear magnetization in physical and spin space described in the three chapters of this section on NMR constitutes one of the most powerful spectroscopic approaches to the study of matter in solution and solid phases. NMR continues to evolve in delightful ways that keeps this spectroscopy fresh and applicable in solving structure and dynamics problems in complex materials.

7
An Introduction to Solution, Solid-State, and Imaging NMR Spectroscopy

Leslie G. Butler

7.1
Introduction

Nuclear magnetic resonance (NMR) is a flexible technique with many applications [1, 2]. For substances dissolved in solution, NMR observation of ^{1}H, ^{13}C, ^{15}N, and ^{31}P yields structures of organic molecules, organometallic complexes, proteins, and nucleic acid oligomers. For solid materials, ^{2}H and ^{13}C NMR yields polymer structure, ^{27}Al and ^{29}Si NMR spectra yield zeolite and cement structures, and ^{17}O and $^{63/65}$Cu NMR yield properties of high-T_c superconductors. For solids containing fluid inclusions, ^{1}H NMR yields porosity and diffusivity information, even from thousands of meters below ground with *in situ* NMR instruments lowered through boreholes into petroleum formations. NMR is a fast, sensitive measure of magnetic fields; based on this, airborne NMR was used to detect submarines, and satellite-mounted NMR mapped the Earth's magnetic field. Adding a magnetic field gradient yields an imaging experiment: ^{1}H and ^{31}P magnetic resonance imaging (MRI) provide three-dimensional views of the human body, even showing specific brain activity. Even our breathing can be visualized with ^{129}Xe MRI.

In synthetic organic and organometallic chemistry, solution-state NMR means a 300–500 MHz NMR spectrometer, high-precision glass sample tubes, 2 ml of deuterated solvent (typically fully deuterated chloroform, acetone, benzene, or dichlorobenzene), several milligrams of pure sample, and a basic suite of ^{1}H and ^{13}C NMR experiments [3–7]. With several hours of spectrometer time and data interpretation, the structures of new compounds with molecular weights up to 2000 Da can be determined, especially when analyzed along with results from NMR databases and mass spectroscopy.

The structure of a protein in solution usually compares well with a crystallographic determination. However, not all proteins crystallize, and crystals of membrane-bound proteins are especially rare. Hence, the 600–950 MHz and newly constructed 1000 MHz NMR spectrometers are largely allocated for biological samples [8, 9]. Although most proteins are studied in solution, membrane-bound proteins may be studied in assembled bilayers. Currently, the greater part of NMR

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

technology research and development efforts is directed toward new techniques in biological NMR, especially magnet development and software for data analysis.

In material science applications, solid-state NMR often employs a 200–750 MHz NMR spectrometer (Table 7.1) with a wide-bore magnet and high-power radio frequency (RF) amplifiers and matching NMR probes [10–12]. This equipment is especially useful for analysis of polymer structures with ^{2}H and ^{13}C NMR and for analysis of zeolites with ^{27}Al and ^{29}Si NMR. In polymers, local dynamics can be studied with time scales ranging from seconds to picoseconds; phase separations can be studied with domain sizes from nanometers to micrometers. For zeolites, the structures are characterized in terms of silicon/aluminum ratios, aluminum–hydrogen distances, and the chemistry of catalytic sites.

Why is NMR so widely used? In brief, NMR gives detailed information on selected nuclei, information about the chemical bonding, the local electronic structure, and the local site dynamics. For example, in protein NMR, each of the 20 amino acids has a distinctive set of resonances. Also, these resonances shift slightly with a twist of the amide bond, and other interactions yield the distance between one amino acid and its neighbors, provided that the distance is less than about 8 Å.

What makes NMR such a unique analytical technique? NMR uses the very weak interaction between a nucleus and the rest of the universe. The interaction between the magnetic moment of a nucleus and the RF field of an NMR pulse/receiver circuit is extremely weak: of the order hundreds of megahertz versus several electronvolts for optical spectroscopy (500 MHz corresponds to about 2 μeV). At first glance, this seems to be an enormous disadvantage as, for an equivalent sample mass, NMR has a much lower signal-to-noise ratio relative to many other spectroscopic techniques. However, the weak interaction also yields extremely high resolution. The weak interaction isolates the nucleus from external perturbation for long periods; relaxation times of the order of seconds are common and, conversely, line widths can be <1 Hz. Small changes to the environment at an NMR-active nucleus can be detected and identified. Most other analytical techniques are burdened with broad line widths.

How sensitive is an NMR resonance to the environment at the nucleus? Consider these observations:

Table 7.1 NMR spectrometers and applications.

^{1}H resonance (MHz)	Magnet	Applications
600–1000	Narrow-bore superconducting	Biological NMR
100–500	Narrow-bore superconducting	Organic chemistry
200–750	Wide-bore superconducting	Materials science
40–100	Benchtop permanent magnet	Quality control
40	1 m open-access permanent magnet	Whole body imaging
200	1 m bore superconducting	Whole body imaging and spectroscopy
About 50	Permanent magnet fringe field	Borehole logging

- In a material such as diamond, the NMR signal can be saturated, and it will be nearly a day before the signal is regained; the spin–lattice relaxation time for ^{13}C in diamond is hours as the rare (1.08 atom%) ^{13}C nuclei in diamond individually have weak interactions with the rest of the universe.
- Following pulse excitation, a coherent signal can typically be observed for 10–100 ms (solid) and 1–10 s (liquid samples). The natural line widths are roughly the inverse of these decay times.
- NMR spectroscopy of organic molecules relies on shifts and couplings between nuclei separated by several chemical bonds. The couplings between nuclei separated by two and three chemical bonds is especially important in protein NMR, even though the coupling is 10 Hz or less.

NMR theory is extensive: a working knowledge for materials science applications requires an understanding of these models and concepts:

- The rotating frame is used for simple descriptions of spin–lattice (T_1) and spin–spin (T_2) relaxation and some basic pulse sequences.
- Time-independent quantum mechanics gives transition frequencies and intensities for static systems (solids) or systems in the fast motion limit (solutions) subject to J-coupling, chemical shift, and quadrupolar coupling interactions.
- Motional averaging, for example, a two-site exchange, will affect both solution and solid-state spectra.
- Time-dependent quantum mechanics can be used to describe the spin system evolution in multiple pulse experiments.

In this short introduction to NMR spectroscopy, a discussion of important NMR parameters will be presented through experiments that cover solution-state ^{1}H NMR, solid-state NMR, and MRI.

7.2
Solution-State ^{1}H NMR

Consider the molecule in 1-chloroethene (vinyl chloride), $ClCHCH_2$, a carcinogenic gas (*http://toxnet.nlm.nih.gov/*) and a precursor for polyvinylchloride. If we study the most common isotopomer, all hydrogens are ^{1}H (nuclear spin (I) = 1/2), both carbons are ^{12}C ($I = 0$), and the chlorine is either ^{35}Cl or ^{37}Cl (both $I = 3/2$).

1-Chloroethene will dissolve in chloroform; thus, the solvent of choice is deuterated chloroform, $CDCl_3$, commonly available in solution-state NMR labs. The typical NMR tube is a thin-walled glass tube and too likely to break to risk a hazardous, volatile sample. A better choice is a thick-walled NMR tube sealed with an attached O-ring valve; flame sealing is sometimes used. As detailed toxicological studies often use isotopic labels to follow the metabolic pathways of a toxin, let us note in the following discussion the ability of NMR to monitor the position of a label, either ^{2}H or ^{13}C, in the 1-chloroethene molecule. In the following discussion, it should become obvious that NMR is an effective method for deducing subtle details of molecular structure and has distinct advantages over mass spectrometry or vibrational spectroscopy.

A typical solution-state ^{1}H NMR spectrum of 1-chloroethene is shown in Figure 7.1. We are first shocked by 11 peaks as we expected only three, one for each hydrogen. The physicist Murray Gell-Mann said at the discovery of the subatomic particle, the quark, ''Who ordered this?'' In general, spectroscopy should yield sufficient, but not overwhelming, information. Here, we will examine the 1-chloroethene spectrum and learn for ourselves if the 11 peaks are overwhelming or just what we might have ordered. A few general questions:

- Can chemical structure be used to predict the spectrum? Conversely, can the spectrum be used to predict the chemical structure?
- Can the spectrum be generated from a few parameters?
- Experimentally, can the adjustment of a few parameters modify the spectrum in a predictable manner?
- Do experimental procedures exist to simplify the spectrum?
- How does the spectrum change with deuteration or ^{13}C labeling?
- How does the spectrum change with chemical modification, for example, fluorine for chlorine?

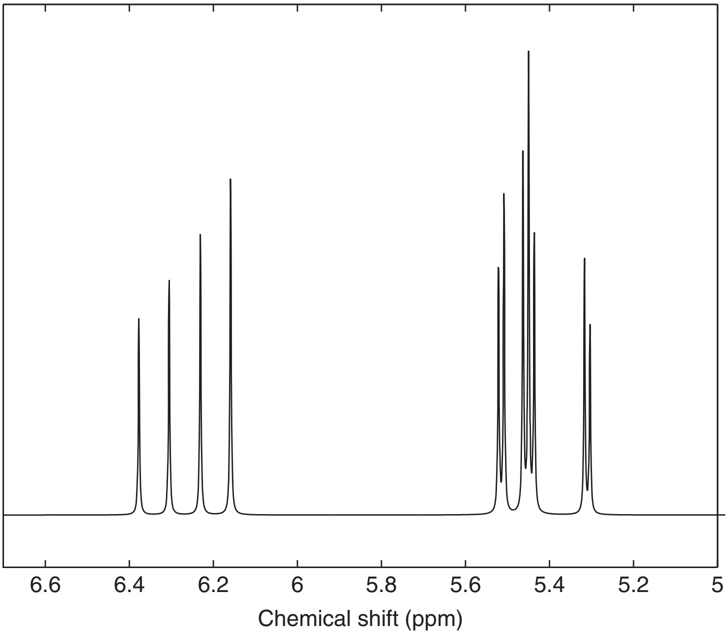

Figure 7.1 Solution-state ^{1}H NMR spectrum (simulated) of 1-chloroethene for $B_0 = 2.3488$ T, $\nu_{RF} = (1-6 \times 10^{-6}) \times 100$ MHz, $T_2 = 1$ s, spectral width = 300 Hz (digitization rate = 3.33 ms per complex data point) and 212 complex data points. At this resolution, 11 distinct peaks are observed.

The parameters that determine the 1-chloroethene spectrum are magnetic field (B_0), detection frequency (ν_{RF}), nuclear spin, gyromagnetic ratio, chemical shift, and J-coupling constants.

Briefly, a ^{1}H nucleus in a magnetic field of 2.3488 T will typically resonate within 1 kHz of 100 MHz. Because of the response of the molecule's core and valence electrons to the magnetic field, the actual field at the nucleus will be slightly different, that is, it will be "shifted" from 2.3488 T, hence the label "chemical shift," with the symbol δ and in units of parts per million. Based on the asymmetric structure of 1-chloroethene, all three hydrogens will have slightly different chemical shifts, as shown in Figure 7.2. For example, in 1-chloroethene, H_a has a chemical shift of 6.26 ppm, while for the analogous vinyl fluoride, the shift for the H_a is reduced to 6.17 ppm. On the basis of years of experience with NMR spectroscopy, chemical shift databases are available for ^{1}H, ^{13}C, ^{15}N, ^{29}Si, ^{19}F, and most other $I = 1/2$ nuclei. In many cases, approximate correlations are noted between chemical bonds, such as carbon–carbon single, double, and triple bonds; the electronegativity of substituents, such as F, Cl, and NO_3; and other molecular features in organic and organometallic compounds. In practice, a synthetic chemist or structural biochemist may become a walking database of ^{1}H, ^{13}C, and ^{15}N chemical shifts. The definition of chemical shift is

$$\delta = \frac{\nu - \nu_{\text{reference}}}{\nu_{\text{reference}}} \times 10^6 \text{ ppm} \tag{7.1}$$

where ν is the observed NMR frequency and $\nu_{\text{reference}}$ is the frequency at which a reference molecule has $\delta = 0$ ppm in that magnetic field.

The J-coupling constants describe short-range, through-bond (as opposed to through-space) interactions that connect the spins of neighboring nuclei. An immensely positive result is connectivity information. A minor negative result is a visually complicated spectrum. However, there are experimental methods that simplify the spectrum: one method is to increase the magnetic field from 2.3488 T by a factor of 4 or 8, as will be discussed shortly.

The solution-state ^{1}H NMR spectrum of 1-chloroethene (Figure 7.1) is easily described by time-independent quantum mechanics using an uncoupled basis set

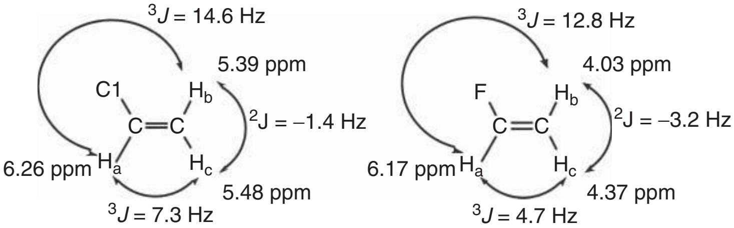

Figure 7.2 ^{1}H NMR parameters, chemical shifts, and J-coupling constants, for 1-chloroethene and 1-fluoroethene.

of spin functions. The total Hamiltonian is

$$\begin{aligned} H_{\text{total}}(\text{Hz}) = & -\frac{\gamma_{\text{H}} B_0}{2\pi}(1+\delta_{\text{A}})S_{z\text{A}} - \frac{\gamma_{\text{H}} B_0}{2\pi}(1+\delta_{\text{B}})S_{z\text{B}} - \frac{\gamma_{\text{H}} B_0}{2\pi}(1+\delta_{\text{c}})S_{z\text{C}} + \cdots \\ & J_{\text{AB}}[S_{x\text{A}} \times S_{x\text{B}} + S_{y\text{A}} \times S_{y\text{B}} + S_{z\text{A}} \times S_{z\text{B}}] + \cdots \\ & J_{\text{AC}}[S_{x\text{A}} \times S_{x\text{C}} + S_{y\text{A}} \times S_{y\text{C}} + S_{z\text{A}} \times S_{z\text{C}}] + \cdots \\ & J_{\text{BC}}[S_{x\text{B}} \times S_{x\text{C}} + S_{y\text{B}} \times S_{y\text{C}} + S_{z\text{B}} \times S_{z\text{C}}] \end{aligned} \tag{7.2}$$

where γ_{H} is the gyromagnetic ratio for hydrogen, B_0 is the applied magnetic field, and $S_{z\text{A}}$, and so on, are the spin functions for $I = 1/2$. The chemical shifts and J-coupling constants are as defined in the line structure above. Evaluation of Eq. (7.2) in matrix form yields an 8×8 matrix in bracket notation:

$$\langle \Psi | H_{\text{total}} | \Psi \rangle = \begin{pmatrix} -150\,000\,851 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & -50\,000\,306 & -0.7 & 0 & 3.65 & 0 & 0 & 0 \\ 0 & -0.7 & -50\,000\,319 & 0 & 7.3 & 0 & 0 & 0 \\ 0 & 0 & 0 & 50\,000\,225 & 0 & 7.3 & 3.65 & 0 \\ 0 & 3.65 & 7.3 & 0 & -50\,000\,236 & 0 & 0 & 0 \\ 0 & 0 & 0 & 7.3 & 0 & 50\,000\,316 & -0.7 & 0 \\ 0 & 0 & 0 & 3.65 & 0 & -0.7 & 50\,000\,311 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 150\,000\,862 \end{pmatrix}_{\text{Hz}} \tag{7.3}$$

The off-diagonal elements from the J-coupling interaction are small and scarcely perturb the energy levels defined by the chemical shift and Zeeman interaction. On the other hand, the experimental resolution is frequently better than 1 Hz, so even small interactions can be observed. The allowed transitions are single quantum; for example, spin H_A will absorb a single quantum of energy near 100 MHz while H_B and H_C stay in one of four possible quantum configurations. Diagonalization of Eq. (7) yields the energy levels; the unitary matrix that performs the matrix diagonalization yields the relative transition probabilities. Listed in Table 7.2 are the 12 allowed transitions.

Of the 12 transitions listed, two are overlapping at the resolution of the spectrum shown in Figure 7.1. The peaks have Lorenztian lineshapes. The full width at half of the maximum peak height (full width at half maximum, FWHM) is given by

$$\Delta\nu = 1/\pi T_2 \tag{7.4}$$

In Figure 7.1, T_2 is set at 1 s, hence the peak widths are 0.3 Hz.

In Figure 7.1, four peaks appear at frequencies just slightly greater than the detection frequency ($\nu_{\text{RF}} = 100\,\text{MHz} + 6\,\text{ppm} = (1 + 6 \times 10^{-6}) \times 100\,\text{MHz}$) and seven resolved peaks occur at lower frequencies. The NMR parameters, chemical shifts, and J-coupling constants, are given in Figure 7.2 and cannot be determined precisely by inspection of the spectrum in Figure 7.1. Basically, the spectrum in Figure 7.1 is difficult to interpret because the off-diagonal elements (Eq. (7.3)) are large with respect to the differences between diagonal elements. As we can increase B_0, which then increases the magnitude of the diagonal elements, spectra acquired at higher magnetic field will show a closer, more obvious relationship with the NMR

Table 7.2 Calculated ^{1}H NMR transitions for 1-chloroethene at $B_0 = 2.3488$ T.

[b] Transition dominated by spin function at this site.

parameters such as chemical shifts and *J*-coupling constants. The NMR spectra of 1-chloroethene at increasing magnetic fields is shown in Figure 7.3.

Here, the linear dependence of the diagonal components of H_{total}, terms such as $-\gamma B_0(1 + \delta_A)S_{zA}$, causes the increased dispersion of peaks at higher magnetic fields. To observe the subtle effects of the *J*-coupling constants, it is convenient to replot the spectra on the chemical shift scale, Eq. (7.1), as shown in Figure 7.4.

When solution-state NMR spectra are plotted on a chemical shift scale, the center-of-mass of a group of peaks defines the chemical shift for that nucleus, provided that the field is large enough to diminish the effect of the off-diagonal *J*-coupling terms. We can see above that good estimates of $\delta(H_A)$ can be read from the plots at all magnetic fields but that values for $\delta(H_B)$ and $\delta(H_C)$ require a 400 MHz or larger NMR spectrometer. Thus, increasing the magnetic field is one experimental method for simplifying the NMR spectrum.

In addition to magnetic field, the two other experimental methods frequently used for spectral simplification and/or modification are selective decoupling and chemical modification. Selective decoupling can be done in a variety of ways; one method is the application of low power RF over a narrow frequency range during the time of NMR signal acquisition. Within a selected, narrow frequency range, low power RF causes the nuclei to undergo rapid absorption and stimulated emission. In simple terms, a nucleus, such as H_B, will flip rapidly between spin up and spin down states. If the flip-rate is fast enough, the *J*-coupling terms involving nucleus H_B in Eq. (7.2) average to zero; the NMR jargon is H_B is "decoupled" from the other spins. The effect of H_B decoupling is shown in Figure 7.5b. Compared to the original 200 MHz spectrum for 1-chloroethene (Figure 7.5a), the decoupled spectrum is quite simple, a four-line pattern that clearly shows two hydrogens with

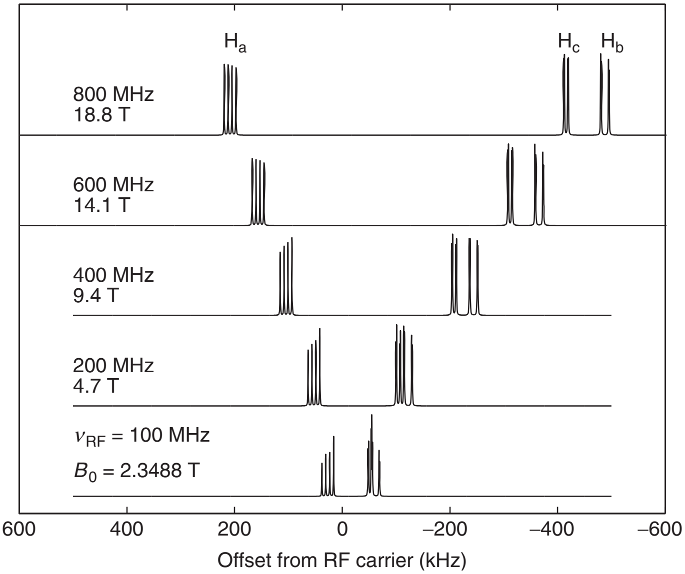

Figure 7.3 Solution-state ^{1}H NMR spectrum of 1-chloroethene, plotted on the frequency scale. For each spectrum, the RF carrier, ν_{RF}, is set to $(1 + 6 \times 10^{-6}) \times 100$ MHz, 200 MHz, and so on.

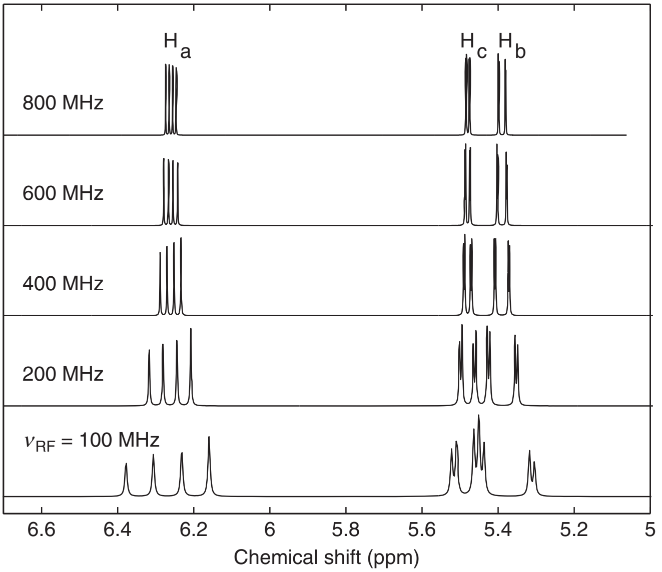

Figure 7.4 Solution-state ^{1}H NMR spectrum of 1-chloroethene, plotted on the chemical shift scale. Here, the zero, 0 ppm, is set by $\nu_{\text{reference}}$, the frequency at which hydrogens of a chemical shift standard are resonant at B_0.

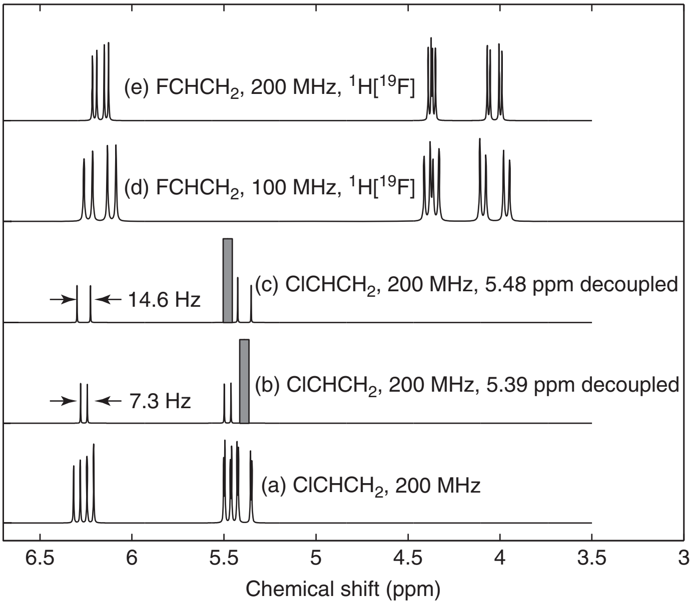

Figure 7.5 (a–e) Solution-state ^{1}H NMR spectrum of 1-chloroethene and 1-fluoroethene. The results of selective homonuclear decoupling are shown in (b,c). The results of heteronuclear decoupling are shown in (d,e). Not shown is the simple, ^{19}F coupled ^{1}H NMR spectrum (or the double negative "^{19}F undecoupled") of 1-fluoroethene, which has twice as many ^{1}H transitions as shown in (d,e) (each line is then a doublet from $^nJ(^1H-^{19}F)$, $n = 2, 3$).

chemical shifts of 6.26 and 5.48 ppm and a J-coupling of 1.3 Hz. Similarly, the decoupling of H_C yields another four-line pattern (Figure 7.5c) showing resonances centered at 6.26 and 5.39 ppm, and a J-coupling of 14.6 Hz.

To explore the relationship between structure and NMR parameters, a series of similar molecules should be studied. Shown in Figure 7.5d,e is 100 and 200 MHz ^{1}H NMR spectra for the analogous 1-fluoroethene. To suppress the effect of $J(^1H-^{19}F)$ coupling, this spectrum is shown as acquired with ^{19}F decoupling. That is, during the experiment, RF power is applied to all ^{19}F resonances. In NMR nomenclature, $^1H\{^{19}F\}$ means ^{1}H observation with ^{19}F decoupling.

A few more details about the ^{1}H NMR spectrum of 1-chloroethene are worthy of discussion. First, the J-coupling from ^{35,37}Cl is averaged to zero because, in solution, the chlorine nucleus has a very short T_1; in effect, the ^{35,37}Cl nuclei are self-decoupled from the hydrogen spins. Second, selective deuteration of 1-chloroethene will yield spectra very similar to Figure 7.5b,c for deuteration at the B and C sites, respectively. The values of $J(^1H-^2H)$ are about one-sixth (=15.351/100 MHz) of the $J(^1H-^1H)$ values shown in Figure 7.2 and the $I = 1$ ^{2}H nucleus creates triplets instead of doublets. The net results are slightly line-broadened versions of the spectra shown in Figure 7.5b,c. Third, ^{13}C labeling at one site will add coupling with the $I = 1/2$ ^{13}C nucleus to the ^{1}H spectrum.

The one-bond coupling, $^1J(^1\text{H}-^{13}\text{C})$, is about 150 Hz and the two-bond coupling, $^2J(^1\text{H}-^{13}\text{C})$, is about 10 Hz. So, the ^{13}C-labeled site will cause a great change, due to $^1J(^1\text{H}-^{13}\text{C})$ coupling, in either the H_A resonances or in both H_B and H_C resonances, depending on which carbon site is labeled.

Almost all NMR spectra are acquired with pulse methods. The ^{1}H NMR spin system is excited with a short duration RF pulse, and the response of the spin system is measured, both the in-phase and out-of-phase components. Based on the terminology of complex numbers, these two components are referred to as the *real and imaginary components*. This NMR signal is called the free-induction decay, FID, a name which harks back to a classical viewpoint of a freely moving magnet precessing within a solenoidal coil, thus inducing a current. In fact, a current is measured in the NMR probe, which is often a coil of wire, and then digitized. When the raw data is viewed, it shows an exponentially decaying set of sinusoidal signals. Figure 7.6 shows the FID for 1-chloroethene, acquired under the conditions leading to the spectrum shown in Figure 7.1.

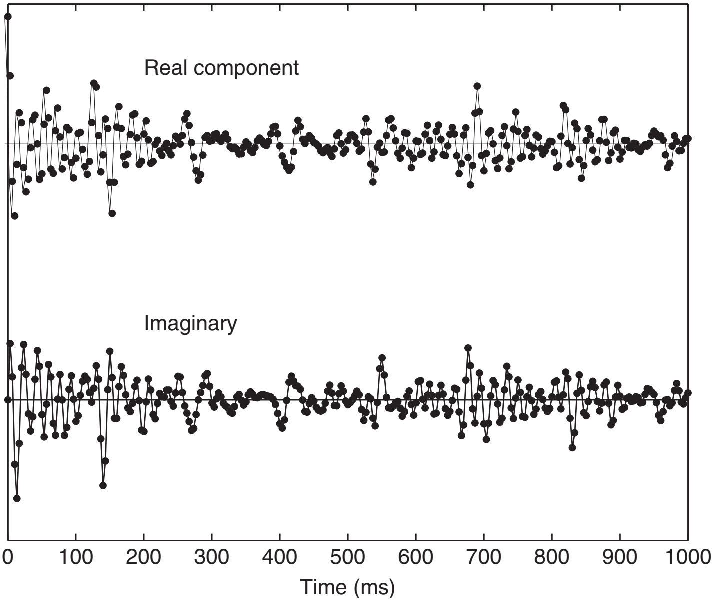

Figure 7.6 The first 1000 ms of the FID corresponding to the spectrum shown in Figure 7.1. The digitization interval is 3.33 ms per complex data point, yielding a spectral width of 300 Hz, an unusually small spectral window. At 9.4 T, ^{1}H NMR is usually done with a 10 kHz spectral window, ^{13}C with 25–50 kHz, and solid-state ^{2}H with 1 MHz (and a corresponding 1 μs digitization rate). While $\nu_{\text{reference}}$ is fixed by the nucleus and the magnetic field, ν_{RF} is adjustable, and usually set near the middle of the peaks of interest. The absolute values of the vertical scale are not used except to note whether or not the first data point is "clipped" by the NMR receiver system; clipping leads to unacceptable spectral distortion.

The data processing usually involves four user-intervention steps: (i) applying a smoothing function to the FID, (ii) Fourier transformation, (iii) phasing the frequency domain data into pure real and imaginary components, and (iv) setting the 0 ppm point for the chemical shift axis. A common smoothing function is a Lorentzian line-broadening function, equivalent to point by point multiplication of the FID by an exponentially damped function. Phasing removes linear changes in phase within the spectrum, producing uniform absorption line shapes for all signals.

To summarize, solution NMR spectra of small organic, organometallic, and biological materials show well-resolved ^{1}H NMR spectra. The two major interactions affecting the spectra are chemical shift and *J*-coupling; extensive databases of interactions aid the identification of the molecule and the assignment of the spectrum. Both low and high magnetic fields are functional, though there is a preference for higher fields that yield greater resolution between peaks and spectra which are easier to interpret.

7.3
Solid-State NMR

Consider hypothetical studies of the orientations and dynamics of a self-assembled monolayer (SAM) of organic thiols chemisorbed on a gold surface. Aside from the chemical information that comes from chemical shifts and *J*-coupling, NMR can also provide orientation information for selected sites within a molecule. Consider a related series of organic thiols and their ^{13}C, ^{2}H, and ^{1}H NMR spectra. The alkyne thiol derivatives shown in Figure 7.7 will be used to demonstrate how to obtain orientation and dynamic information. We will first consider static samples, then samples in which the molecule is executing one of several modes of motion. For static samples, we seek information about the angle between the magnetic

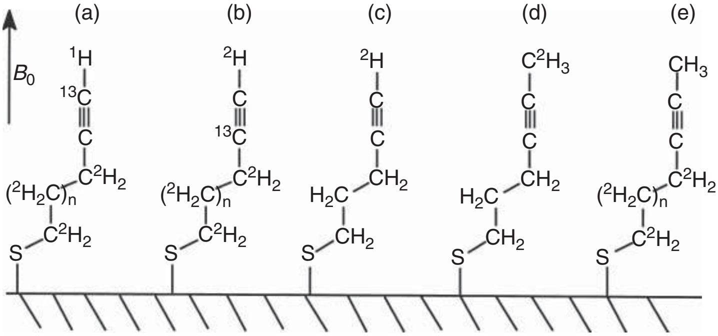

Figure 7.7 Alkyne thiol derivatives illustrating (a) ^{13}C–^{1}H dipolar interaction, (b) ^{13}C chemical shift anisotropy, (c) ^{2}H quadrupolar interaction, (d) dynamics of a deuterated methyl site, and (e) ^{1}H $T_{1\rho}$ relaxation times. Assume a gold-coated glass slide that is uniformly covered with one of these molecules. Because of signal-to-noise considerations, a number of these slides may be stacked together in the NMR sample coil.

field and a labeled portion of the molecule. For molecules that are in motion, we seek the rate of motion, the activation energy, and the mode of motion. The mode of motion can be random, isotropic molecular motion; thermally activated motion about a molecular axis; or rapid motion of the entire sample about a magic angle, a special angle with respect to the magnetic field.

NMR of solids differs from solution-state NMR in several important ways. First, the solution-state ‘‘tumbling’’ of molecules is, of course, restricted in the solid phase. In the absence of rapid isotropic motion, magnetic dipolar interaction between neighboring spins affects the NMR line shape. Second, the chemical shift interaction is not just a simple scalar, but a tensor quantity. In solution-state NMR, only the scalar average is seen, while in solid-state NMR, the tensor elements are observed. In the solid-state, the chemical shift tensor yields a variety of possible NMR line shapes. Likewise, the quadrupolar interaction also creates a variety of line shapes. Third, a single molecular motion can dominate the process of thermal equilibration of the NMR spin system with its environment.

7.3.1
Dipolar Interaction

The alkyne thiol, $\mathrm{R{-}C{\equiv}{}^{13}C{-}{}^{1}H}$, has two neighboring magnetic spins, both aligned with the large magnetic field, B_0. From the viewpoint of the ^{13}C site, the magnetic field is a sum of B_0 and the small magnetic field generated by the ^{1}H nucleus. The magnetic field at ^{13}C varies with the orientation of the ^{13}C–^{1}H unit with respect to B_0 and with the nuclear spin quantum state (m_s) of the ^{1}H site. When the ^{13}C–^{1}H unit is parallel with B_0 ($\theta = 0^\circ$) and $m_s(^{1}\mathrm{H}) = +1/2$, the total magnetic field at ^{13}C is a maximum, yielding an absorption about 24 kHz above the isotropic ^{13}C chemical shift, as shown in Figure 7.8 by the leftmost vertical line to the dashed line. The dashed line represents the subspectrum for all ^{13}C spins dipolar coupled to a ^{1}H in the $m_s = +1/2$ spin state. As the ^{13}C–^{1}H unit is rotated to a perpendicular position, the dipolar magnetic field from ^{1}H ($m_s = +1/2$) decreases until the ^{13}C peak is at -12 kHz (vertical bar to dashed line) relative to the ^{13}C chemical shift. The ^{13}C–^{1}H dipolar interaction is described by

$$H_{\mathrm{dipolar}}(\mathrm{J}) = \left(\frac{\mu_0}{4\pi}\right)\hbar^2\gamma_s\gamma_I\left[\frac{\mathbf{S}\times\mathbf{I}}{r^3} - 3\frac{\mathbf{S}\times\mathbf{r}\mathbf{I}\times\mathbf{r}}{r^5}\right] \tag{7.5}$$

$$\omega[^{13}\mathrm{C}{-}^{1}\mathrm{H}] = \left(\frac{\mu_0}{4\pi}\right)\hbar\frac{\gamma_{^{13}\mathrm{C}}\gamma_{^{1}\mathrm{H}}}{r^3} = (2\pi)(23.6\,\mathrm{kHz}) \quad \{\text{for } r = 108.5\,\mathrm{pm}\} \tag{7.6}$$

The NMR signal amplitude is larger for $\theta = 90^\circ$ than $\theta = 0^\circ$. In a powder, there are many possible orientations of the molecule. For this axially-symmetric ^{13}C–^{1}H unit, one can imagine the range of possible orientations as the Earth with an arrow pointing from the center to the surface. Only one arrow orientation points to the North Pole, but an infinite number of orientations point to the equator (fortunately, the NMR sample has a finite number of molecules). Thus, relatively few ^{13}C–^{1}H

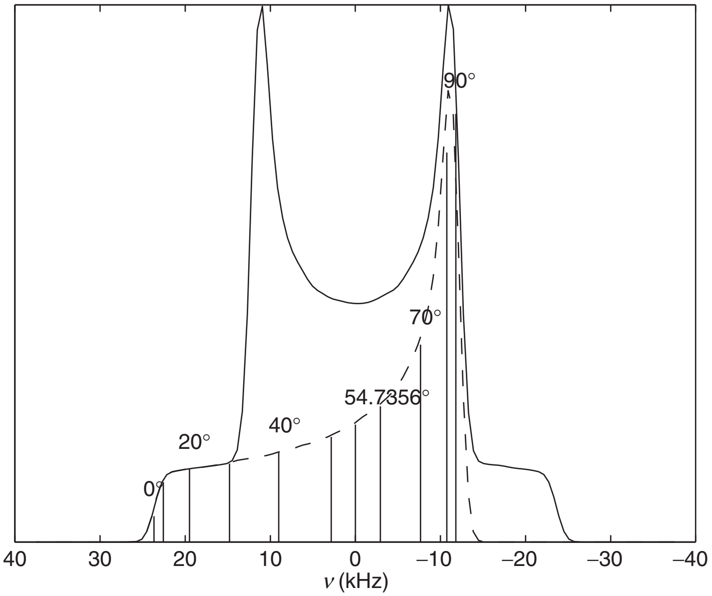

Figure 7.8 Solid-state ^{13}C NMR "powder pattern" line shape for the case of ^{13}C−^{1}H dipolar interaction and an ensemble of randomly oriented ^{13}C−^{1}H units. The frequency axis is centered on the ^{13}C resonance. The upper trace (—) is the observed line shape while the lower trace (— — —) is a subspectrum from ^{13}C sites adjacent to a ^{1}H site in the $m_s = +1/2$ spin state. Not shown is the corresponding subspectrum for ^{1}H $m_s = -1/2$. Vertical bars show the ^{13}C resonance frequency at $\theta = 0°$, $10°$, ..., $90°$, including $\theta = 54.7356°$, an orientation of the ^{13}C−^{1}H unit for which the dipolar interaction is zero.

sites are oriented at $\theta = 0°$ and contribute to the absorption at +24 kHz; many more molecules contribute to the −12 kHz absorption corresponding to the $\theta = 90°$ orientation.

The ^{13}C−^{1}H dipolar powder pattern has features that affect other NMR experiments. First, this is an inhomogeneously broadened line composed of many, narrow but homogenously broadened peaks. Second, the two subspectra generated by $m_s(^{1}H) = \pm 1/2$ are mirror images of each other. Third, powder pattern averages of axially-symmetric units, such as C≡^{13}C−^{1}H, give the characteristic "Pake doublet" [1, 10–12]. The "Pake doublet" is obscured by interactions between three or more spins, hence the deuteration of the methylene chain in molecule A (Figure 7.7). Fourth, the orientation at which the dipolar interaction is zero, $\theta = 54.7356°$, is a critical feature of the "magic angle spinning experiment," to be discussed later.

Finally, ^{13}C NMR of a stack of gold-coated glass slides will likely yield information about the orientation of the R−C≡^{13}C−^{1}H molecules. This experiment is easier at moderate fields than at high fields. If the R−C≡^{13}C−^{1}H molecules are uniformly tilted with respect to the gold-coated glass slide, and the surface is perpendicular to B_0, then a pair of peaks should be seen in the ^{13}C NMR spectrum, one for each spin state of ^{1}H, and the peak separation will yield the tilt angle. The experimental problems are surface roughness, low signal-to-noise ratio because of the small number of ^{13}C spins in the NMR sample volume, and the range of magnetic fields at the ^{13}C nuclei due to the difference between the magnetic susceptibility of gold versus air, especially near the sides of the gold layers. This line-broadening effect increases linearly with the magnetic field strength; thus, the optimum field strength is a field sufficient to obtain a signal.

For simplicity, the spectrum in Figure 7.8 assumes an isotropic ^{13}C chemical shift. As it turns out, all known ^{13}C alkyne sites have highly anisotropic chemical shifts, which are best described by tensors. This is a nice lead-in to a discussion of chemical shift anisotropy.

7.3.2
Chemical Shift Anisotropy

The chemical shift at a nucleus is due to the core and valence electrons near that nucleus. The bonding electrons in the axially-symmetric $-^{13}\mathrm{C}{\equiv}\mathrm{C}$ unit (Figure 7.7b) increase the field at the $\theta = 0^\circ$ orientation, causing the ^{13}C resonance to occur at lower frequency than expected; on the chemical shift scale, the resonance is at -69 ppm. When the $-^{13}\mathrm{C}{\equiv}\mathrm{C}$ unit has the more probable orientation of $\theta = 90^\circ$, the magnetic field is less at ^{13}C than for the chemical shift standard, tetramethylsilane

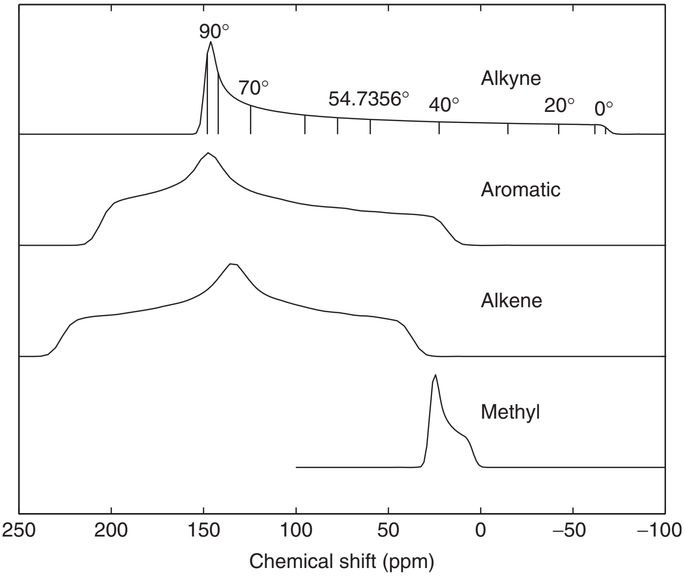

Figure 7.9 Solid-state ^{13}C{^{1}H} NMR "powder pattern" line shape for ^{13}C chemical shift anisotropy and an ensemble of randomly oriented $-^{13}\mathrm{C}{\equiv}\mathrm{C}$ (alkyne) units. Vertical bars show the ^{13}C resonance frequency at $\theta = 0^\circ$, 10°, …, 90°, including $\theta = 54.7356^\circ$, an orientation of the $-^{13}\mathrm{C}{\equiv}\mathrm{C}$ unit for which the peak position corresponds to the isotropic chemical shift observed in solution-state NMR. Also shown are the typical chemical shift anisotropy powder patterns for ^{13}C aromatic, alkene, and methyl sites.

(TMS), yielding a peak near 148 ppm, as shown in Figure 7.9. The chemical shift anisotropy depends upon the bonding at carbon, as can be seen in the other traces in Figure 7.9 which shows the predicted $^{13}C\{^1H\}$ NMR powder pattern line shapes for aromatic, olefinic, and methyl sites. As can be seen, the extraction of molecular orientation from the line shape is particularly straightforward for the alkyne.

The chemical shift anisotropy is usually described in a principal axis system, which is usually not the molecular axis system. In the principal axis system, the chemical shift tensor is diagonal. The elements of this tensor contribute to the NMR spectrum via these two equations:

$$\delta^{\text{lab}} = R^{-1}(\phi,\theta,\psi)\begin{vmatrix} \delta_{xx}^{\text{PAS}} & 0 & 0 \\ 0 & \delta_{yy}^{\text{PAS}} & 0 \\ 0 & 0 & \delta_{zz}^{\text{PAS}} \end{vmatrix} R(\phi,\theta,\psi) \tag{7.7}$$

$$H_{\text{total}}(\text{Hz}) = H_{\text{Zeeman}} + H_{\text{chemical shift}} = -\frac{\gamma B_0}{2\pi}(1+\delta_{zz}^{\text{lab}})S_z \tag{7.8}$$

In summary, orientation of $R{-}^{13}C{\equiv}C{-}^1H$ molecules (Figure 7.7b) chemisorbed on gold surfaces can be obtained from $^{13}C\{^1H\}$ NMR of a stack of gold-coated glass slides. The same issues of signal-to-noise and magnetic susceptibility line-broadening discussed earlier will also apply to the $^{13}C[^1H]$ NMR experiment.

7.3.3
Quadrupolar Interaction

The quadrupolar interaction occurs for nuclei with $I \geq 1$ and tends to align the nucleus with the electric charge distribution near the nucleus. While there are many more $I \geq 1$ nuclei than $I = 1/2$ nuclei, the typical NMR spectrometer is equipped to observe with ease only ^2H ($I = 1$), ^{27}Al (5/2), and maybe ^{17}O (5/2), ^{11}B (3/2), ^7Li (3/2), and ^{23}Na (3/2). Less common are experiments for $^{63,65}Cu$ (both 3/2), ^{91}Zr (5/2), ^{93}Nb (9/2), $^{35,37}Cl$ (3/2), $^{79,81}Br$ (3/2), and ^{127}I (5/2).

In short, the electric charge asymmetry of the nucleus and asymmetry of the charge distribution around the nucleus causes the electric quadrupolar interaction. In electrostatics, magnetic and electric interactions can be described in a progression of moments: monopole, dipole, quadrupole, and so on. For an $I = 1/2$ nucleus such as ^1H, the relevant moments are: a non-zero electric monopole moment (+1 charge), a small magnetic dipole moment, and zero values for nuclear magnetic monopole, nuclear magnetic quadrupole, and nuclear electric dipole moments. As more protons and neutrons are added to the nucleus, the nuclear electric quadrupole moment can become non-zero. In much the same way that the magnetic dipole aligns with a magnetic field, an electric quadrupole moment aligns with the electric field gradient (EFG). The quadrupolar interaction can be small, about 170 kHz for many ^2H sites, to over 1 GHz for some ^{127}I sites. The EFG can be computed from the positions of all charges, both electrons and neighboring nuclei, near the quadrupolar nucleus. In practice, most molecular orbital programs can calculate accurate EFGs for ^2H, ^{14}N, ^{17}O, and other nuclei in medium size molecules such as nitrobenzene. Thus, the observation of quadrupolar spectra and comparison with calculated EFGs can aid investigations of many different structural questions.

The quadrupolar interaction is described by a tensor. The EFG is described with size, shape, and orientation parameters: The size of the EFG tensor is given by the quadrupolar coupling constant in Hertz, variously labeled as C_q, $e^2q_{zz}Q/h$, and QCC (not recommended). The shape of the EFG tensor is given by the asymmetry parameter, η. The EFG tensor has a well-defined orientation with respect to the molecular or crystal structure. For the quadrupolar nucleus, the important nuclear properties are spin and quadrupole moment: $I = 1$, 3/2, 5/2, 3, 7/2, and 9/2 are frequently encountered. The nuclear electric quadrupole moment is given by Q in units of m^2. So, for a given materials science study, one generally selects a nucleus (I, Q), and then measures C_q and η as a function of structure with frequent comparisons to calculated EFG tensors from molecular orbital calculations (C_q, η, orientation). The quadrupolar hamiltonian is

$$H_{\text{quadrupolar}}(\text{Hz}) = \frac{1}{6I(2I-1)} \sum_{\alpha\beta}^{x,y,z}{}' \quad Q_{\alpha\beta}^{\text{lab}} \left[\frac{3}{2} \left(I_\alpha I_\beta + I_\beta I_\alpha - \delta_{\alpha\beta} I^2 \right) \right] \tag{7.9}$$

$$Q^{\text{lab}} = R^{-1}(\phi,\theta,\psi) C_q \begin{vmatrix} \frac{\eta-1}{2} & 0 & 0 \\ 0 & -\frac{\eta-1}{2} & 0 \\ 0 & 0 & 1 \end{vmatrix} R(\phi,\theta,\psi) \tag{7.10}$$

Representative quadrupolar nuclei and some quadrupolar interaction data are listed in Table 7.3. Simulated spectra for several of these sites are shown in Figure 7.10 as if the spectra were acquired on a 9.4 T (400 MHz) NMR spectrometer with a probe having a fantastically wide spectral width. In practice, the α-alumina spectrum can barely be acquired and the andalusite and nitro spectra are essentially unobservable. Even the ^{2}H spectrum can be difficult to acquire without distortion from probe ringdown effects.

The deuterated alkyne thiol, Figure 7.7c, is a relatively easy molecule to prepare at levels of >80% deuteration and, in general, the ^{2}H NMR experiment yields spectra with good signal-to-noise ratios. Thus, it is reasonable to expect a ^{2}H quadrupolar powder pattern NMR spectrum showing a combination of the features of the ^{2}H NMR (Figure 7.10) with the orientational aspects of the Pake doublet (Figure 7.8). If a SAM has high orientational order and an oriented sample is studied (stacks

Table 7.3 Representative C_q and η for ^{2}H in some sites [13].

Site	C_q (kHz)	η
C(sp^3)–^{2}H	170–175	~0
C(aromatic)–^{2}H	180–185	~0.1
C(sp)–^{2}H	200–210	0
O–^{2}H	50–320	0–1
N–^{2}H	50–280	0–1

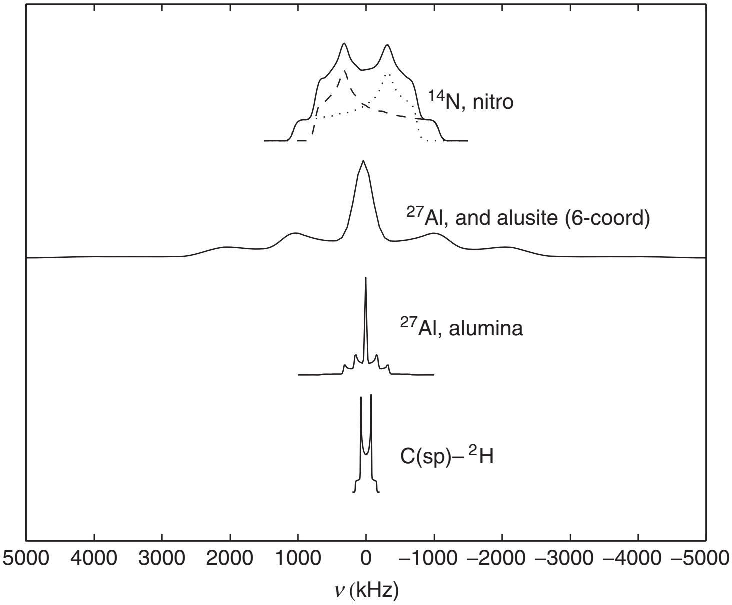

Figure 7.10 Static, solid-state quadrupolar NMR line shapes for some ^{2}H, ^{27}Al, and ^{14}N sites in powder (non-oriented) samples at a field of 9.4 T (400 MHz for ^{1}H). The useful bandwidth of a solid-state NMR spectrometer is typically 1 MHz; thus, spectra cannot be acquired for the andalusite or nitro sites. Also shown for ^{14}N are subspectra making up the total line shape: the transition $|+1\rangle \rightarrow |0\rangle$ yields the subspectrum (— — —) and the transition $|0\rangle \rightarrow |-1\rangle$ yields the subspectrum (. . .).

of glass slides), then the ^{2}H spectrum could show two peaks corresponding to the $|+1\rangle \rightarrow |0\rangle$ and $|0\rangle \rightarrow |-1\rangle$ transitions. The frequency difference between the two peaks would then give the angle between the C–^{2}H bond and B_0 (Figure 7.8). Conversely, a random orientation between the C–^{2}H bonds and B_0 yields a line shape like the Pake doublet (Figures 7.8 and 7.10).

7.3.4
Magic Angle Spinning (MAS) NMR

The quadrupolar powder patterns of Figure 7.10 and the chemical shift powder patterns of Figure 7.9 provide much insight into local chemical structure and dynamics. However, if the sample contains two or more different ^{2}H or ^{13}C sites, say, then overlapping patterns can be difficult to interpret. Therefore, we seek a method which can “turn off” the quadrupolar interaction and the chemical shift tensor effects. A clue is obtained from solution NMR; the line widths are much narrower because the rapid molecular tumbling averages the interactions. For the chemical shift tensor, the average is the isotropic chemical shift, δ_{iso}, as introduced in the solution NMR section. For the quadrupolar interaction, the average is zero. Given a solid sample, the question is how to quickly average the orientation of each nuclear site with respect to B_0, and to do so with a simple instrument modification. A clue comes from the orientations of sites detailed in Figure 7.8 and Figure 7.9. At an orientation of 54.7356°, the dipolar and quadrupolar interactions are zero and the chemical shift tensor average is δ_{iso}.

Magic angle spinning (MAS) NMR of solids consists of rapid rotation of the sample about an axis set at 54.7356° relative to B_0. The rotational velocity should be greater than the static (non-spinning) line width. For ^{13}C and $B_0 = 9.4$ T, typical rotation rates are about 10 kHz, that is, 600 000 rpm. At these high rotation rates, the strength of the sample holder (the rotor) is critical, with zirconia a common material. To further reduce stress, the maximum diameter of the rotor is often reduced to 5 mm or less. The drive mechanism is compressed air, and compressed air is also used for all of the bearing surfaces. Obviously, failure of the bearing air supply is very likely to cause destruction of the zirconia rotor and perhaps the rest of the MAS probe.

When the MAS experiment is applied to $I = 1/2$ nuclei such as ^{13}C, ^{29}Si, and ^{31}P, advantage is taken of the ^{1}H spin system, assuming the sample also contains abundant ^{1}H sites. A pulse sequence incorporating dipolar decoupling and cross polarization is used for two reasons: (i) to reduce the ^{13}C, ^{29}Si, and ^{31}P line width because the MAS rotational rate is usually not fast with respect to dipolar coupling (see Figure 7.8 for an example of ^{1}H–^{13}C dipolar coupling) and (ii) to increase the signal-to-noise ratio. More details and examples of the cross polarization-magic angle spinning (CP/MAS) experiment are given in a following chapter.

When the MAS experiment is applied to quadrupolar nuclei such as ^{27}Al, the quality of the NMR spectrum depends dramatically on the magnitude of C_q compared with both the MAS spin rate and the magnetic field, B_0. Excellent spectra are obtained for small C_q sites when studied with high-speed MAS spin rates at high B_0. Conversely, ^{27}Al sites can be "invisible" for high C_q values and modest MAS spin rates and B_0; note the evolution in line shapes for the ^{27}Al MAS NMR spectra in Figure 7.11. Likewise, the four-coordinate AlO_4 sites in an aluminum isoproxide complex, with $C_q = 12.3$ MHz, are observable at 20 kHz and 19.6 T while three-coordinate aluminum sites in related complexes, with $C_q > 30$ MHz, are not observable [14].

7.3.5
T_1 and $T_{1\rho}$ Relaxation

Whenever we talk about spins aligning with B_0, we know that the spin system must release energy. For the ^{1}H spins in a $-CH_3$ group in a 400 MHz NMR spectrometer, the alignment of each ^{1}H will release a 400 MHz quantum of energy. At 400 MHz, the spontaneous release of energy by photon emission is extremely slow; for comparison, the emission of a visible photon from an excited rhodamine dye molecule is much faster. Instead, at 400 MHz, energy release is stimulated by the motion of neighboring magnetic dipole moments, that is, the three ^{1}H spins in a methyl group contribute to the relaxation of each other, provided the methyl group is moving. In most $R-CH_3$ groups, the methyl group rotates quite

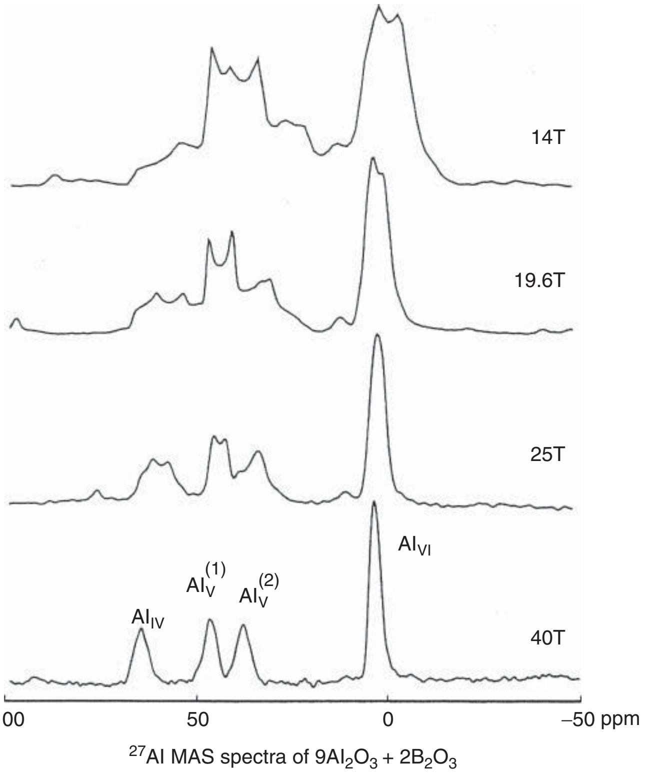

Figure 7.11 ^{27}Al MAS NMR line shapes as a function of magnetic field. The spectra of the ceramic $9Al_2O_3 + 2B_2O_3$ have been acquired with a spin rate of 35 kHz. (Figure courtesy of Dr. Zhehong Gan, National High Magnetic Field Laboratory [15]. Reprinted with permission.)

fast, with rotation rates of the order of gigahertz, and correlation times of the order of picoseconds, at room temperature. At very low temperature, ^{1}H NMR of methyl groups can provide detailed information of motional processes, both classical motion and quantum-mechanical tunneling. In the more common room temperature and -100 to 200 °C experiments, relaxation experiments will probe motions with thermal activation energies of about 5–30 kJ mol^{-1}.

There are many relaxation paths and experiments to measure the relaxation kinetics. Three common relaxation pathways are

- T_1, spin–lattice relaxation. Measures the rate of energy exchange between the spin system and the vibrational and phonon modes of the lattice. Has B_0 dependence.
- T_2, spin–spin relaxation. Measures the loss of coherence of the NMR signal during a FID.
- $T_{1\rho}$, spin–lattice in the rotating frame relaxation. While an on-resonance RF pulse is applied, this parameter is a measure of the rate of energy exchange

between the spin system and the vibrational and phonon modes of the lattice. $T_{1\rho}$ depends upon the magnitude of both B_0 and B_1, where B_1 is the amplitude of the RF pulse.

For common experiments in the solid state, T_1 is critical to determining the length of the experiment. It is possible that raising or lowering the sample temperature can dramatically improve the experimental set-up. Also, in some cases, measurement of T_1 or $T_{1\rho}$ values can yield insight into molecular motion. Shown in Figure 7.12 are idealized T_1 and $T_{1\rho}$ values for three different thermal activation energies. There are several obvious features. The most efficient spin–lattice relaxation, that is, shortest T_1 value, occurs when the correlation time is approximately equal to the inverse of the resonance frequency, $\tau\omega_0 \sim 1$, as listed in Table 7.4. Second, the slopes of the T_1 and $T_{1\rho}$ curves are determined by the activation energy; the plot shows relaxation times for activation energies of 5, 15, and 30 kJ mol^{-1}. Third, when slow frequency motions are suspected, that is, moderate temperatures and high activation energies, then $T_{1\rho}$ experiments at variable B_1 fields are more convenient than switching from magnet to magnet to access T_1 data.

The correlation times shown in Figure 7.13 range from 1 ps to 10 s. The corresponding T_1 and $T_{1\rho}$ values are all accessible given a range of magnets, variable temperature probes, and appropriate RF pulse sequences. Thus, the ability

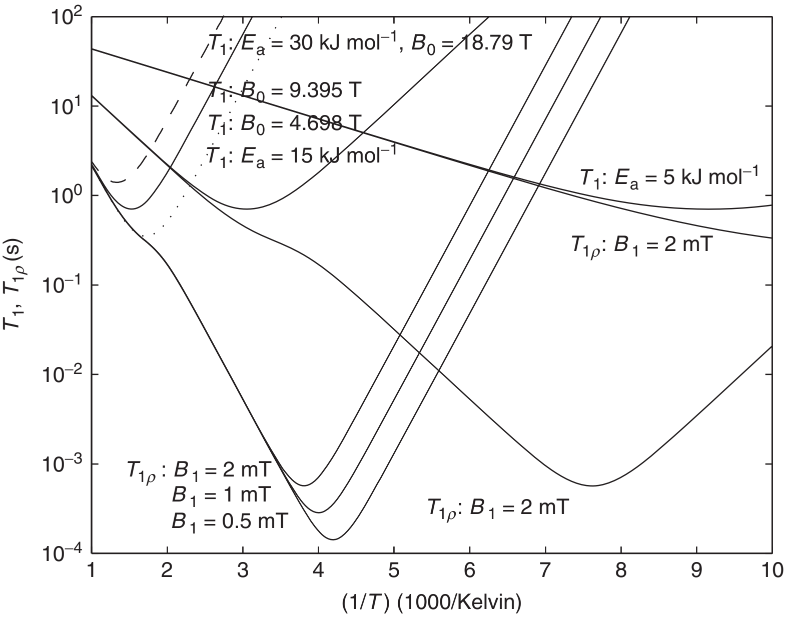

Figure 7.12 Simulated spin–lattice (T_1) and spin–lattice in the rotating frame ($T_{1\rho}$) relaxation times for a ^{1}H moving with respect to the molecular structure, for example, methyl group rotation. Shown here, from left to right, are three sets of curves corresponding to $E_a = 30$, 15, and 5 kJ mol^{-1}. $B_0 = 9.395$ T (^{1}H = 400 MHz) except for T_1 at $B_0 = 4.698$ T (. . .) and 18.79 T (— — —) corresponding to 200 and 800 MHz, respectively.

Table 7.4 Activation energies and temperatures of T_1 minima, correlation times, and magnetic field (given as the resonant frequency in radians per second).

E_a (kJ mol^{-1})	T_{min} (K)	τ_{min} (ps)	ω_0 (10^9 rad s^{-1})
30	750	120	5.0265
30	660	240	2.5133
30	580	500	1.2566
15	330	240	2.5133
5	110	240	2.5133

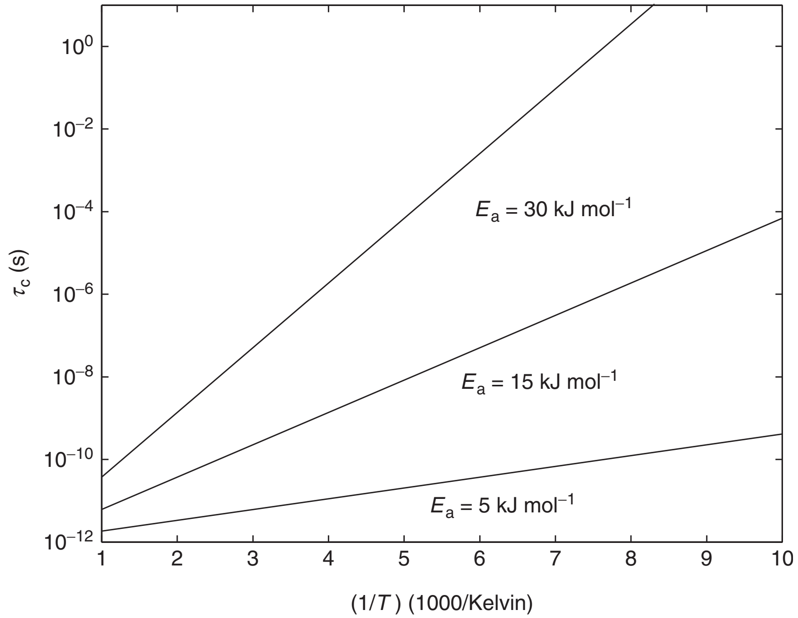

Figure 7.13 Correlation times used to generate the T_1 and $T_{1\rho}$ values of the previous figure from the Arrhenius relationship $\tau = \tau_0 \exp(-E_a/RT)$ where $\tau_0 = 10\text{–}12$ s.

of NMR to measure dynamic processes is quite powerful; quick survey experiments can be done with any NMR signal and more detailed studies can be done with specifically labeled samples. To return to the SAM samples, compound *E* of Figure 7.7 may be expected to show two T_1 minima, the first in the range of 10–50 K corresponding to thermal activation of methyl group rotation and a second minimum at higher temperature due to a larger motion of the alkyl chain. There is one significant problem with the use of relaxation methods to monitor kinetic processes: while the rate constants and activation energies can be measured, often the mode of motion is not clearly determined. In the case of compound *E*, the higher temperature minimum could be assigned to a simple motion at the end of the alkyl chain or to a cooperative motion of all of the alkyl chains. With only relaxation methods, the mode of motion remains ambiguous.

7.3.6
Dynamics

In solid-state NMR, a common technique for measuring the rate of molecular motion, and the mode of motion, is ^{2}H NMR. For C–^{2}H bonds, the value of C_q is usually known, and for a static system yields a predictable powder pattern. Recall that each orientation of the C–^{2}H bond with respect to B_0 yields a discrete pair of transition frequencies. If the C–^{2}H bond orientation should change, then the transition frequencies may change. For modes of motion such as methyl group rotation, the transition frequencies average to new values, but still offset from the Zeeman frequency. With increasing rate of methyl group rotation, the ^{2}H NMR evolves smoothing to a new, motionally averaged, line shape, as shown in Figure 7.14. For compound D (Figure 7.7), this experiment could show the onset of fast methyl group rotation and then the onset of more complex molecular motions such as chain motion or migration of the chain across the surface.

Solid-state ^{2}H NMR is, among techniques that measure molecular motion, capable of measuring an extremely wide range of motional rates. When ^{2}H T_1 measurements are included, rate constants of more than 10 orders of magnitude are accessible. In addition to methyl group rotation, the combination of deuteration

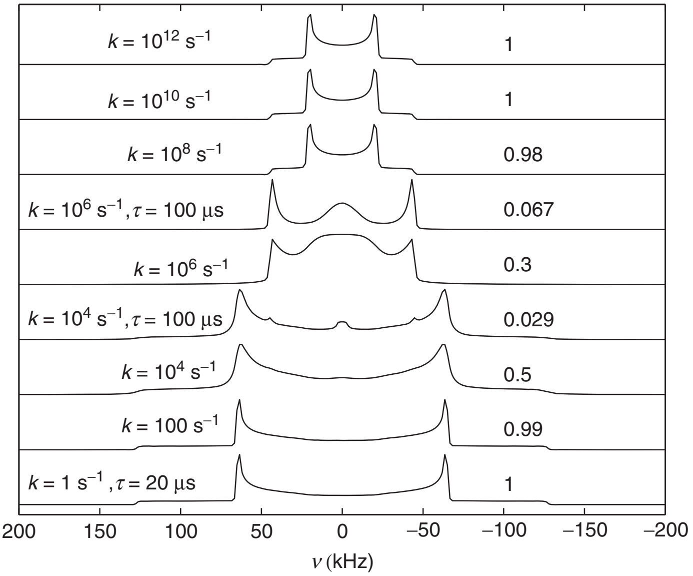

Figure 7.14 Simulated ^{2}H NMR line shapes of a methyl group as a function of methyl group rotation rate, k. The interpulse spacing, τ, is 20 μs, unless otherwise specified. The relative amplitudes of each spectrum are given on the right.

and solid-state ^{2}H NMR has yielded molecular dynamic information on phenyl groups, aliphatic chains, and ethene bound to transition metal centers.

7.4
Imaging

MRI is NMR spectroscopy with magnetic field gradients applied to the sample. Thus, every volume element within a sample can be exposed to a specific magnetic field. As RF and magnetic fields can penetrate many samples, NMR is a widely applicable imaging technique. However, the most convenient NMR imaging methods work only with narrow NMR resonances, such as the ^{1}H NMR resonances of water and lipids or the ^{3}He and ^{129}Xe resonances of helium and xenon [8].

In any imaging experiment, the critical issues are sample preparation, image contrast, spatial resolution, field of view, and total time of the experiment. Relative to other imaging techniques, the NMR spectroscopists's control over the image contrast mechanisms is exceptional. Of course, MRI images are affected by the number of nuclei in each volume element. In addition, the NMR relaxation dynamics, T_1 and T_2, can be used to control image contrast, especially for the soft tissues in the human body. Sample preparation is perfectly simple for the patient: remove metal objects and lie still. For inanimate objects, sample preparation of this simplicity enables many unique experiments: variable temperature, variable pressure and/or flow, and measurements as a function of time. The other NMR interactions discussed earlier find modest applications in MRI. The chemical shift interaction is used in ^{31}P MRI of muscle tissue to monitor metabolism via phosphocreatine/ATP concentrations.

An MRI pulse sequence, spin–warp, is shown here as a 2D imaging sequence (Figure 7.15). An initial ^{1}H 90_x pulse converts ^{1}H z-magnetization to magnetization aligned with the y'-axis of the rotating frame. In this chapter, this is the first NMR pulse sequence to be described with the rotating frame concept. The description

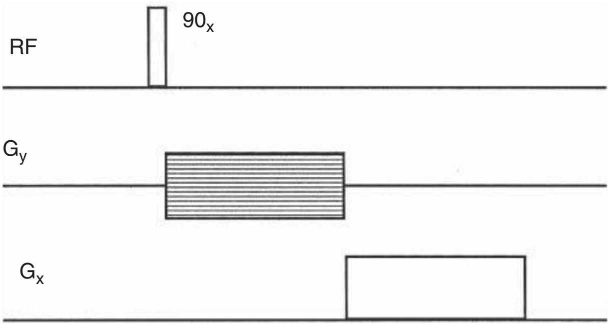

Figure 7.15 Spin–warp pulse sequence for 2D imaging. In successive experiments, the amplitude of G_y is varied while the amplitude of G_x is fixed. The NMR signal is acquired during the application of G_x.

of other pulse sequences, such as two pulse sequences used for T_1 and T_2 measurement are given in many textbooks. We chose the rotating coordinate system to have B_0 parellel to the z-axis; the x' and y' axes are chosen to be synchronized with the RF frequency of the initial pulse in a pulse sequence. The primes denote the two moving axes; primes are generally omitted from labels such as "90_x" because it is understood that the RF pulse is referenced to the rotating coordinate system.

To visualize the effect of a pulse sequence with the rotating frame description, one makes the following assumptions:

- The magnetization vector, $\boldsymbol{M}$, represents the vector sum of all the magnetic moments in the sample.
- The coordinate system chosen is rotating about an axis parallel to B_0 at a rate equal to the ^{1}H resonance frequency.
- In the rotating frame, the initial orientation of $\boldsymbol{M}$ is along the $+z$ axis (denoted as $\boldsymbol{M}_z$) and a 90_x pulse results from the application of a magnetic field along the x'-axis (denoted as B_{1x}).
- The motion of $\boldsymbol{M}_z$ in response to B_{1x} is a torque which causes $\boldsymbol{M}$ to precess toward the y'-axis. Of course, when $\boldsymbol{M}$ is aligned with the y'-axis, the RF pulse is terminated. Then, $\boldsymbol{M}'_y$ will stay aligned with the y-axis until: (i) its resonance frequency changes or (ii) another RF pulse is applied to the sample.
- The detected NMR signal is described with complex numbers. M'_y is positive, real, and magnetization along the x-axis, M'_x, is imaginary. Note: when pulse sequences are analyzed in greater detail, and with more regard to sign conventions, the axis labels will change. Nevertheless, the rotating frame model remains quite useful.

A hypothetical sample is shown in Figure 7.16. This sample has five spins at $x = -3$, $y = +2\,\text{cm}$ and one spin at $x = 1$, $y = 0\,\text{cm}$. We assume that all spins will, in the absence of any magnetic field gradients, have exactly the same resonance frequency. The evolution of the magnetization in the rotating frame illustrates how the sample spin density distribution is imaged.

Shown in Figure 7.17 are plots of $\boldsymbol{M}_x$ and $\boldsymbol{M}_y$, starting immediately after the 90_x pulse of the spin–warp 2D imaging pulse sequence. For $G_y = 0\,\text{mT}\,\text{m}^{-1}$ (Figure 7.17a), magnetization stays aligned with the $+y$ axis for 10 ms; the resonant frequency is exactly equal to the rotating frame frequency. Then, with the application of the G_x gradient, the resonant frequency changes for spins at sample sites with nonzero x-coordinates. For $G_y = +0.1175\,\text{mT}\,\text{m}^{-1}$ and $y = +2\,\text{cm}$, the change in resonant frequency is $+100\,\text{Hz}$,

$$\Delta\nu = \frac{\gamma}{2\pi}\Delta^{\chi} G_y = (42.57\,\text{MHz}\,\text{T}^{-1})(+0.02\,\text{m})(+0.1175\,\text{mT}\,\text{m}^{-1}) = +100\,\text{Hz} \tag{7.11}$$

creating the sinusoidal dependence in the magnetization along the y-axis (rotating frame) in Figure 7.17b, and, separated in phase by ±90°, a component along the x-axis. An even larger gradient increases the offset frequency. The phase of the

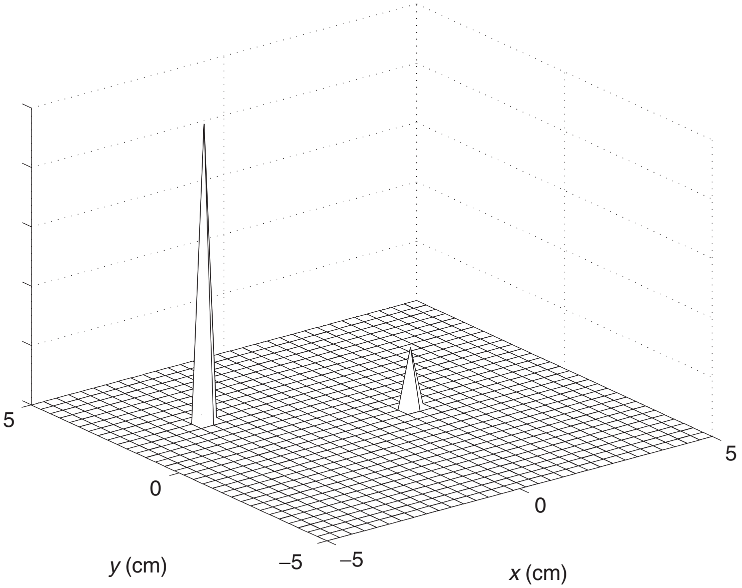

Figure 7.16 Hypothetical sample with five ^{1}H nuclei at $x = -3$, $y = 2$ cm, and one ^{1}H nucleus at $x = 1$, $y = 0$ cm.

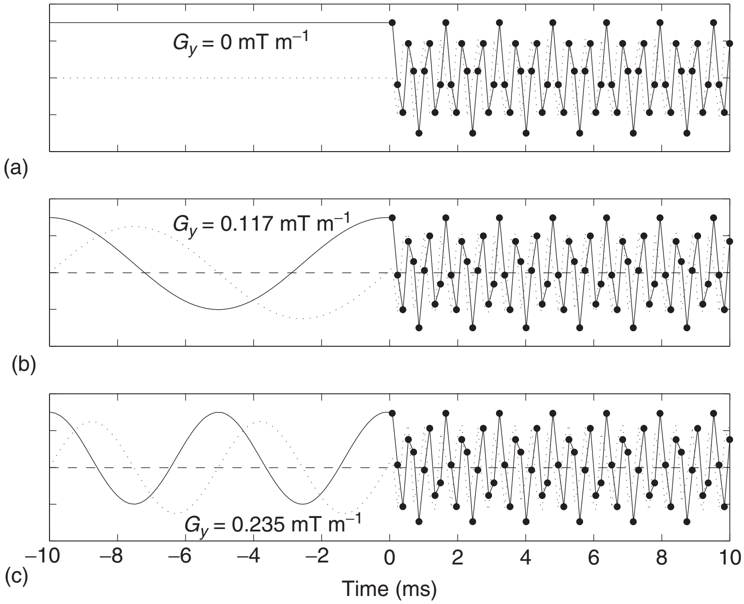

Figure 7.17 (a–c) Magnetization in the rotating frame: $\boldsymbol{M}_y$ (—) and $\boldsymbol{M}_x$ (. . .). The acquired data (●) is taken during the application of the G_x gradient.

imaginary component changes by 180° for $G_y < 0\,\mathrm{T\,m^{-1}}$ or sample position <0 cm. The digitized values are indicated (•) in Figure 7.17 and again, the frequency of the signal depends upon G_x and the location of the spins in the sample. A complete 2D spin–warp experiment consists of 2^n different values of G_y and, for each G_y value, a digitized FID with 2^n data points.

For the purpose of image filtering, a smoothing function is often applied to the 2D FID data set. Shown in Figure 7.18 is the smoothed 2D FID data array (real component). This surface plot shows both the oscillation set by G_x and the variable phase of that oscillation set by G_y. This last point, the phase encoding by a pulse or gradient, is a key feature of multidimensional NMR experiments.

Lastly, 2D Fourier transformation of the smoothed 2D FID data set yields the image (Figure 7.19), which corresponds quite well to the original distribution of spin density through the field of view.

Besides the spin–warp sequence, the echo planar sequence is widely used in biomedical applications. Figure 7.20 shows an image recently acquired of a young girl's sprained knee. The instrument used a permanent magnet system configured to reduce the claustrophobic feeling of a more traditional solenodial magnet.

Besides imaging, pulsed magnetic field gradients are also used to study self-diffusion of solutes and solvents. Basically, the pulsed field gradients ''encode'' a structure on the spin system, and the evolution of this structure yields the rate of translational motion in the solution. Since magnetic field gradients can be quite large and the time of application can be of the order of milliseconds,

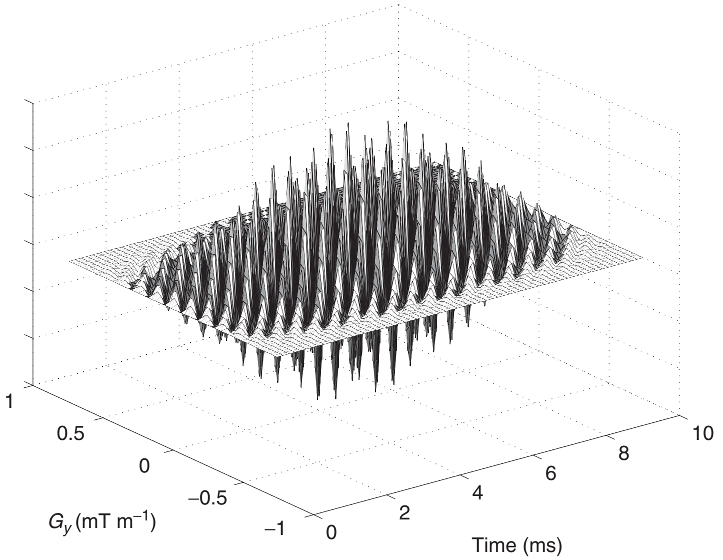

Figure 7.18 The real (M_y) component 2D FID data set after smoothing with a sine function. The oscillation frequency along the time axis is set by G_x and the initial phase of each oscillation is set by G_y.

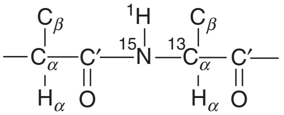
the structure can be created at sub-micron resolution. Therefore, quite small translational motions are measured.

7.5
3D NMR: The HNCA Pulse Sequence

Multiple pulse NMR sequences for the solution state can be modeled with either product operator or density matrix calculations. Here, we use the latter for analyzing a pulse sequence for three-dimensional NMR, the HNCA pulse sequence. The HNCA pulse sequence is used to establish connectivity between the amide hydrogen, the amide nitrogen, and the α-carbon in an amino acid in a polypeptide sequence. The detected ^{1}H NMR signal shows a modulation that is dependent upon $^1J(^1\mathrm{H}{-}^{15}\mathrm{N})$ and $^2J(^1\mathrm{H}{-}^{13}\mathrm{C})$, a modulation thay will be simulated with density matrix calculations. Because a polypeptide has many amide hydrogens, amide nitrogens, and α-carbons, a necessary step for assigning the NMR spectra is identifying neighboring atoms. Fortunately, these three nuclei are coupled by unique and nearly uniform *J*-coupling constants (Figure 7.21).

The HNCA pulse sequence has groups of three pulse sequences optimized for the *J*-coupling constants. The rotating frame description can be applied to parts of the pulse sequence (Figure 7.22), but is insufficient to describe the entire sequence. With tools such as Mathematica or Matlab, it is straightforward to simulate the pulse sequence (Figure 7.23). These tools allow for the evaluation of the exponent of a Hermitian matrix, a common step in time-dependent quantum mechanics.

In this 3D NMR pulse sequence, two time increments, t_1 and t_2, are successively incremented. Because of the *J*-coupling, each time increment leads to a modulation of the detected ^{1}H NMR signal. Shown here (Figure 7.24) are simulated ^{1}H NMR spectra acquired at various time increments. A large array of these spectra, processed in total by 3D FFT (fast Fourier transform), will lead to a cube of data, which is typically analyzed slice by slice.



$^1J(^1\mathrm{H}{-}^{15}\mathrm{N}) = +90$ Hz

$^2J(^1\mathrm{H}{-}^{13}\mathrm{C}_\alpha) = +11$ Hz

$\sigma 4 = U\ .\ \sigma 3\ .\ \text{Transpose [Conjugate [U]]}\;;$

Figure 7.23 A brief portion of a Mathematica program used to simulate the HNCA pulse sequence. With an analysis such as this, it is possible to follow the basic features of a complex pulse sequence, in particular, how the detected signal changes with the magnitude of the *J*-coupling constants. The complete program is long, but repetitive, with commands as shown above repeated from the first pulse to the last pulse.

NMR of proteins uses a suite of 2D and 3D NMR pulse sequences like HNCA with the objective of acquiring connectivity information. Besides the signal-to-noise ratio for the detected signal, other issues are the separation of one ^{15}N resonance from another, and likewise, the separation of one $^{13}C_{\alpha}$ resonance from another. The S/N and resolution issues both push the experiment to higher and higher magnetic fields.

7.6
Conclusion

NMR spectroscopy is a very effective method to examine the interactions between nuclei and their environments. NMR spectra yield information that can be used to determine the structure of complex organic, organometallic, and biological molecules as these structures exist in solution. For similar molecules in the solid state, the hierarchy of dominant NMR interactions changes, and other information becomes available, yielding more emphasis on chemical bonding and molecular dynamics. The application of magnetic field gradients enables imaging experiments such as MRI and self-diffusion measurements. The NMR interactions are well-described by time-independent and time-dependent quantum mechanics.

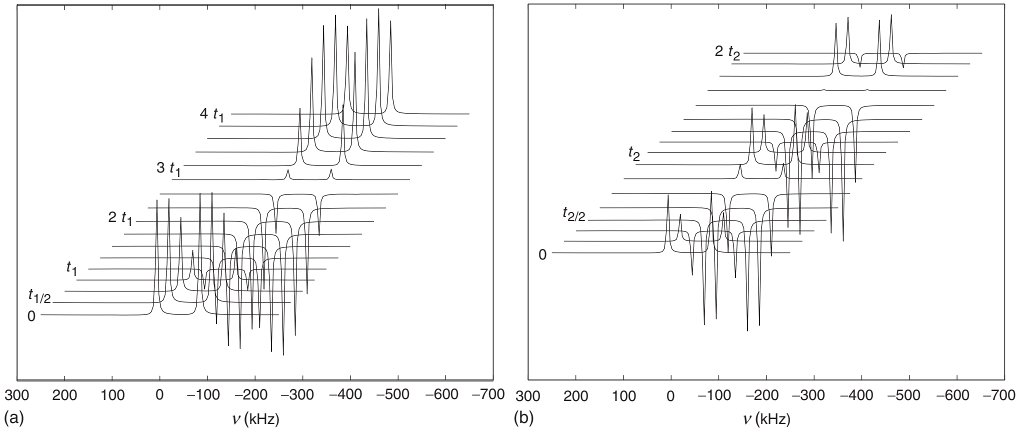

Figure 7.24 Simulated amide ^1H NMR spectra from an HNCA pulse sequence, shown here without ^{15}N decoupling. (a) The ^1H NMR signal as a function of t_1 evolution, and (b) t_2 evolution. These evolutions will only be seen for ^1H *J*-coupled to ^{15}N and ^{13}C.

Solution NMR Spectroscopy

Gary E. Martin, Chad E. Hadden, and David J. Russell

8.1

Introduction

NMR, or nuclear magnetic resonance spectroscopy, affords one of the richest sources of molecular connectivity information available to the structural chemist. Since the inception of NMR, which originated as a curiosity of the physicist when the principle was first discovered just over 50 years ago [1, 2], the discipline has gone on to become universally recognized for its unique capability to precisely define molecular structures through a variety of fundamental parameters. It is entirely safe to say that NMR has become the cornerstone technique for the elucidation of chemical structure.

The fundamental parameters of the NMR experiment have been covered in a previous chapter and will be mentioned here only briefly. Structure elucidation by NMR at the simplest level may simply entail a comparison of the chemical shifts of the molecule of interest with a database library of chemical shift information. Commonly studied nuclides include, ^{1}H, ^{13}C, ^{19}F, and ^{31}P for organic molecules; less commonly, for reasons of sensitivity, other nuclides such as ^{15}N may be investigated. In addition to the nuclides just cited, which are of primary interest to investigators working with organic and bio-organic molecules, studies of the diverse array of metallic nuclides that comprise the periodic table are also possible [3–12]. The assumption will be made that individuals reading this chapter have the ability to utilize NMR chemical shift data bases and we will thus focus our attention on the utilization of experiments that ‘‘exploit’’ fundamental NMR parameters. At the next level of complexity, an investigator is likely to take an interest in scalar (J) spin coupling interactions between appropriate nuclide pairs, which may include ^{1}H–^{1}H, ^{1}H–^{13}C, or more recently ^{1}H–^{15}N. Homo- or heteronuclear scalar (through bond) couplings may either be directly observable, probed by decoupling techniques, or alternatively, they may provide the basis for performing homo- or heteronuclear chemical shift correlation experiments. On a similar plane are through-space connectivity and molecular motion measurements such as the nuclear Overhauser effect (NOE), molecular diffusion measurements, and others.

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

A convenient collection of explanations of some of the terminology of NMR spectroscopy to which some may wish to refer is the monograph, *A Handbook of Nuclear Magnetic Resonance*, by Freeman [13]. In addition, there are also numerous monographs dealing with various aspects of NMR that have appeared over the last 10–15 years that are worthy of note [14–32]. Those cited are by no means intended to be an exhaustive compilation, but rather are those volumes that the authors have found useful.

Beyond simple one-dimensional (1D) NMR spectra, users will generally begin to consider multidimensional NMR experiments. Such experiments allow the segregation of information between two discrete frequency domains. The earliest two-dimensional (2D) NMR experiments were homonuclear experiments in which both frequency domains were used for proton chemical shift information. Here, the scalar coupling between two protons in a chemical structure is exploited to generate off-diagonal responses in a diagonally symmetric data matrix (spectrum) to correlate protons to one another in a fashion analogous to correlating proton resonances with homonuclear decoupling. These experiments are called COSY experiments, which is an acronym for correlated spectroscopy. A diverse array of 2D NMR experiments exist in which proton chemical shift information may be relegated to one axis while ^{13}C or even ^{15}N chemical shift information may be on the other axis of the experiment, to give just two examples. These techniques will be treated following the presentation of simpler, 1D NMR methods.

8.2
1D (One-Dimensional) NMR Methods

The simplest 1D NMR experiments involve the application of a pulse followed by observation of the resulting signal in the time domain, with subsequent Fourier transformation of the data to the frequency domain for presentation in a format that we, as chemists, can understand. Pulsed NMR methods had their inception in 1966 [33] and have almost completely supplanted earlier continuous wave (CW) methods. For reasons of sensitivity, only ^{1}H 1D NMR spectra were typically acquired prior to the 1970s. The advent of pulsed Fourier transform NMR instruments made it possible to acquire natural abundance ^{13}C NMR spectra on a routine basis in the early 1970s. With the routine availability of ^{13}C NMR data came the compilation of chemical shift data bases and a very different way of approaching chemical structure elucidation.

We will briefly consider in this section various aspects of homonuclear spin-decoupling experiments and nuclear Overhauser effect (NOE) difference spectra. Obviously any detailed treatment is far beyond the size limitations of this chapter. Moving next to 1D ^{13}C NMR techniques, we will briefly consider the utilization of selective population transfer (SPT) and experiments which rely on these principles such as insensitive nuclei enhanced by polarization transfer (INEPT) and distortionless enhancement by polarization transfer (DEPT), off-resonance proton decoupling techniques, decoupler gating experiments, and finally spin–lattice or T_1 relaxation techniques, which also have application to proton NMR spectroscopy in many instances to establish acquisition parameters for 2D NMR experiments, and so on.

8.2.1
Proton Spin Decoupling Experiments

Proton spins interact with one another through scalar (J) coupling mechanisms. These processes give rise to the familiar multiplets seen in proton spectra, for example, the quartet for the methylene and a triplet for the methyl signal of an ethyl group. In the case of simple molecules, spin multiplets are likely to be well separated. Alphabetically, a system of two sets of spins that are widely separated, that is, $\Delta\nu \gg J$ (where $\Delta\nu$ is the difference in the chemical shifts of the two spin-coupled nuclides) will be referred to as an *AX spin system*. Such a system is also referred to as a *first order spectrum*. As molecular complexity increases, spectral congestion generally increases in parallel. With increasing spectral congestion, chemical shift differences between coupled spins frequently decrease. As $\Delta\nu$ begins to become comparable to J, spin systems become less first order in nature, making spectral interpretation by visual inspection progressively more difficult.

Prior to the advent of 2D NMR methods in the mid-1970s, it was common to use spin decoupling as a method of deciphering which proton was coupled to another, the second located perhaps in a congested region of a spectrum. This experiment uses radiofrequency (RF) irradiation, at a frequency coinciding with a proton resonance of interest, to alter the spectral response of the protons coupled to the target resonance. As a function of the strength of the RF field applied, a range of phenomena can be observed. In order of increasing RF field strength, one begins from selective population transfer (SPT) in which a single resonance line of a multiplet, or a ^{13}C satellite resonance for that matter, is selectively irradiated without perturbing other resonance lines of the same multiplet. A more intense field will give a result known as *spin tickling*. The interested reader is referred to the monograph of Freeman [13] for a discussion of this phenomenon. At higher RF field strength complete spin-decoupling occurs. Applying RF irradiation at this field strength to a proton that is resolved will collapse the scalar coupling(s) of the proton(s) to which the irradiated proton is J-coupled. Spin decoupling is well documented in any of the monographs cited above, and the interested reader is referred to these sources for further discussion. If an investigator can see the collapsed spin multiplets by simple visual inspection of the resulting spectrum, he or she is finished and can move on with the investigation of the structure. In more complex spectra, the location of the protons affected by the irradiation of one proton may not be easily discerned. In such cases, one may wish to resort to decoupled difference spectra.

8.2.2
Proton Decoupled Difference Spectroscopy

Difference spectroscopy, as the name implies, requires spectral subtraction. Two spectra are acquired. One in which the proton of interest is decoupled and a second reference spectrum in which the irradiation is applied in an isolated region far from the nearest proton resonance. The two spectra are then subtracted from one another, the resulting difference spectrum highlighting protons that were affected by the decoupling process [34]. Several excellent examples of applications of this technique are found in the monograph by Nakanishi [24].

8.2.3
Nuclear Overhauser Effect (NOE) Difference Spectroscopy

The nuclear Overhauser effect or NOE is a spatial phenomenon involving two magnetically active nuclides in close proximity. Generally, we think of these experiments in terms of $^1H-^1H$ interactions, but heteronuclide pairs also exhibit these effects. In the $^1H-^1H$ homonuclear case, given two protons in spatial proximity that are not coupled to one another through bonds, the irradiation of one proton (saturation) will lead to an observable enhancement in the signal of the neighboring proton through dipolar cross-relaxation mechanisms. Simplified in the extreme, this is the nuclear Overhauser effect or an NOE. Two excellent monographs treat these experiments in considerable detail. The aging volume by Noggle and Schrimer [35], while dated, is still an excellent reference. The more recent and comprehensive monograph by Neuhaus and Williamson [36] is probably the best source of information on the NOE currently available.

While homonuclear NOEs may range to as great as 50% enhancements of signal intensity, it is much more common to observe NOEs of only a small percentage. Visually observing perhaps what may only be a 2–3% enhancement of the intensity of a signal is very difficult. In contrast, by using a difference approach, in which only signals enhanced by a given irradiation remain in the spectrum, it is a facile process to determine which protons exhibit a NOE when a neighbor is irradiated. The principle is the same as that used in preparing difference-decoupled spectra. Two spectra are acquired, one in which the proton of interest is irradiated and a second in which the irradiation is in an isolated region of the spectrum. The reference spectrum is subtracted and the difference spectrum is examined. Applications for the use of NOEs are widely varied. NOEs may be used to determine stereochemical relationships, to measure distances between a pair of protons, and for many other purposes. The interested reader is referred to the monographs cited above for further information and examples.

8.2.4
Selective Population Transfer (SPT)

Applying RF fields of lower intensity to selectively perturb a single resonance or satellite line is the basis of the SPT or selective population transfer experiment. Perhaps the most interesting example of the utilization of SPT experiments, which form the basis for the INEPT, DEPT, and other spectral editing experiments that have been developed, is found in the consideration of an AX heteronuclear spin system, for example, $^1H-^{13}C$ or $^1H-^{15}N$ where the heteronuclear spin is insensitive relative to the proton. The energy level diagram for such a spin system will have four transition lines corresponding to the four resonance lines in the spectra of the two nuclides; the proton resonance will be a doublet due to $^{n}J_{CH}$. The observed ^{1}H spectrum will consist of three lines, actually, the central line comprising ~98.9% of the total resonance intensity will arise from $^{1}H{-}^{12}C$; the ^{13}C satellite lines will be separated from the central resonance by $\pm ^{n}J_{CH}/2$, and will have an aggregate intensity of ~1.1%. Based on the gyromagnetic ratios of the heteronuclides, γ_H and γ_C in this case, the four transitions associated with the energy level diagram of this heteronuclear AX spin system can be assigned numerical values. In the case of the Boltzmann equilibrium state, the two resonance lines for ^{13}C will each have an intensity of +1. By selectively inverting one of the proton transitions, and then sampling the perturbed system, the ^{13}C resonance can be observed with transition intensities of +5 and −3 (this special case is termed spin population inversion (SPI)). This signal enhancement is the basis for the sensitivity improvements obtained with the INEPT and DEPT experiments. SPT has also been employed as a means of making resonance assignments. Nagel *et al.* [37] have reported an excellent example in the course of determining the structure of the complex alkaloid oxaline. When this technique is applied to ^{15}N, even larger enhancement of the involved resonances is observed because of the greater difference between the gyromagnetic ratios of ^{1}H and ^{15}N.

8.2.5
J-Modulated Spin Echo Experiments

While the SPT experiment has obvious utility, it is cumbersome to use unless the selective nature of the experiment is specifically being exploited for structure elucidation purposes. A group of experiments that may be categorized as *J*-modulated spin echo experiments allows the simultaneous investigation of the entire spectrum. As the name of this group of experiments implies, they utilize a spin echo of the type shown in Eq. (8.1), over which a scalar coupling driven process (using $^{1}J_{CH}$ most commonly) is superimposed:

$$\tau - 180^{\circ} - \tau \tag{8.1}$$

Experiments that fall into this category include INEPT, DEPT, and APT (attached proton test). These experiments are discussed in considerable detail in any of the monographs cited in the Introduction to this chapter to which the interested reader is referred. Below, we will focus briefly on the INEPT and DEPT experiments since these are conceptually useful for the development of 2D heteronuclear shift correlation spectroscopy.

8.2.5.1 INEPT (Insensitive Nucleus Enhancement by Polarization Transfer)

While the SPT method, as the name indicates, is a selective experiment, techniques derived from the principle of population transfer of a non-selective nature are also available. The first of these to appear was the INEPT experiment [38]. The pulse sequence schematics for INEPT and refocused INEPT are shown in Figure 8.1.

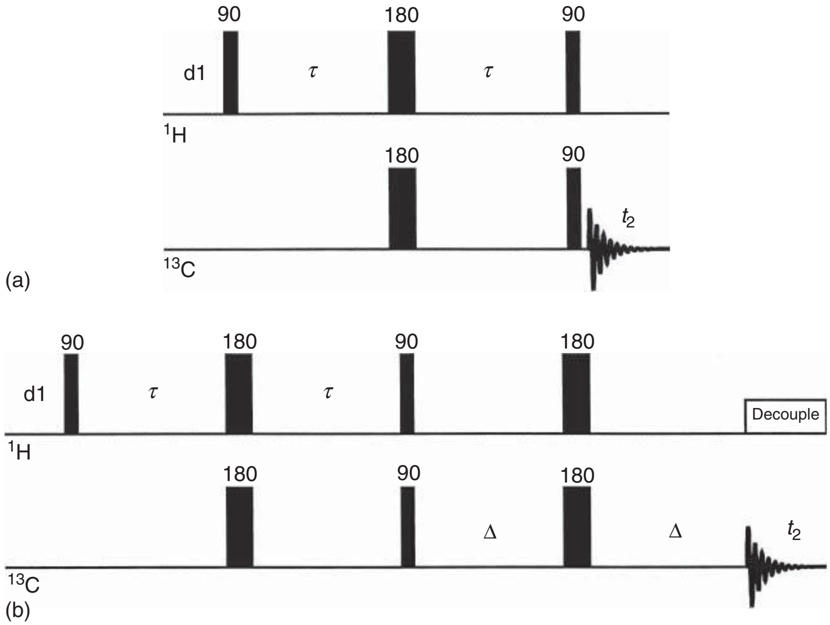

Figure 8.1 (a,b) Pulse sequences for the INEPT and INEPT-R experiments [38–40]. These experiments rely on spin population transfer (SPT) and provide the means of detecting ^{13}C or other insensitive nuclides with enhanced sensitivity.

As with the SPT experiment described above, INEPT and its successor, the DEPT experiment, both operate with enhanced sensitivity through the perturbation of the Boltzmann populations. This prototypical non-selective experiment is now relatively seldom used as more refined variants have been developed. The INEPT experiment ($\tau = (4J)^{-1}$, Figure 8.1a) generates antiphase responses analogous to those observed with SPT experiments. The antiphase components of magnetization can, however, be refocused by adding a delay of 2Δ with a ^{1}H/^{13}C 180° pulse sandwich in the center of the interval where $\Delta = 1/x^{n}J_{\mathrm{CH}}$ ($x = 4$–8) [39, 40]. This modification, since the antiphase components of magnetization are refocused, also allows the utilization of broadband decoupling during acquisition.

8.2.5.2 **DEPT (Distortionless Enhancement Polarization Transfer)**

The next level of refinement in non-selective polarization transfer experiments was the DEPT experiment developed by Doddrell and co-workers [41, 42]. The DEPT pulse sequence schematic shown in Figure 8.2 employs a variable flip angle read pulse, θ, as the last proton pulse of the sequence. By varying the flip angle of this pulse, edited subspectra based on resonance multiplicity (CH, CH_2, and CH_3) can be readily generated. When $\theta = 45^\circ$, a spectrum in which all protonated carbons have positive intensity is produced; quaternary carbons are suppressed and absent. When $\theta = 90^\circ$, only methine carbons are observed and have positive intensity. Finally, when $\theta = 135^\circ$, a spectrum in which methine

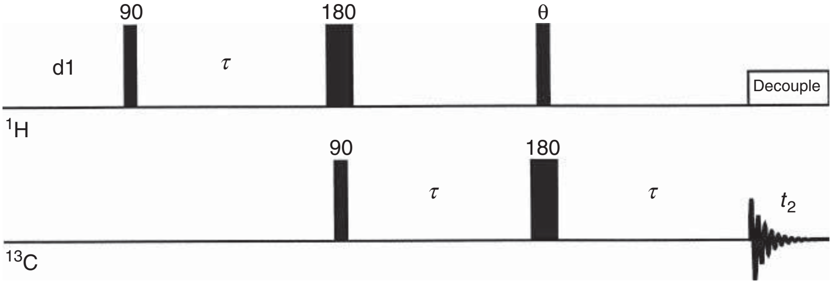

Figure 8.2 Pulse sequence for the DEPT experiment [41, 42]. By adjusting the variable flip angle read pulse, θ, it is possible to generate edited subspectra based on resonance multiplicity (CH, CH_2, and CH_3). When $\theta = 45°$, all protonated carbons will exhibit positive intensity. When $\theta = 90°$, only methine carbons are observed and have positive intensity. When $\theta = 135°$ a spectrum is produced in which methine and methyl resonances have positive intensity while methylene resonances have negative intensity. Plotting the $\theta = 90°$ spectrum gives a methane-only subspectrum; the difference spectrum obtained by subtracting the $\theta = 135°$ spectrum from the $\theta = 45°$ spectrum gives a methylene-only spectrum; finally, a methyl-only spectrum can be generated by adding the experimental results of the $\theta = 45°$ and 135° experiments. An example of the edited subspectra of a model compound are shown in Figure 8.3.

and methyl resonances have positive intensity while methylenes are negative is obtained. Given these three spectra, plotting the result with $\theta = 90°$ gives a CH-only spectrum. Plotting the difference spectrum obtained by subtracting the $\theta = 135°$ spectrum from the $\theta = 45°$ spectrum gives a methylene-only spectrum. A methyl-only spectrum can be generated by adding the results of the $\theta = 45°$ and 135° experiments and subtracting the result of the $\theta = 90°$ experiment. Simple subtraction will give residual responses in the edited subspectra, which can be eliminated by using multiplication coefficients if necessary. Residual responses, however, rarely confuse the sorting of carbon resonance by multiplicity. Examples of DEPT-edited subspectra are shown in Figure 8.3.

8.2.6
Off-Resonance Decoupling

If a low power RF field is selectively applied to a specific proton resonance and a ^{13}C spectrum is subsequently recorded, the resulting spectrum will nominally be proton coupled, with the exception of the carbon associated with the selected proton. In this fashion, by performing a series of such experiments, it is possible to correlate carbon resonances with their directly attached protons. As the decoupling frequency is moved off-resonance, residual coupling, J_R, will be observed in the carbon spectrum with J_R a function of the strength of the applied RF field and how far off resonance it is applied. By preparing a series of such experiments, various carbon multiplets will successively collapse and reappear as the frequency of the applied proton decoupling field is systematically varied from one experiment to the next. Such experiments were an early forerunner of 2D heteronuclear shift

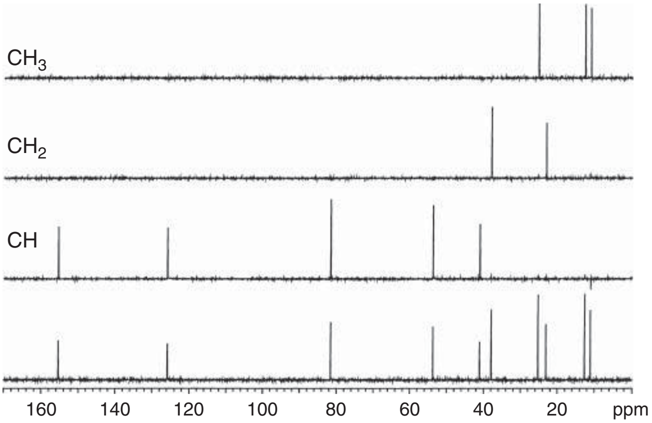

Figure 8.3 Multiplicity-edited DEPT spectra recorded at 125 MHz for a sample of santonin (**1**).

correlation experiments. Perhaps it is worthy of note that a whole qualitative dimension of spectral information is available from inspecting multiplicity shape as a function of J_R. Such information frequently allows specific assignment of resonances within multiplicity groups. This information is lost, however, in spectral editing sequences like INEPT and DEPT that rely on sign and intensity variation of the coupled or decoupled resonance [43].

8.2.7
Relaxation Measurements

Following the application of a pulse or pulses to an NMR sample and the acquisition of whatever data are of interest, time is required for the system to return to some level of equilibrium. Two fundamental relaxation processes govern the return of a perturbed spin system to equilibrium. These processes are spin–lattice or T_1 relaxation, and spin–spin or T_2 relaxation. A variety of means are available to measure both of these fundamental processes [27, 29, 31]. We will limit the discussion here to the former.

Spin–lattice relaxation is the time constant for the recovery of magnetization along the z-axis in a NMR experiment. Various methods are available for the measurement of spin–lattice relaxation times. The interested reader is referred to the series of monographs edited by Levy on carbon-13 NMR spectroscopy [44, 45] for more details. The energy transfer between nuclear moments and the "lattice," the three-dimensional (3D) system containing the nuclei, provides the mechanism to study molecular motion, for example, rotations and translations, with correlation times of the order of the nuclear Larmour frequencies, tens to hundreds of megahertz. We will limit our discussion here to the simple inversion recovery T_1 relaxation time measurement experiment, which, in addition to providing a convenient means for the quick estimation of T_1 to establish the necessary interpulse delay in 2D NMR experiments, also provides a useful entry point into the discussion of multi-dimensional NMR experiments.

The inversion recovery experiment, applies a 180° pulse to align the magnetization along the $-z$-axis using the pulse sequence shown in Figure 8.4. A variable delay, τ, follows, which is adjusted across a range of values in a series of experiments, generally beginning with periods much shorter than the actual relaxation time through delays which are several times longer than the relaxation time to be measured. Following the τ interval, the evolved state of the magnetization is sampled using a 90° pulse. The intensity of the observed response can range from fully negative intensity, when τ is much shorter than T_1, through full positive responses when $\tau > 5T_1$, as shown in Figure 8.5. The signal intensity will be zero at the crossover point when $\tau = 0.69T_1$. Each data point represents a separate experiment differing from the other experiments in the series by the duration of τ. The T_1 relaxation time is encoded in the signal intensity in this series of

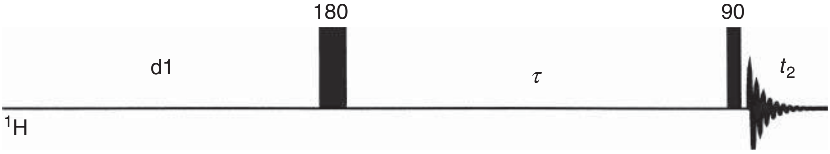

Figure 8.4 Spin–lattice (T_1) inversion recovery pulse sequence. The 180° pulse inverts magnetization, allowing it to recover along the z-axis. The duration of the delay, τ, is varied from $\ll T_1$ to several times the longest expected T_1 relaxation time in the molecule. The resulting, varying states of relaxation are sampled by the 90° pulse. The "null point," when there is essentially no signal intensity corresponds to 0.69 T_1. The results of an inversion recovery experiment applied to ^{1}H for strychnine (**2**) are shown in Figure 8.5.

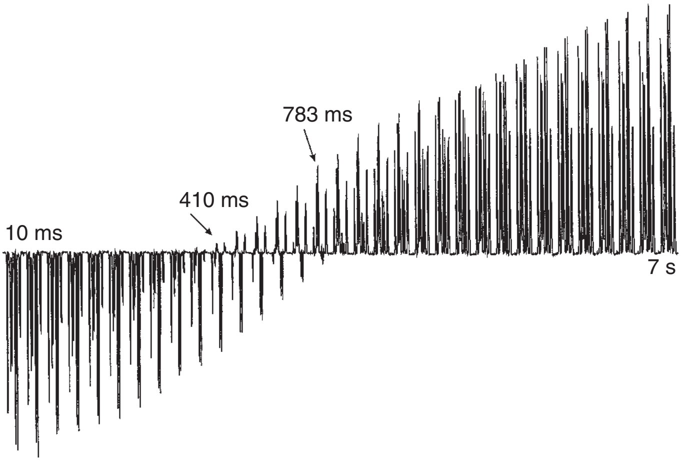

Figure 8.5 Inversion recovery experiment results for strychnine (**2**) shown as a horizontal stack plot where the duration of the delay, τ, between the 180° and 90° pulses is increased from right to left.

experiments through the successive variation of the duration of τ. This process is exactly analogous to the encoding of chemical shift information, or other spectral parametric information, in a 2D NMR experiment.

To establish interpulse delays for 2D NMR experiments, it is frequently convenient to run a very quick proton T_1 relaxation measurement. Given the sensitivity of modern spectrometers, this can usually be done with only a single or a few transients for each of the τ values in the series, and typically requires 10 min or less. By visual inspection, the T_1 relaxation time can be estimated from the τ value at which response intensity is zero. A knowledge of the T_1 relaxation time is also useful for establishing mixing times for nuclear Overhauser enhancement spectroscopy (NOESY) and rotating frame Overhauser enhanced spectroscopy (ROESY) experiments, which empirically can generally be performed by setting the mixing time to $\sim 0.7T_1$ and $\sim 0.5T_1$, respectively.

8.3
Two-Dimensional NMR Experiments

Two-dimensional NMR spectroscopy has been the topic of numerous monographs [14–17, 23–27, 29–31]. It is the intent here to provide the reader with a brief introduction and the means of accessing key aspects of what has become a voluminous literature on the subject. Briefly, 2D NMR experiments are comprised of several fundamental segments or building blocks. Three periods are obligatory in a 2D NMR experiment. These consist of a preparation period, the evolution period, t_1, which corresponds to what will be the indirectly digitized time domain, and a detection period, t_2, which is the directly detected time domain. In addition, some 2D NMR experiments contain a fourth period for "mixing" that is inserted between evolution and detection. Double Fourier transformation of the resulting data matrix affords a 2D frequency matrix in which responses are a function of two frequencies as shown by Eq. (8.2):

$$S(t_1, t_2) \longrightarrow s(F_1, F_2) \tag{8.2}$$

The two frequency axes may consist of a diverse assortment of pairs of fundamental NMR parameters. Examples might include chemical shift on one axis and a frequency axis for scalar couplings on the second as in the 2D *J*-resolved NMR experiments. Both axes may be proton chemical shift, in which responses may be correlated by scalar (*J*) coupling as in the COSY experiment [46–48], by dipolar relaxation pathways as in the NOESY [35, 36, 49–51] and ROESY [35, 36, 52, 53] experiments, or by chemical exchange pathways as in the exchange spectroscopy (EXSY) experiment [54–59]. Other examples may involve chemical shift on one axis and a multiple quantum frequency on the second axis. Examples here would include proton double [60–62] and zero quantum spectroscopy [63–67], ^{13}C–^{13}C INADEQUATE [68, 69], and so on. The available axes in a 2D NMR experiment may also be used for heteronuclear chemical shift correlation, for example, ^{1}H–^{13}C or

^1H–^{15}N, where the respective nuclide pairs are correlated via their one-bond ($^1J_{XH}$) or multiple bond ($^nJ_{XN}$) heteronuclear couplings [14, 16, 17, 23–27, 29–31, 70–72].

While the subject of 2D NMR spectroscopy may initially appear a daunting one, the simplest point of entry into 2D NMR is undoubtedly via *J*-resolved experiments [73, 74]. From a fundamental understanding of the segregation of spectral parameter information between frequency domains in a 2D *J* experiment, the reader can successfully begin to delve into homo- and heteronuclear 2D NMR techniques.

8.3.1
2D *J*-Resolved NMR Experiments

2D *J*-resolved NMR experiments are a conceptual amalgamation of two topics discussed above, the *J*-modulated spin echo and the 2D characteristic of the spin–lattice relaxation experiments. As the name of these experiments implies, scalar coupling information, *J*, will be displayed in the one frequency domain; chemical shift information will be presented in the second frequency domain. The simplest 2D *J* experiments sort ^{13}C chemical shift information in the detected time domain, labeled t_2 by convention, while the heteronuclear scalar couplings of each carbon are sorted into the indirectly determined time domain, t_1 (do not confuse lower case t_1 with the spin–lattice relaxation time, T_1).

The pulse sequence for an amplitude modulated heteronuclear 2D *J* experiment is shown in Figure 8.6 [75]. The experiment consists of a 90° ^{13}C pulse to rotate magnetization into the *xy*-plane where it begins to evolve with the decoupler turned on. After the first half of the evolution time has elapsed, $t_1/2$, a 180° ^{13}C pulse is applied and the decoupler is gated off for the second half of the evolution period. As might be expected at this point, two processes are ongoing in the second half of the evolution period. First, having applied a 180° ^{13}C pulse at $t_1/2$, we should expect

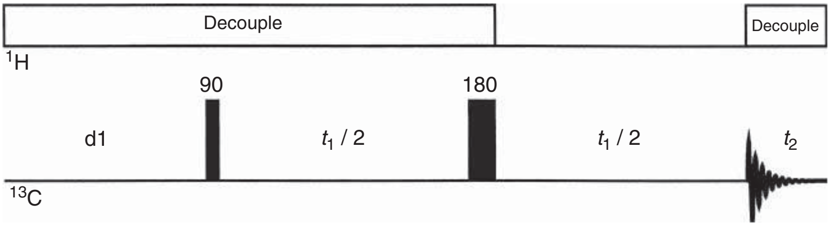

Figure 8.6 Pulse sequence for the amplitude modulated 2D *J*-resolved NMR experiment. The experiment is based on a *J*-modulated spin echo. The first 90° pulse tips magnetization into the *xy*-plane where it evolves during the first half of the evolution period, $t_1/2$. The 180° pulse is applied and the decoupler is simultaneously gated off for the second half of evolution. Decoupling is resumed when acquisition is started. The evolution of magnetization under the influence of the heteronuclear coupling during the second half of the evolution period leads to a 2D spectrum in which heteronuclear couplings are scaled by a factor of 2 and sorted as a function of the ^{13}C chemical shift as shown by the contour plot presented in Figure 8.9.

that magnetization will be refocused in a spin echo at time $= t_1$. Second, since the decoupler has been gated off for the second half of the evolution period, the spin echo will be *J*-modulated by the evolution of heteronuclear couplings during the second $t_1/2$ interval.

A 2D *J* experiment, or any 2D NMR experiment for that matter, consists of a series of 1D experiments in which the duration of the evolution time, t_1, is systematically incremented in some fashion from one experiment to the next. In the specific case of a 2D *J* experiment, the incremented parameter is the dwell time, which corresponds to 1/sw1, where sw1 is the desired spectral width of the second frequency domain, F_1, in hertz. Typical one-bond heteronuclear couplings range from about 125–160 Hz for aliphatic to aromatic compounds, respectively, with some heteroaromatics having one-bond couplings ranging up to about 210 Hz. In most cases, the spectral width in the second frequency domain of a 2D *J* experiment can be set to a total of 100 Hz, keeping in mind that couplings will be scaled by $J/2$ since *J*-modulation occurs for only half of the evolution time.

Experimentally, the results of performing a 2D *J* experiment such as that shown in Figure 8.6 are represented by the following several figures. First, as shown in Figure 8.7, response intensity is amplitude modulated for a given carbon from one experiment to the next as the evolution time, t_1 is incremented. The amplitude modulated resonance corresponds to the data arising from the first Fourier transformation as defined by Eq. (8.3):

$$S(t_1, t_2) \longrightarrow s(t_1, F_2) \tag{8.3}$$

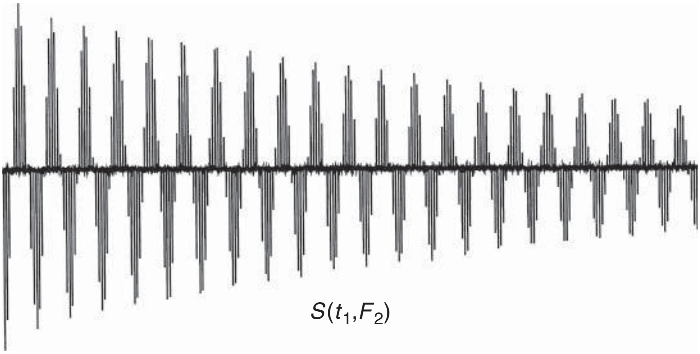

Figure 8.7 Amplitude modulation of a single ^{13}C resonance extracted from a partially processed amplitude modulated 2D *J*-resolved experiment. The data set was subjected to the first Fourier transform to give a data set of the form $S[t_1, F_2]$ from which the data shown were extracted. Successive incrementation of the duration of the evolution period, t_1, leads to the amplitude modulation of the ^{13}C signal observed. The heteronuclear coupling information is encoded into the modulation frequency. Each peak in this horizontal stack plot is obtained for a different value of the evolution time, t_1. Generally, these data would be shown in a stack plot of the type shown in Figure 8.8. They are shown here as a simple horizontally plotted series of 256 spectra to emphasize the amplitude modulation of the carbon resonance.

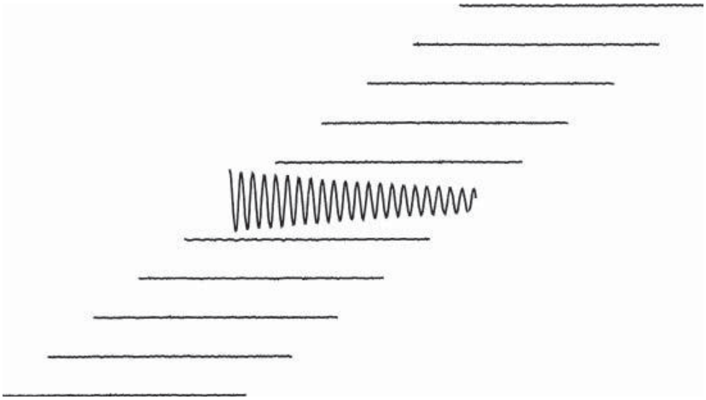

Figure 8.8 Interferograms from the region surrounding the amplitude modulated resonance shown in Figure 8.7. These data would correspond to transposition of the $S[t_1, F_2]$ data set to the form $S[F_2, t_1]$. Fourier transformation of the interferograms extracts the heteronuclear coupling information encoded into the amplitude modulation of the resonance, sorted by ^{13}C chemical shift. The final, Fourier transformed result of the amplitude modulated 2D *J*-resolved experiment is shown in Figure 8.9.

Transposition of the 2D data matrix, as defined by Eq. (8.4) allows us to look at the modulation of response intensity in the time domain, which is analogous to looking at a free induction decay (FID). These data are shown in Figure 8.8:

$$S(t_1, F_2) \longrightarrow s(F_2, t_1) \tag{8.4}$$

Completion of the second Fourier transform Eq. (8.5) gives the resulting 2D *J* spectrum, which is shown as a contour plot in Figure 8.9:

$$S(F_2, t_1) \longrightarrow s(F_2, F_1) \tag{8.5}$$

The data shown in Figure 8.9 were acquired for santonin (**1**). The ^{13}C chemical spectrum of the sesquiterpene is shown plotted along the F_2 axis. If a projection were done through the F_1 or second frequency domain, a so-called *J* spectrum would be obtained, which in this case is not especially useful. Each of the carbons contains, at its respective chemical shift in F_2, responses due to the scalar (*J*) couplings of that carbon. For protonated carbons, the larger spacing arises from the $^1J_{CH}$ coupling; the smaller spacings, when clearly resolved in this presentation, for example, the carbon near 80 ppm just downfield of the chloroform response, are a result of the $^nJ_{CH}$ coupling, where $n = 2$ or 3. The non-protonated carbons, for example, the two non-protonated vinyl carbons, exhibit responses centered on the axis $F_1 = 0$ Hz due to $^nJ_{CH}$ couplings but do not have larger $^1J_{CH}$ responses.

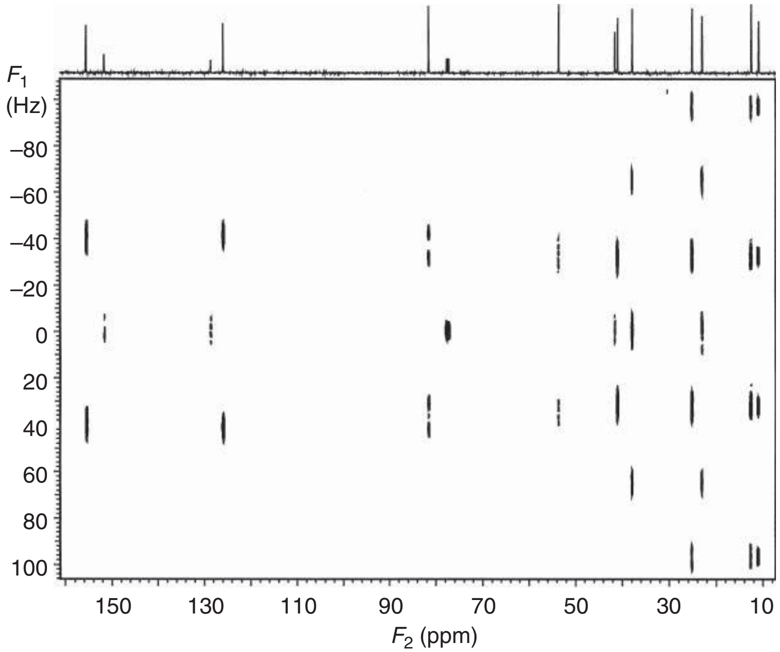

Figure 8.9 Contour plot of the amplitude modulated 2D *J*-resolved NMR spectrum of the simple alkaloid santonin (**1**) recorded at 400 MHz. The ^{13}C reference spectrum is plotted along the horizontal axis; the so-called *J* spectrum (not shown) is obtained by projection through the data matrix. Heteronuclear couplings are scaled by a factor of 2 since they evolve without decoupling for only half of the evolution period, t_1.

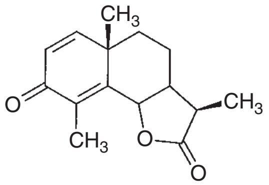

1

In addition to the use of *J* spectroscopy for $^1H-^{13}C$ heteronuclear coupling, there are also homonuclear variants of the experiment [76]. For the most part, however, the 2D *J*-resolved experiments have fallen into disuse as there are more efficient means of deriving the same spectral information.

8.3.2
Homonuclear 2D NMR Spectroscopy

There are probably, at present, about four homonuclear 2D NMR experiments in common usage for small molecules. These include COSY [46–48], TOCSY (total correlation spectroscopy) [77–79], NOESY [35, 36, 49–51], and ROESY

[35, 36, 52, 53], the latter two corresponding to nuclear Overhauser and spin-locked Overhauser correlated experiments, respectively. Several less frequently employed homonuclear 2D experiments are also possible and include: $^{13}C-^{13}C$ [68, 69]; ^{1}H double quantum spectroscopy [60–62], ^{1}H zero quantum spectroscopy [63–67], and others ^{H}H. We will discuss the primary experiments in the category briefly in turn, and we will direct the reader interested in other homonuclear 2D variants to the appropriate literature.

8.3.2.1 COSY, Homonuclear Correlated Spectroscopy

The COSY experiment was developed early in the history of 2D NMR [46–48]. Both frequency axes in the experiment are used to display proton chemical shift information in most cases. The actual proton spectrum of these experiments resides along the diagonal in the 2D spectrum. Individual proton resonances in the experiment are correlated to one another via scalar (*J*) coupling through off-diagonal correlation responses. Geminal ($^{2}J_{HH}$) and vicinal ($^{3}J_{HH}$) correlations will almost always be observed if the scalar coupling between the protons in question is of a reasonable size. Depending on the extent of digitization in the second frequency domain, weak vicinal couplings (those for protons whose couplings are weak because of Karplus considerations) and longer-range couplings may or may not be observed. The observation of weaker responses is also, in part, a function of the mathematical weighting functions used in processing the data. It is entirely possible through data processing procedures to retain or eliminate weak vicinal and longer-range proton–proton correlation responses.

The pulse sequence used for the COSY experiment is extremely simple, consisting of a pair of 90° pulses separated by the incremented evolution period, t_1, as shown in Figure 8.10. The incrementation of the evolution time is generally set to afford

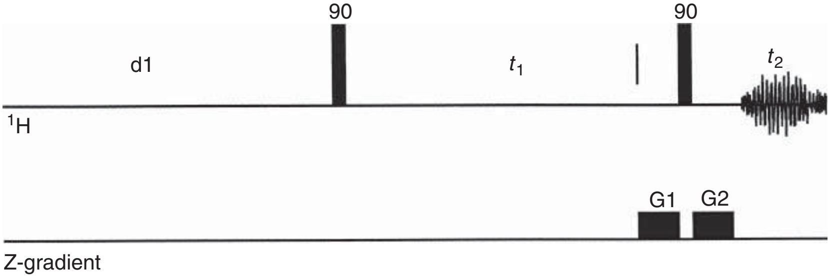

Figure 8.10 Pulse sequence for homonuclear correlation spectroscopy, COSY/GCCOSY [46–48]. Although the gradient version of the experiment is shown, the pulse sequences are the same except for the two gradients and their associated delays. The non-gradient experiment employs a four-step phase cycle; the gradient experiment allows the acquisition of data with a single transient/t_1 increment since the coherence transfer pathway is selected by the gradients. The proton spectrum appears along the diagonal of the diagonally symmetric data matrix. Correlations between scalar (*J*) coupled resonances are denoted by off-diagonal elements in the spectrum, as shown in Figure 8.11.

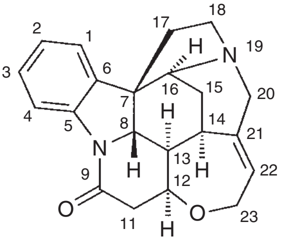
a square data matrix since it is desirable to have both frequency axes identical in homonuclear correlation experiments. In the case of macro-driven modern NMR instruments, setting the spectral width in the second frequency domain of an experiment like COSY is usually transparent. In general, for a survey experiment, it is useful to acquire perhaps 2K points in the observed time domain (t_2; 1K points after Fourier transformation) and similar to one-sixth as many points in the second time domain, t_1, as the transformed result in F_2. Generally, for a survey COSY experiment we find it convenient to acquire 128–160 files in the second time domain. After processing, these data will yield a spectrum in which geminal and most vicinal correlation responses will be observed. When weaker or long-range homonuclear correlation responses are sought, higher levels of digitization of t_1 are necessary, up to a maximum of half the number of points acquired in t_2.

Processing COSY data usually employs sinebell multiplication, with zero filling in the second frequency domain to yield a square data matrix. As an example, consider the COSY spectrum of the aliphatic region of strychnine (**2**) shown in Figure 8.11. The COSY data shown were acquired using the general survey conditions suggested above. The data are presented as a contour plot, which is analogous to a topographic map. *Peaks* are defined by contours; weak responses in the spectrum may be represented by one or only a few contour levels while stronger peaks may require numerous contours for representation. The diagonal in this presentation corresponds to the proton reference spectrum that is plotted above the contour plot. Protons in the molecular structure that are scalar coupled to one another are correlated in the experimental spectrum by the off-diagonal responses. Several correlation pathways are shown in Figure 8.11. A full discussion of the interpretation and or utilization of COSY data is beyond the scope of this treatment and the interested reader is referred to any of the monographs on the subject of 2D NMR cited in the introduction to this chapter. Briefly, however, referring to the H11α/β geminal proton resonances at 3.11 and 2.6 ppm, we note that these protons are correlated to one another in the spectrum with correlations also observed to the H12 proton resonating at 4.23 ppm. If one were to continue from the H12 correlation on the diagonal, in a step-wise fashion, the H13 methine resonance at 1.3 ppm could next be assigned, as shown in Figure 8.11. Continuing in this fashion, the contiguous proton spin system can be constructed as far as it is possible to follow correlations from one proton to the next, in principle to the H16 resonance.



2

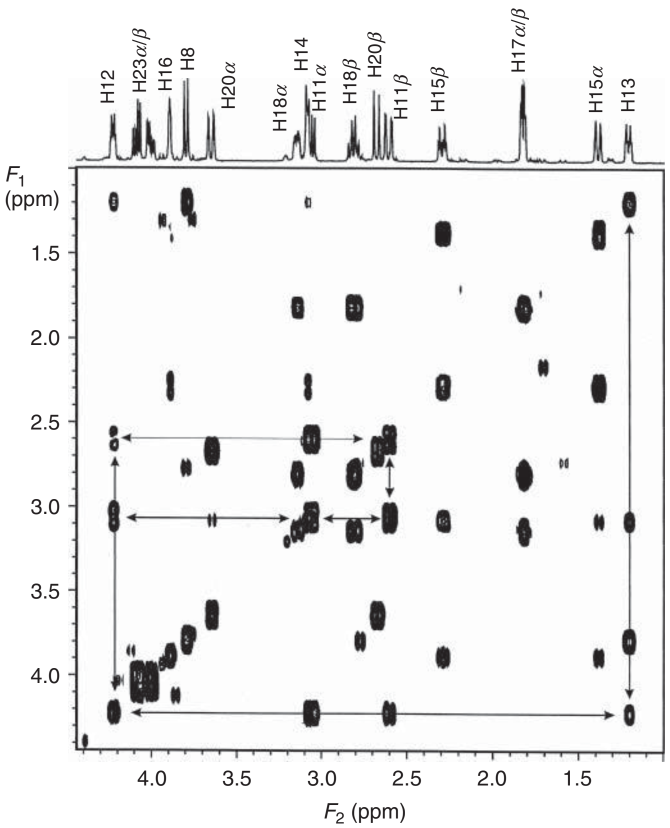


Figure 8.11 COSY spectrum of the aliphatic region of the strychnine (**2**) ^{1}H spectrum. Connectivities are shown from the anisochronous, geminal H11 resonances to H12, and in turn to the H13 resonance. The COSY spectrum is essentially the equivalent to the simultaneous acquisition of all possible selective homonuclear spin decoupling experiments. The COSY experiment has become one of the fundamental cornerstone experiments used in the determination of natural product structures and for many related structural studies.

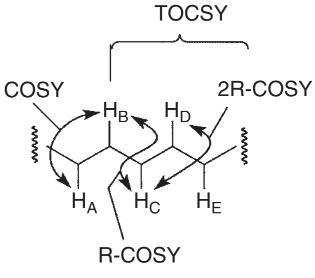
8.3.2.2 **Homonuclear TOCSY, Total Correlated Spectroscopy**

In an effort to extend the correlation ability of the COSY experiment just described, the relayed-correlated spectroscopy or R-COSY experiment [80, 81] was developed. While the COSY experiment correlates $H_A \rightarrow H_B$ in the hypothetical structural fragment shown by **3**, the R-COSY experiment ideally extends the correlation a step further $H_A \rightarrow H_B \rightarrow H_C$ via an additional delay following the evolution period and a 90° pulse. Double relayed-correlated spectroscopy or 2R-COSY is a trivial extension of the R-COSY experiment that repeats the relay process, giving correlation from H_A ultimately to H_D, assuming that the delays were set appropriately for the intervening homonuclear couplings. Likewise, the so-called long-range correlated spectroscopy or LR-COSY experiment [82] used a fixed delay to emphasize long-range homonuclear couplings in much the same sense as in long-range heteronuclear shift correlation experiments which are described below. The assemblage of experiments has been largely supplanted by a single experiment known as *homonuclear TOCSY*, which is the experimental amalgamation of the series of ideas just advanced.



3

The homonuclear TOCSY experiment [77, 79] utilizes the fundamental COSY pulse sequence and evolution time followed by a delay and then an isotropic mixing period; the pulse sequence is shown in Figure 8.12. Homonuclear vicinal coupling coherence is established during the evolution period; magnetization is propagated from the vicinal neighbor to its vicinal neighbor, and so on. The extent to which magnetization is propagated is a function of the mixing time and the size of the homonuclear coupling constants between the vicinally coupled protons in question. The longer the mixing time, the further magnetization is propagated through the contiguous homonuclear vicinal coupling network. Shorter mixing times, for example, ~12 ms for aromatic systems and 18–24 ms for aliphatic or alicyclic systems will establish correlations to protons one or two bonds removed from the starting resonance. In the case of **3**, shorter mixing times will establish correlations from H_A to protons as far removed as H_C or H_D depending on the size of the intervening homonuclear couplings. Longer mixing times, for example, 18–24 ms for aromatic compounds and 24–36 ms for aliphatic/alicyclic molecules will transfer magnetization still further. It should be remembered, however, that these are only approximations.

Returning to the example of strychnine (**2**), a 30 ms TOCSY spectrum of the aliphatic region of the proton spectrum at 500 MHz is shown in Figure 8.13. Again,

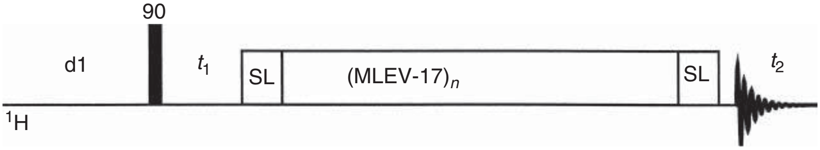


Figure 8.12 Homonuclear TOCSY pulse sequence [77–79]. Isotropic mixing is provided by a pulse train, and serves to propagate magnetization from a given proton to its scalar coupled neighbor. The extent to which coherence will be transferred along a series of coupled, homonuclear spins, is a function of the duration of the mixing time.

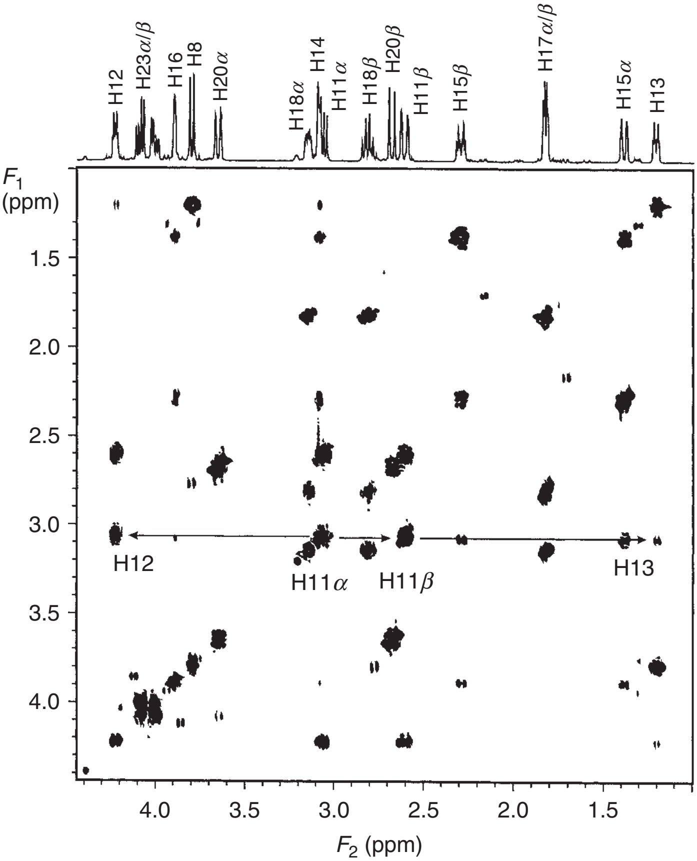

Figure 8.13 TOCSY spectrum of the aliphatic region of the strychnine (**2**) proton spectrum recorded with a mixing time of 30 ms. Correlations from the H11 protons are shown as in the COSY spectrum shown in Figure 8.11. The off-diagonal elements from the H11 resonances correlate them to each other (geminally) and to the H12 resonance as in the COSY spectrum. However, in addition, the 30 ms mixing time is long enough to propagate magnetization from the H11 resonances to H12 and then on to the H13 resonance.

starting from the H11 geminal methylene pair, correlations are established as far as H13 through the intervening protons.

8.3.2.3 NOESY, Nuclear Overhauser Enhancement Spectroscopy

The NOESY experiment is another of the homonuclear autocorrelated experiments in which both frequency axes display chemical shift information (usually ^{1}H, although ^{19}F experiments are certainly possible in perfluorinated compounds, and possibly ^{13}C for molecules biosynthesized using 1,2-^{13}C acetate). The experiment begins in a fashion analogous to the COSY experiment and again employs a

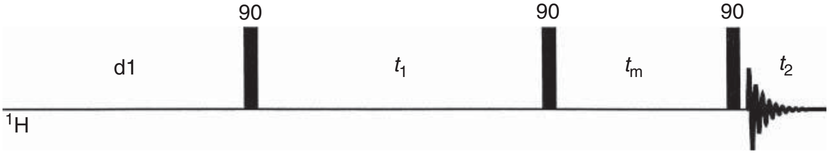

Figure 8.14 NOESY pulse sequence. The NOESY experiment is one which uses a mixing period, τ_m, in addition to the obligatory preparation, evolution, and detection periods. Protons are labeled with the individual chemical shifts during the evolution period, t_1. The mixing period, τ_m, allows dipolar cross relaxation to occur, which is detected with the final 90° pulse of the sequence. The duration of the mixing time is usually set to about $0.7T_1$, which corresponds to the null point when an inversion recovery T_1 relaxation measurement is done.

mixing period to permit the dipolar relaxation processes to occur, which are being sampled to correlate resonances (Figure 8.14) [35, 36, 49–51]. As noted above, a convenient means of establishing the duration of the mixing period is afforded from a simple spin–lattice (T_1) inversion–recovery relaxation experiment. The "null" point in the inversion–recovery experiment is $\sim 0.69T_1$, which is a useful rule-of-thumb for setting the duration of the mixing time in a NOESY experiment. The NOESY spectrum of strychnine (**2**) recorded with a 350 ms mixing time, is shown in Figure 8.15. Several brief observations concerning the spectrum shown are warranted. First, the relative orientation of the H12 resonance relative to the H11α and H11β protons is readily established from the data. In addition, it is also possible to establish a correlation across the oxepin ether linkage from the 11- to 23-position in the molecule. This affords new structural connectivity information, which is probably very difficult to obtain via a homonuclear scalar coupling, if it is observable at all.

8.3.2.4 **ROESY, Rotating Frame Overhauser Enhanced Spectroscopy**

The ROESY experiment combines ideas drawn from the TOCSY and NOESY experiments. Protons are correlated to one another via ROEs (rotating frame Overhauser effects) [35, 36, 52, 53]. ROEs are developed in the ROESY experiment through the use of a spin-locking field in a manner analogous to the propagation of magnetization in the homonuclear TOCSY experiment (Figure 8.16). The duration of the mixing time in a ROESY experiment can also be conveniently set from a simple inversion–recovery experiment. Recalling that the "null" point in the inversion recovery experiment is $\sim 0.69T_1$, the rough approximation of the average T_1 relaxation time for the proton(s) of interest can be easily determined. As a general rule of thumb, setting the mixing time in a ROESY experiment to $\sim 0.5T_1$ will generally provide usable data.

Again returning to strychnine (**2**) as a structural model, the ROESY spectrum with a mixing time of 250 ms is shown in Figure 8.17. Comparison of the correlations observed in the ROESY spectrum shows them to be qualitatively similar to those seen in the NOESY experiment shown in Figure 8.15.

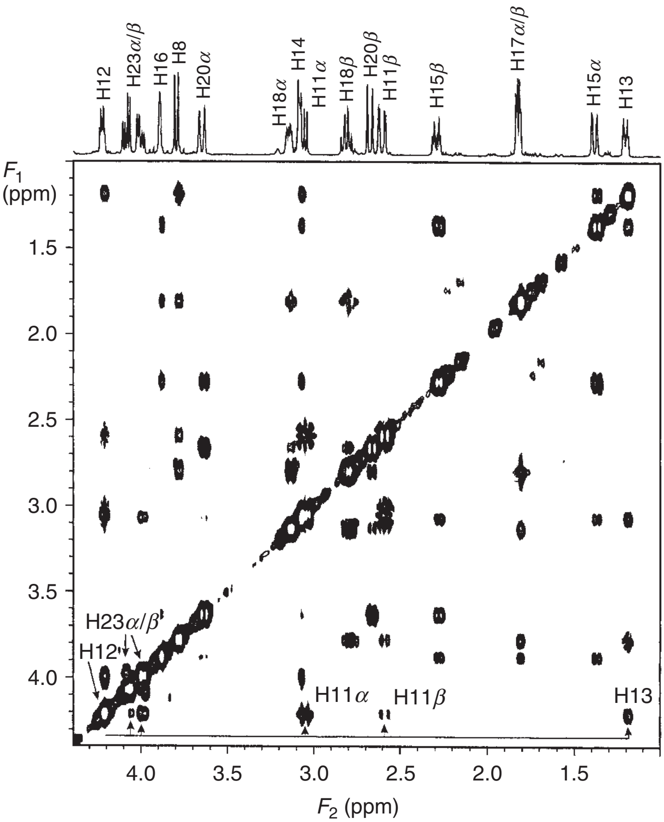

Figure 8.15 NOESY spectrum of the aliphatic region of the strychnine (**2**) proton spectrum recorded with a 350 ms mixing time. These data are useful, in establishing correlations between protons that are not scalar coupled, for example, the correlation between the 23- and 12-methine proton, as shown by the labeled connectivities in the spectrum. In addition, these data also show that the H12 methine and H13 methine resonance are located on the same side of the molecule. The more intense response of the 23- and 11-anisochronous methylene resonances are also located on the same side of the molecule, α, as the H12 resonance, providing a convenient means of differentiating and assigning these resonances.

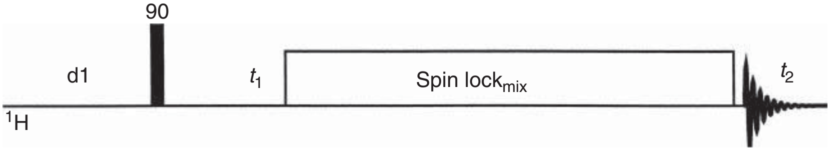

Figure 8.16 ROESY pulse sequence [35, 36, 52, 53]. Protons are labeled with their respective chemical shifts during the evolution time, t_1, as with the COSY and NOESY experiments. ROEs are developed by the isotropic mixing sequence applied during the mixing time, τ_m, which is generally set to about $0.5T_1$.

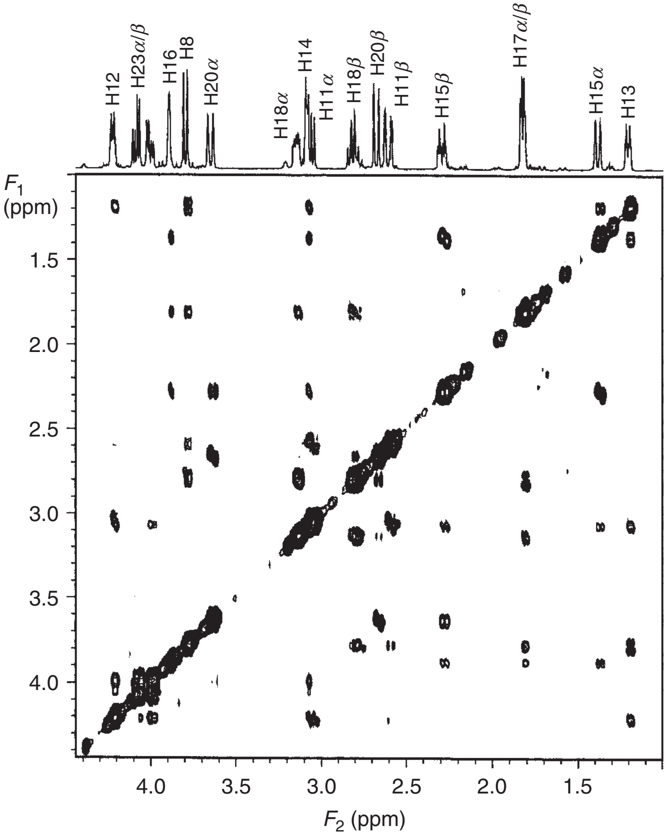

Figure 8.17 ROESY spectrum of the aliphatic region of strychnine (**2**) recorded with a 250 ms mixing time. The correlations observed and the assignment information which can be derived from them is the same as for the NOESY experiment presented in Figure 8.15.

8.3.2.5 **NOESY Versus ROESY**

The comparable responses in the NOESY and ROESY experiment obviously beg the question of which experiment is preferable? Dipolar relaxation processes are dependent on molecular motion (tumbling), as defined by the reorientational correlation time, τ_c. Very small molecules will generally afford quite usable NOESY spectra as they tumble quite rapidly in solution. Larger "small" molecules will generally reorient in solution more slowly; dipolar relaxation processes are consequently less efficient. Correspondingly, the size of the NOE response diminishes, making them more difficult to observe. Eventually, when molecules are large enough, they are tumbling slowly enough that the sign of the NOE is reversed and they begin again to exhibit progressively larger but negative NOEs. As a general guideline, when the molecular weight is approximately the same as the spectrometer observation frequency, NOEs will generally be weaker and more difficult to observed. In the intermediate condition, ROESY experiments, which rely on a spin-lock rather than being dependent on molecular tumbling, will still give reliable data. Fundamentally, there is no reason why ROESY experiments cannot be performed on very small molecules as well. The choice becomes one of preference and perhaps the prior experience of the spectroscopist doing the work.

8.3.2.6 **Other Homonuclear Autocorrelation Experiments**

In addition to the homonuclear autocorrelated experiments just described, there are numerous additional autocorrelated experiments, the description of which is beyond the scope of this chapter. What follows is a brief, non-exhaustive listing of some of these experiments that will provide the interested reader with some entry points into the literature.

Previous sections have exploited the scalar coupling, J, and dipolar relaxation mechanisms for purposes of autocorrelation. It is certainly possible, however, to correlate resonances via other fundamental processes. Some examples include exchange processes. As a group, these experiments are sometimes collectively referred to as *EXSY* experiments [54–59].

Resonances can also be correlated via multiple quantum frequencies. One seminal example is found in the work of Müller [83] in which heteronuclear multiple quantum coherence (HMQC) was used for heteronuclear shift correlation. We will discuss this further in the sections on heteronuclear shift correlation experiments later in this chapter. For homonuclear correlation of resonances via multiple quantum coherence, Freeman and co-workers pioneered the development of the $^{13}C-^{13}C$ INADEQUATE experiment [68, 69]. Remarkably, the INADEQUATE experiment allows an investigator to trace out the carbon skeleton of a molecule using adjacent $^{13}C-^{13}C$ resonant pairs at natural abundance. Unfortunately the statistical probability of such molecules in a sample is about 1 molecule in 10 000 at the natural abundance of ^{13}C which is $\sim 1.1\%$. Thus, $^{13}C-^{13}C$ INADEQUATE requires very large samples, frequently making the experiment inappropriate for natural product structure elucidation when sample sizes are limited.

Applying the idea of using multiple quantum coherence to correlate protons has also been explored. Mareci and Freeman [60] reported the first experimental demonstration of proton double quantum correlated spectroscopy. The F_2 axis in these experiments is used to present ^1H chemical shift in the usual fashion. In contrast, the F_1 axis is used for the double quantum frequency axis. Protons correlated to one another via double quantum coherence will exhibit a response in F_1 at the algebraic sum of the offsets of the coupled resonances relative to the transmitter frequency. A scant few applications have been reported including an exploratory study of strychnine (**2**) [61] and the structural characterization of the marine natural product plumericin [62].

Correlation in the second frequency domain using zero quantum coherence has also been described by Müller [63] and in work by Hall and co-workers [84–87]. Unlike higher quantum coherence experiments, zero quantum spectroscopy is insensitive to magnetic field inhomogeneities. Responses in the second frequency domain are observed at the zero quantum frequency, which is the algebraic difference of the coupled resonances relative to the transmitter. Again, only a scant few examples appear in the literature, including an exploratory study of strychnine (**2**) [64] and the characterization of several marine natural products [65]. One area of potential utility for zero quantum correlated spectroscopy is in the characterization of molecules with heavily congested proton spectra, for example, polynuclear aromatics [66, 67] although this area has yet to receive much attention from investigators.

8.3.3
Gradient Homonuclear 2D NMR Experiments

Traditionally, coherence transfer pathway selection has been accomplished by phase cycling routines. The desired components of magnetization are successively added to the memory storage location while undesired components are alternately added and then subtracted on subsequent scans such that at the end of the phase cycle they are ideally eliminated [88, 89]. The two most common phase cycling prescriptions are probably the CYCLOPS [90] and EXORCYCLE [91] routines. As an alternative to phase cycling, coherence transfer pathways can also be selected through the use of pulsed field gradients (PFGs) [92–94]. The gradient-selection procedure allows the selected coherence to remain in phase and the signal for it to thus be acquired while unwanted coherences are dephased and not detected. Essentially no, or minimal, phase cycling is required to generate largely artifact-free spectra. The spectral quality of gradient-selected experiments is not, however, without penalty. Since only one coherence transfer pathway is selected, other comparable pathways are not selected and thus do not contribute to the detected signal, resulting in a sensitivity loss when compared to phase cycle-based experiments [95]. This shortcoming of using gradients can be partially circumvented by using PEPs (preservation of equivalent pathways) methods as suggested in the work of Cavanaugh and co-workers [96–98]. When not severely sample limited (D.J. Russell, C.E. Hadden, and G.E. Martin, 1999, unpublished results) [99], the use of gradient NMR experiments is strongly recommended.

Gradient homonuclear 2D NMR experiments give results (albeit with the exception of noise) that are indistinguishable from phase-cycled experiments. Experiments such as GCOSY [100, 101] can be performed by accumulating a single transient per t_1 increment when not sample limited rather than using the obligatory four-step phase cycle of the conventional COSY experiment. A comparison of the COSY and GCOSY spectra of the aliphatic region of strychnine (**2**) recorded by accumulating 4 and 1 transient per t_1 increment, respectively, are shown in Figure 8.18. GTOCSY (gradient total correlation spectroscopy) [101–103], GNOESY (gradient nuclear Overhauser enhancement spectroscopy (also known as *GOESY*) [101, 104], and GROESY (gradient rotating frame Overhauser enhanced spectroscopy) [101–103] experiments can be performed with similar minimal phase cycling and corresponding time savings and reduced artifact response intensity. Gradient heteronuclear and gradient selective 1D NMR experiments are discussed below.

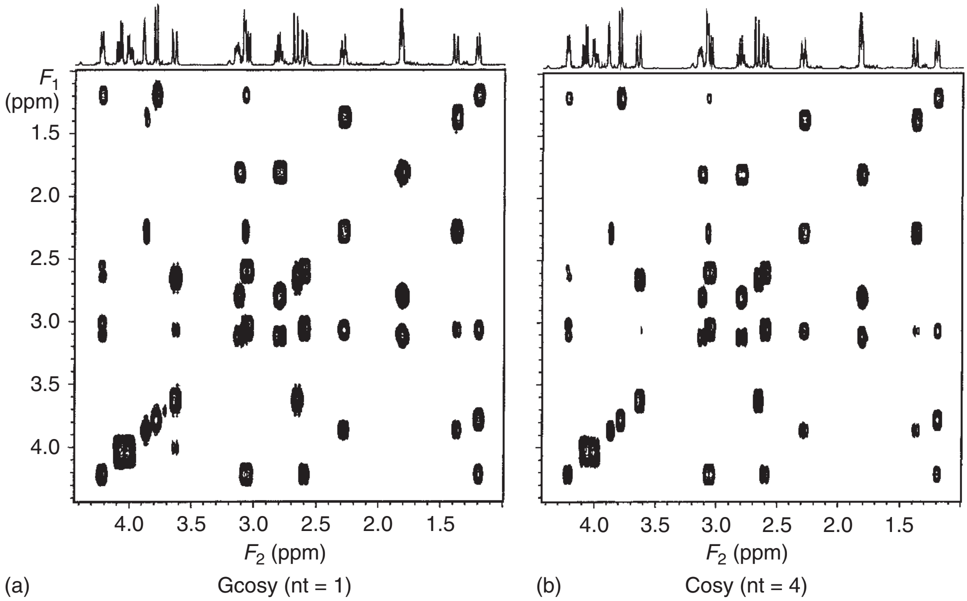

Figure 8.18 Comparative presentation of the GCOSY (nt = 1) (a) and COSY (nt = 4) (b) spectra of the aliphatic region of strychnine (**2**). The spectra differ only in that the former data were acquired by accumulating a single transient/t_1 increment while the latter required the acquisition of four transients/t_1 increment to satisfy phase cycling requirements.

8.3.4
Heteronuclear Shift Correlation

The development of heteronuclear 2D shift correlated spectroscopy began, indirectly, with the idea of "walking" the decoupler through the ^{1}H spectrum with the decoupler operating to collapse a single frequency while acquiring ^{13}C spectra. As successive experiments are recorded, each with the decoupler repositioned, resonances will begin to collapse from multiplets, will appear as a singlet when the decoupler is on resonance, and will then resume multiplet structures as the decoupler moves away again. The SPT (spin population transfer) experiments discussed above represented the next level of sophistication in this development saga. Finally, heteronucleus-detected 2D heteronuclear shift correlation experiments evolved through a series of steps that are discussed in chronological detail in the monograph by Martin and Zektzer [16].

Initially, heteronuclear shift correlation experiments exploited the large one-bond ($^1J_{CH}$) heteronuclear coupling to afford direct correlation spectra. Long-range heteronuclear shift correlation, via $^nJ_{CH}$ couplings was proposed but not experimentally realized in the visionary communication of Hallenga and van Binst [105]. It remained for Reynolds andco-workers in 1984 [106] to report the first experimental demonstration of this important experiment. Reynold's seminal report sparked a flurry of activity to develop new heteronucleus-detected long-range heteronuclear shift correlation experiments which were the topic of a 1986 review by one of the authors [107].

Heteronucleus-detected shift correlation experiments have now been largely supplanted by far more sensitive proton- or ''inverse''-detected methods. The heteronucleus-detected experiments are now largely reserved, in laboratories with modern NMR spectrometers, for those occasions when very high digital resolution is needed in the carbon frequency domain because of high spectral congestion [108, 109]. The remainder of this section will focus on the now widely utilized proton-detected heteronuclear shift correlation methods.

8.3.5
Direct Heteronuclear Chemical Shift Correlation Methods

The ''direct'' heteronuclear shift correlation experiments exploit the one-bond ($^1J_{CH}$) heteronuclear coupling as the basis of establishing chemical shift correlations. The concept of using multiple quantum coherence was developed by Müller in 1979 [83]; that of using single quantum coherence came out of the work of Bodenhausen and Ruben in 1980 [110].

8.3.5.1 HMQC, Heteronuclear Multiple Quantum Coherence

From the standpoint of experimental complexity, the HMQC experiment for direct correlation purposes is much simpler than the heteronuclear single quantum coherence (HSQC) experiment described below. The HMQC experiment has its origins in the work of Bax *et al.* in 1983 [111], which was directed at establishing $^1H-^{15}N$ correlations. The version of the experiment that came into common usage was that described by Bax and Subramanian in 1986 [112]. The gradient version of this experiment shown in Figure 8.19 was reported in 1991 by Hurd and John [115]. In general, the gradient version of the heteronuclear shift correlation experiment will be the preferred method, with the exception of very small samples, when it will be preferable to revert to the non-gradient version of the experiment to avoid signal losses associated with the use of the gradient methods [95, 99]. The topic of gradient heteronuclear shift correlation experiments was the topic of an early benchmark paper by Ruiz-Cabello and co-workers [113] and also of a more recent review by Parella [114]. The interested reader is referred to these excellent reports, to the various monographs cited in Section 8.1, or to the reviews cited in the section dealing with selective 1D experiments below.

Figure 8.19 shows the gradient version of the HMQC experiment since in most cases users will want to opt for the improved performance of the gradient experiment. Following a preparation period, HMQC (zero and double) is created by the 90° X-nucleus pulse applied at the initiation of the evolution period, t_1. Evolution occurs and the 180° ^1H pulse serves to refocus proton chemical shift evolution and interchanges zero and double quantum coherence terms. At the end of the evolution period, unobservable HMQC is reconverted to observable, antiphase single quantum coherence by the 90° X-nucleus pulse the ends the evolution

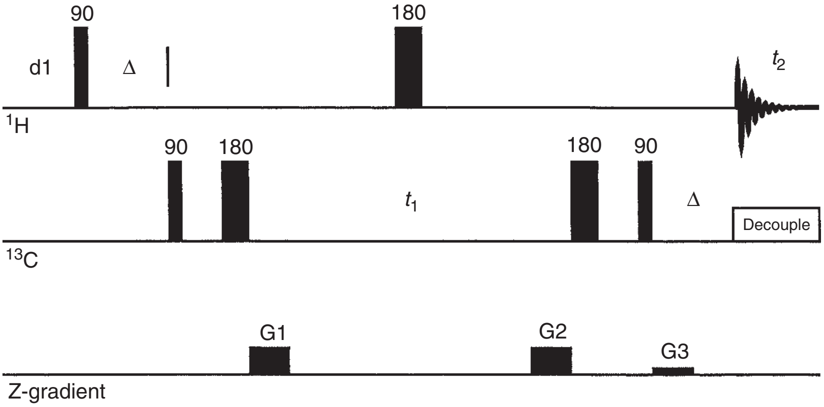

Figure 8.19 Schematic representation of the gradient heteronuclear multiple quantum coherence or GHMQC pulse sequence. The gradient version of this experiment now in use [115] is derived from the earlier non-gradient experiment described by Bax and Subramanian [112]. Coherence pathway selection is obtained by the application of gradients in a ratio of 2 : 2 : 1 as shown. Other ratios are also possible, as considered in the reports of Ruiz-Cabello *et al.* [113] and Parella [114]. The experiment creates heteronuclear multiple quantum coherence with the 90° ^{13}C pulse that precedes evolution. Both zero and double quantum coherences are created and begin to evolve through the first half of the evolution period. The 180° ^{1}H pulse midway through evolution interchanges zero and double quantum coherence terms in addition to "decoupling" proton chemical shift evolution during evolution. Antiphase proton single quantum coherence is recreated by the final 90° ^{13}C pulse which is then allowed to refocus before acquisition and the application of broadband heteronuclear decoupling. The GHMQC experiment is infrequently used in the author's laboratory relative to the GHSQC experiment which gives substantially better resolution in the second frequency domain [70, 116–118] (Figure 8.20, Figure 8.21, and Figure 8.22).

period. The three coherence pathway selection gradients are nominally applied in a 2 : 2 : ±1 ratio for ^{1}H–^{13}C heteronuclear shift correlation measurements and in a 5 : 5 : ±1 for ^{1}H–^{15}N correlation. (Note: other gradient ratios are possible, for example, 5 : 3 : 4 for ^{1}H–^{13}C, and so on. See the work of Ruiz-Cabello *et al.* [113] or that of Parella [114] for a further discussion on this point.) At this point, the antiphase proton single quantum coherence is labeled with the chemical shift of the directly bound ^{13}C. Magnetization is refocused and acquisition and broadband heteronuclear decoupling are initiated simultaneously.

The HMQC/GHMQC (gradient heteronuclear multiple quantum coherence) experiments are quite useful and were treated in an early review by Martin and Crouch [71]. Relative to the single quantum variant of the experiment discussed below, the effective F_1 resolution of the multiple quantum experiment suffers due to homonuclear coupling modulation during the evolution period, which leads to broadened responses being observed in the F_1 dimension. The difference in the effective resolution of the HMQC versus HSQC experiments was noted in a review on applications of inverse-detection in alkaloid chemistry by Martin and Crouch [70] and has since been treated in more detail by Reynolds and others [116–118]. On this basis, the HSQC/GHSQC (gradient heteronuclear single quantum coherence) experiments discussed in the following section should be preferentially used on a routine basis in the opinion of the authors.

8.3.6
HSQC, Heteronuclear Single Quantum Coherence Chemical Shift Correlation Techniques

The idea of heteronuclear single quantum coherence experiments derives from the early work of Bodenhausen and Ruben [110]. The contemporary variant of their experiment is shown in Figure 8.20. The fundamental concept of the experiment, regardless of refinements to augment the performance of the experiment, is unchanged. The experiment utilizes an INEPT step to transfer single quantum magnetization from proton to the heteronuclide immediately prior to the beginning of the evolution time. During evolution chemical shift labeling for the heteronuclide occurs; proton chemical shift evolution is reversed by the 180° ^{1}H pulse applied midway through the evolution period. Following evolution, magnetization is transferred back to the protons and refocused to allow data acquisition with broadband decoupling.

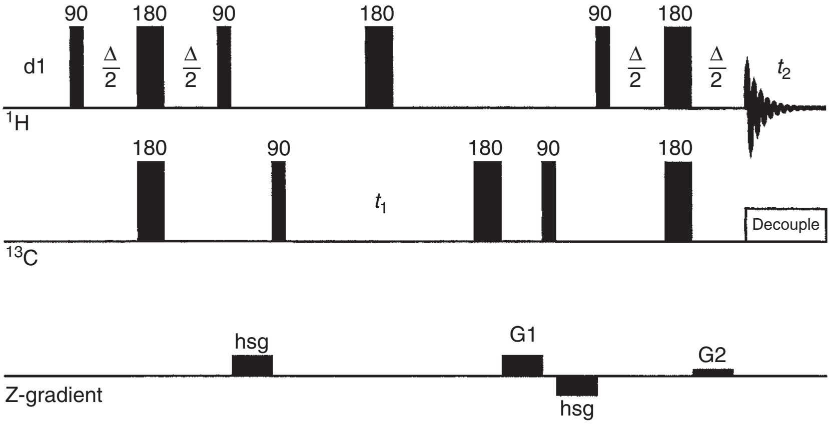

Figure 8.20 Schematic representation of the gradient heteronuclear single quantum coherence or GHSQC pulse sequence. The non-gradient version of this experiment was described originally by Bodenhausen and Ruben [110]. Heteronuclear single quantum coherence is created by the first INEPT segment of the experiment which evolves during the evolution period, t_1. The reverse INEPT step following evolution converts the heteronuclear single quantum coherence to proton single quantum coherence which is then detected. The gradient version of the experiment currently in use in the author's laboratory is shown. While phase-sensitive, the experiment offers only about half the sensitivity of the non-gradient variant since only one of the two equivalent coherence pathways is selected by the simple gradient version of the experiment [95]. More complex variants of the experiment developed by Cavanaugh and co-workers [96–98] utilize a technique known as *preservation of equivalent pathways* or PEP to recover both coherence pathways giving a $\sqrt{2}$ improvement in signal-to-noise for methine resonances.

The gradient or GHSQC version of the experiment applies a pair of gradients rather than the three gradients used in the GHMQC experiment (Figure 8.19). Gradients are applied in the ratio of 4 : 1 for $^1H-^{13}C$ heteronuclear correlation. The first gradient, G1, is applied during the evolution period while the second gradient, G2, is applied during the final refocusing delay following the 180° pulse sandwich just prior to acquisition. More sophisticated variants of the experiment use a process known as *PEPs* [96–98] to record high sensitivity, phase-sensitive 2D HSQC spectra. The PEP variant of the experiment employs a second reverse INEPT "block" to reclaim both orthogonal components of magnetization thereby giving a $\sqrt{2}$ improvement in signal-to-noise. The phase of one of the 90° X-pulses and that of the G2 gradient are inverted on alternate scans and the data are stored separately to provide a phase-sensitive final result.

The phase-sensitive GHSQC spectrum of strychnine is shown in Figure 8.21a.

8.3.6.1 Multiplicity-Edited Heteronuclear Shift Correlation Experiments

Heteronuclear chemical shift correlation methods establish the direct link between protons and the respective, directly attached carbons (or nitrogens). In the case of methylenes with inequivalent (anisochronous) protons, the "multiplicity" of the carbon in question is irrefutably obvious. For isotropic methylenes and other resonances, the multiplicity of the resonance (CH, CH_2, or CH_3) in question may be less obvious. Early work by Kessler and co-workers [119] addressed this issue via the development of the DEPT–HMQC experiment. Multiplicity editing is also available for experiments such as GHSQC. An extra pair of delays and pulses, with the flip angle of the proton pulse being adjustable, allow the acquisition of data in which the response phase is indicative of resonance multiplicity [120–122]. The multiplicity-edited GHSQC sequence presently in use in the author's laboratory is shown in Figure 8.22; the framed segment of the pulse sequence provides the multiplicity editing. Adjusting the flip angle α of the proton pulse to 180° affords a spectrum in which the phase of the methine/methyl resonances is opposite to that of the methylenes. By setting the "adjustable" pulse to $\alpha = 90^\circ$ a spectrum containing only methine resonances is obtained. The multiplicity-edited GHSQC spectrum of the aliphatic region of the spectrum of strychnine (**2**) is shown in Figure 8.21b; responses plotted in red denote inverted methylene resonances while black responses denote positive methine resonances (there are no methyl groups in strychnine).

8.3.6.2 Accordion-Optimized Direct Heteronuclear Shift Correlation Experiments

Following the development of accordion-optimized long-range heteronuclear shift correlation experiments (Section 8.3.7.3), Hadden and Angwin [123] have recently reported the development of an accordion-optimized direct correlation experiment, accordion-optimized direct correlation single quantum coherence (ADSQC). Additionally, Zannger and Armitage [124] also reported the accordion-HMQC experiment. These experiments provide a convenient means of circumventing the choice of optimization in the direct correlation experiments. Under most

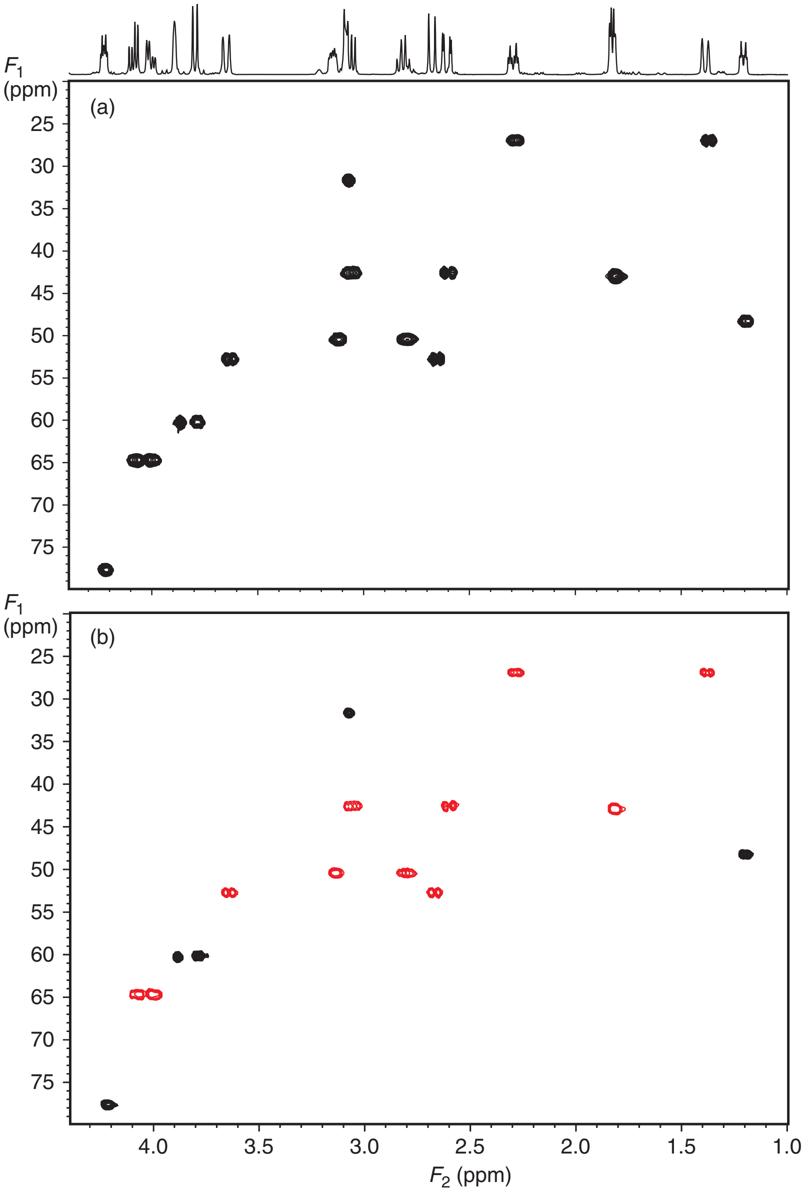

Figure 8.21 (a) GHSQC spectrum of the aliphatic region of the strychnine (**2**) spectrum recorded using the pulse sequence shown in (b). Multiplicity-edited GHSQC [119–122] spectrum of strychnine showing methylene resonances in red and opposite in phase from methine and methyl resonances that are shown in black (no methyls are in the strychnine structure). These data were acquired using the pulse sequence shown in Figure 8.22 with the multiplicity editing step following the reverse INEPT portion of the experiment.

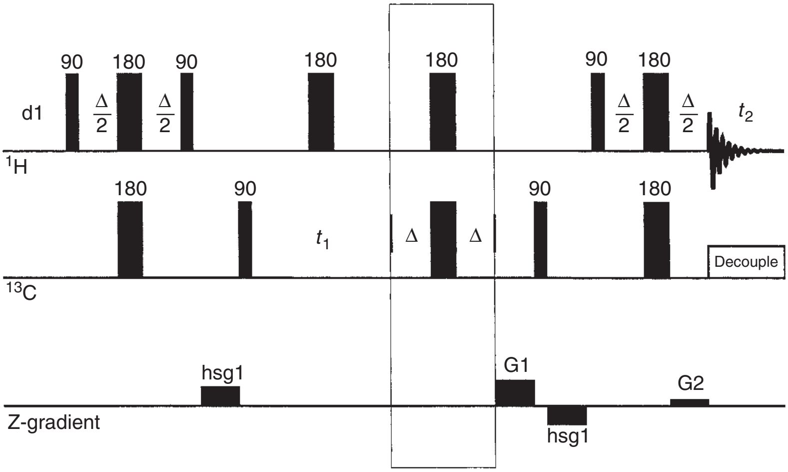

Figure 8.22 Schematic representation of the multiplicity-edited GHSQC pulse sequence in use in the author's laboratory with the multiplicity editing step following the evolution period [119–122].

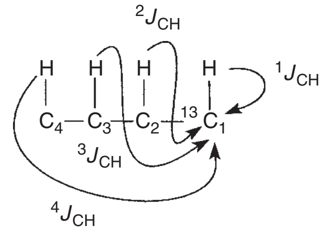
circumstances a one-bond correlation experiment is not problematic; survey optimization of the one-bond delays for ∼140 Hz provides quite reliable results. However, molecules containing some heterocyclic moieties, for example, furans and other species having proton–carbon pairs with exceptionally large one-bond coupling constants may fail to give direct correlation responses under standard survey conditions. As an example, the two-position of furan has a 208 Hz $^1J_{CH}$ coupling that reproducibly fails to give a direct correlation response under standard survey conditions. By optimizing the ADSQC or accordion-HMQC over a range of one-bond couplings, for example, 120–210 Hz, this problem can be avoided.

8.3.7
Long-Range Heteronuclear Chemical Shift Correlation

Successful exploitation of the use of one-bond ($^1J_{CH}$) heteronuclear coupling constants in the development of direct heteronuclear shift correlation experiments in the late 1970s prompted the visionary suggestion of Hallenga and van Binst [105] in 1980 of doing the same experiment using instead the long-range heteronuclear coupling, $^nJ_{CH}$. Unfortunately, the long-range heteronuclear chemical shift correlation experiment was not realized in their seminal work. Rather, it remained for Reynolds and co-workers [106] in 1984 to demonstrate experimentally the viability of long-range heteronuclear chemical shift correlation experiments.

Reynolds' initial report sparked the development of numerous long-range heteronuclear shift correlation experiments that continued through about 1986. Experiments developed included the constant time correlation by long-range coupling (COLOC) experiment [125, 126], experiments designed to decouple one-bond modulation effects [127, 128], and the XCORFE experiment of Reynolds and co-workers

[129] that allowed the differentiation of $^{2}J_{CH}$ from $^{3}J_{CH}$ long-range couplings to protonated carbon resonances (**4**). The heteronucleus-detected long-range shift correlation experiments are the topic of a 1986 review by Martin and Zektzer [107].



4

Bax and Summers [130] 1986 report of the proton-detected heteronuclear multiple bond correlation (HMBC) experiment essentially ushered to a close the development of new, heteronuclide-detected long-range chemical shift correlation experiments. Aside from the development of a gradient-enhanced heteronuclear multiple bond correlation (GHMBC) experiment [131, 132] there was a nearly decade-long hiatus in the development of new, inverse-detected, long-range heteronuclear shift correlation methods. More recently, the reported development of new proton-detected long-range experiments has resumed and is treated briefly in the following sections of this chapter.

The increase in sensitivity afforded by the proton-detected HMBC experiment revolutionized structure elucidation studies. The utilization of HMBC data in the characterization of alkaloid structures has been reviewed [70] and is also treated in a more general review of the application of inverse-detected methods in natural products structure elucidation [71]. Other applications of the experiment are quite numerous and any complete survey is beyond the scope of this chapter. It should also be noted here that within the past five years it has become feasible to perform long-range $^{1}H-^{15}N$ heteronuclear shift correlation experiments at natural abundance, which is the subject of a recent review by two of the authors [72].

8.3.7.1 **HMBC, Heteronuclear Multiple Bond Correlation**

The original pulse sequence for the HMBC experiment, as reported in 1986 by Bax and Summers [130] is shown in Figure 8.23a. The sequence begins with a pulse sequence operator known as a *low-pass J-filter*. Alternatively, dual stage gradient low-pass *J*-filters [133, 134] or double pulsed field gradient spin echoes (DPGSEs) [135] can be substituted for the low-pass *J*-filter and afford substantially better suppression of residual direct response signals. This component of the experiment is designed to remove unwanted direct correlation responses. While the 90° X-pulse in the low-pass *J*-filter is phase cycled as 0022, the receiver phase is cycled 0202, which effectively adds and subtracts the unwanted direct response component of magnetization. The first delay, Δ, is optimized as a function of $1/2(^{1}J_{CH})$. The second 90° X-pulse, which is applied after a delay, δ, of $1/2(^{n}J_{CH})$, where $n = 2$ or 3 and corresponds to an optimization in the range of 6–10 Hz, creates heteronuclear zero and double quantum coherence that begins to evolve through the evolution

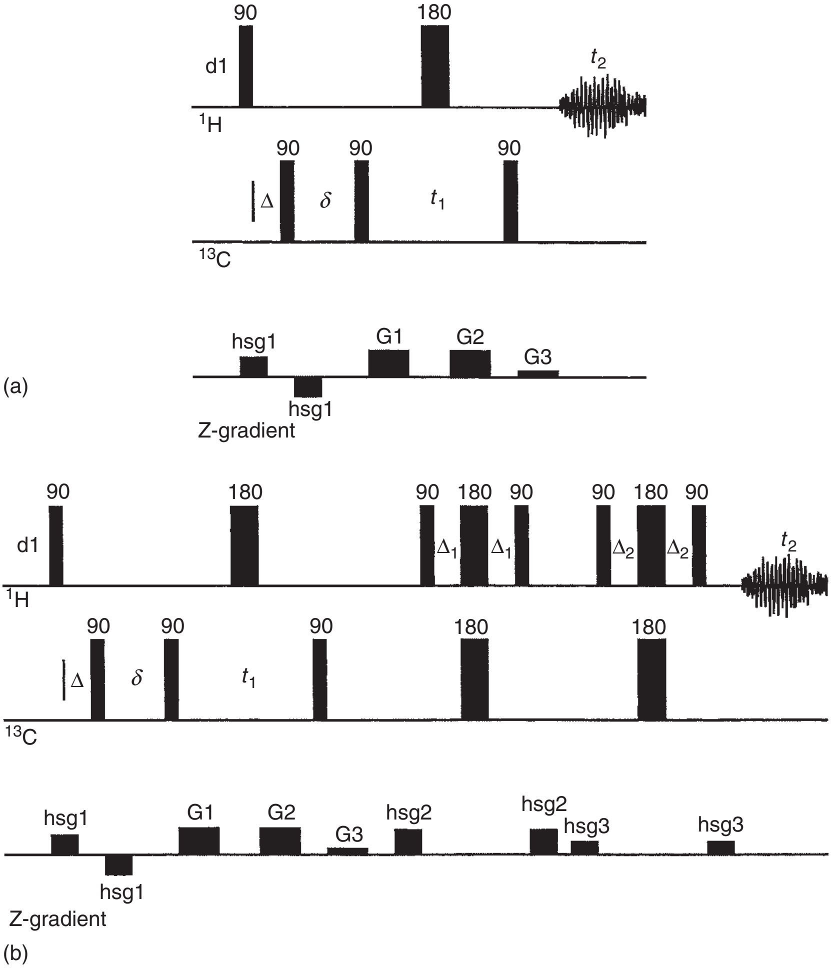


Figure 8.23 (a) Schematic representation of the original HMBC experiment of Bax and Summers [130]. The experiment begins with a low-pass *J*-filter. The phase of the first 90° ^{13}C pulse is alternated 0202 while the receiver phase is cycled as 0022. In this fashion, the magnetization arising from the direct correlation responses is alternately added and subtracted in memory and ultimately canceled. Much like the HMQC experiment, HMBC creates zero and double quantum coherences but does so for the long-range couplings rather than the direct couplings. Given that long-range couplings are typically in the range of about 6–10 Hz, delays in the range from 83 to 50 s, respectively, are typical. The HMBC experiment has been largely replaced by the gradient or GHMBC experiment [125, 126] in many NMR laboratories. (b) The version of the GHMBC experiment currently in use in the author's laboratories is shown here and employs a double pulsed field gradient spin echo (DPFGSE) [135] to suppress the residual, unwanted direct correlation responses. For very weak samples, recent work has shown that it is actually preferable to utilize the non-gradient phase cycled version of the HMBC experiment rather than the newer gradient versions of the experiment [99].

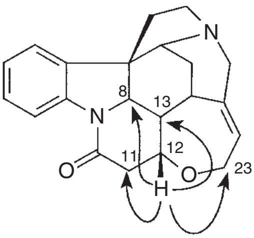
period, t_1. The 180° ^{1}H pulse interchanges zero and double quantum coherence terms and simultaneously removes proton chemical shift evolution. The last 90° X-pulse pulse converts the HMQCs back into observable single quantum coherence, which is then detected. Gradient versions of the experiment were developed in the early 1990s by Willker and co-workers [131] and by Rinaldi and Keifer [132] and are now generally used *in lieu* of the original, non-gradient version of the experiment (Figure 8.23b).

The aliphatic region of the 6 Hz optimized GHMBC spectrum of strychnine is shown in Figure 8.24a. In the specific case of the H-12 resonance of strychnine, only a single long-range correlation of the several possible long-range couplings (shown in **5**) is observed in the spectrum. We will use the H12 correlations as a performance comparison for several of the more recently developed, accordion-optimized long-range experiments described below. Correlations which predominate in HMBC/GHMBC spectra are $^2J_{CH}$ and $^3J_{CH}$ with $^4J_{CH}$ long-range correlations observed only occasionally. In the specific case of strychnine, four $^4J_{CH}$ couplings are typically observed in the 10 Hz optimized GHMBC spectrum.



5

Structure elucidation strategies that employ long-range heteronuclear shift correlation experiments generally use the correlations observed to position quaternary atoms relative to protonated carbon fragments, for example, in the case of a correlation from H-12 to the C-8 quaternary carbon, or to bridge heteroatoms, for example, the correlation from H-12 to C-23 across the oxepin ether linkage, as shown above.

Figure 8.24 (a) GHMBC experiment recorded using the gradient variant of the pulse sequence shown in Figure 8.23a. The spectrum shown is the aliphatic region of the strychnine (**2**) spectrum; the long-range delays in the GHMBC sequence delays in the experiment were optimized for 6 Hz. Note that for the H12 resonance (furthest downfield at 4.27 ppm) only one response is observed in the data shown, which correlates H12 to C8. Care must be exercised when interpreting weak responses in HMBC/GHMBC experiment such as that denoted with the arrow that correlates the H18a resonance via two bonds to C17. (b) Data from a 6–10 Hz optimized ACCORD-HMBC (Figure 8.25) experiment [136, 134] for the same region of the strychnine (**2**) spectrum. The ability to sample a broad range of potential long-range couplings in a single experiment is well demonstrated by these data. When compared to the GHMBC spectrum shown in Figure 8.24a, the H12 resonance, for instance, shows four correlation responses. While the H18a–C17 correlation response was weak in the GHMBC data, it is now quite strong. Furthermore, the characteristic F_1 "skew" of the ACCORD-HMBC data provides a convenient means of response authentication: legitimate long-range correlations will be skewed, making them readily distinguishable from weak noise peaks. 8.3.7.2 Variants of the Basic HMBC Experiment

Beginning in 1995, a number of reports of variants of the HMBC/GHMBC experiment began to appear. The inclusion of a refocusing delay to allow broadband decoupling during acquisition was described by Bermel *et al.* [137]; Furihata and Seto [138] subsequently described this experiment giving it the acronym D-HMBC experiment, apparently unaware of the prior work by Bermel *et al.* A report of a pseudo-3D variant followed, each plane of the third dimension having a different long-range optimization [139]. Projection of the F_2/F_3 plane gave, albeit rather inefficiently, the equivalent of an accordion-optimized spectrum. Marek and coworkers [140] described a phase-sensitive single quantum long-range experiment, GSQMBC, that allowed in the case of some multiplets, the measurement of long-range heteronuclear couplings. Another phase-sensitive method was reported in 1998 by Sheng and van Halbeek [141] for the purpose of extracting long-range heteronuclear couplings. Later in 1998, Furihata and Seto [142] described several constant time variants of the basic HMBC experiment in an effort to suppress homonuclear coupling modulations that arise during the incrementation of the evolution time, t_1. These experiments set the stage for the subsequent development of accordion-optimized long-range experiments.

8.3.7.3 Accordion-Optimized Long-Range Heteronuclear Shift Correlation Methods

The idea of accordion-optimization is by no means new [143]. The idea of applying this method to the optimization of the long-range delay of HMBC-type experiments, however, was only reported in 1998 by Wagner and Berger [136] in their description of the ACCORD-HMBC experiment. The ACCORD-HMBC pulse sequence is shown in Figure 8.25. Quite simply, the ACCORD-HMBC experiment is governed by the limits $1/2^nJ_{\text{min}}$ to $1/2^nJ_{\text{max}}$, which correspond to τ_{max} to τ_{min}, respectively. As the evolution time, t_1, is systematically incremented, the duration of the variable delay, Vd, is decremented from τ_{max} to τ_{min} in increments of $(\tau_{\text{max}} - \tau_{\text{min}})/n_{\text{i}}$, where n_{i} is the number of increments of the evolution period. In this fashion, the ACCORD-HMBC experiment essentially integrates across a range of potential long-range couplings, allowing the complete range to be sampled in a single experiment.

A drawback of accordion-optimization of the long-range delay in the ACCORD-HMBC experiment is F_1 "skew" caused by homonuclear coupling modulation occurring during the variable delay, which serves as a pseudo-evolution period for these processes [134]. Conversely, F_1 skew also serves as a determinant of response authenticity for weak long-range responses since noise or other random signals cannot exhibit F_1 skew.

Comparison of the performance of a statically optimized GHMBC (i.e., optimized for a single value of the long-range delay) experiment with ACCORD-HMBC is shown by comparing the spectral segments shown in Figure 8.24. The 6 Hz optimized GHMBC results are shown in Figure 8.24a. A single correlation from the H12 resonance is observed in this data. In contrast, for the 6–10 Hz optimized ACCORD-HMBC spectrum presented in Figure 8.24b, four correlations, those shown by **5**, are observed from the H12 resonance. In addition, some correlations, such as the H18a–C17 correlation, which is observed with weak response intensity

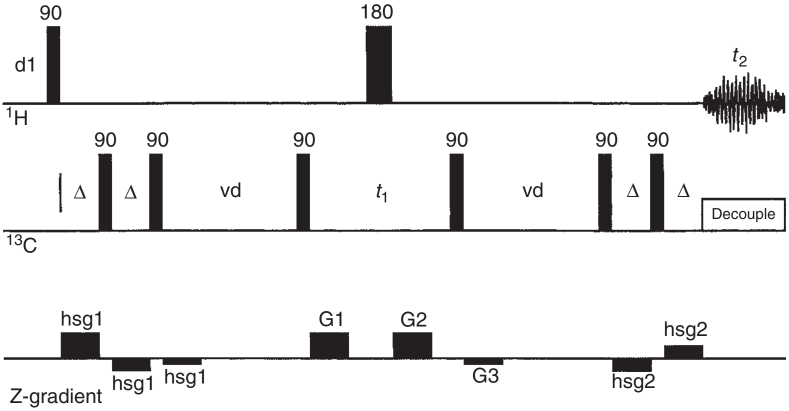

Figure 8.25 Pulse sequence schematic for the ACCORD-HMBC experiment pioneered by Wagner and Berger [136]. The experiment begins with a gradient dual-stage low-pass *J*-filter to suppress unwanted direct correlation responses. A variable duration delay, Vd, follows, the duration of which is decremented from $1/2^nJ_{\text{min}}$ to $1/2^nJ_{\text{max}}$ (τ_{max} and τ_{min}, respectively) in successive increments of the evolution time, t_1. In this fashion, all possible long-range couplings in the user-selected range are sampled in a single experiment. The 90° ^{13}C pulse following the variable delay functions in the usual fashion to create heteronuclear zero and double quantum coherences which are manipulated as in the HMBC/GHMBC experiment (Figure 8.23). To allow broadband heteronuclear decoupling during acquisition, Wagner and Berger originally proposed a symmetric experiment so that all long-range couplings are refocused immediately prior to acquisition. In practice, we have found that it is actually desirable to initiate acquisition following the final coherence pathway selection gradient to avoid potential signal losses due to the long, variable delay.

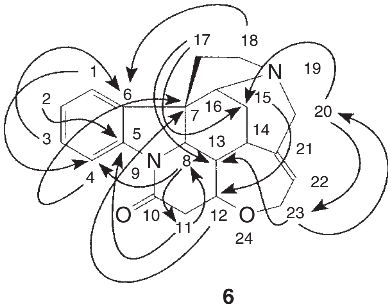
in the 6 Hz optimized GHMBC spectrum, are observed with much better response intensity in the accordion-optimized experiment.

An ACCORD-HMBC spectrum of the aliphatic region of strychnine optimized over the range 2–25 Hz is shown in Figure 8.26. It is interesting to note that while only four $^4J_{\text{CH}}$ long-range couplings are observed in the 10 Hz GHMBC spectrum of strychnine, 17 such couplings are observable in this very aggressively optimized ACCORD-HMBC spectrum, as shown in **6** [134].



6

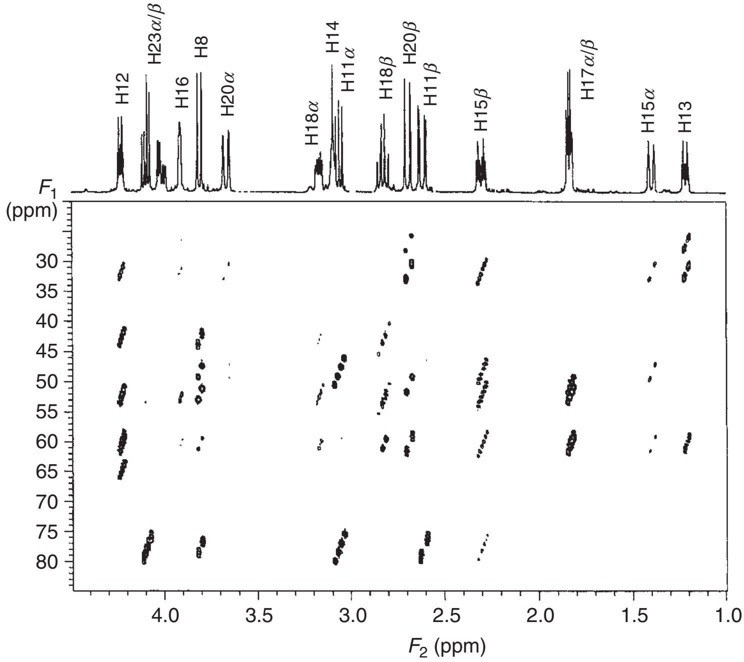


Figure 8.26 Results of an aggressively optimized 2–25 Hz ACCORD-HMBC experiment performed on strychnine (**2**) are presented here. Such data might be used when it becomes necessary to resort to relatively uncommon four-bond (${}^{4}J_{\mathrm{CH}}$) long-range couplings to solve a structural problem. In the 10 Hz optimized GHMBC spectrum of strychnine (**2**) a total of four four-bond long-range couplings are observed. In contrast, the 2–25 Hz ACCORD-HMBC experimental data shown identified 17 four-bond long-range couplings as shown by **6**. (Reproduced with permission – Wiley-VCH.)

Homonuclear coupling modulation during the variable delay in the ACCORD-HMBC experiment prompted the development of a constant time variable delay to replace the simple variable delay in the ACCORD-HMBC experiment. This pulse sequence element was incorporated into the IMPEACH-MBC (improved performance accordion heteronuclear multiple bond correlation) experiment [144]. The constant time variable delay segregates the manipulation of homo- and heteronuclear components of magnetization. First, by keeping the overall duration of this pulse sequence operator constant, homonuclear coupling modulation can be made to occur in constant time, thereby rendering the effect of this modulation unobservable. This then requires a modification of the delay to maintain its variable character for long-range heteronuclear couplings. This task is accomplished by adding a second variable delay, D, within the overall constant time variable delay which contains the following element:

$$\begin{array}{l} D/2 - 180^{\circ}\,{}^{13}\mathrm{C} - D/2 - \mathrm{Vd} \\ |\longleftarrow\ {}^{n}J_{\mathrm{CH}}\ \text{refocused}\ \longrightarrow|\longleftarrow\ {}^{n}J_{\mathrm{CH}}\ \text{evolves}\ \longrightarrow| \end{array} \tag{8.6}$$

The variable delay, D, is halved about a 180° ^{13}C pulse which serves to refocus $^{n}J_{CH}$ components of magnetization at D. These same components of magnetization then experience a variable delay, Vd, during which they are sampled. The accordion range is determined as in the ACCORD-HMBC experiment. However, as the duration of Vd is decremented from τ_{max} by $(\tau_{max} - \tau_{min})/n_i$, rather than allowing the overall duration of the delay to be decremented, the interval $[(\tau_{max} - \tau_{min})/n_i]/2$ is instead added to each of the $D/2$ intervals keeping the total duration constant. Thus, while homonuclear coupling processes evolve in a constant time, $^{n}J_{CH}$ components of magnetization are refocused at D and evolve only during the variable delay, Vd, thereby eliminating F_1 skew with the exception of that which arises due to the incrementation of the evolution period, t_1, which is identical to what one observes in the HMBC/GHMBC experiments.

While uncontrolled F_1 response skew of the type encountered in the ACCORD-HMBC experiment is undesirable [134], user-defined F_1 skew can be a useful determinant of response authenticity. A further generation accordion-optimized long-range experiment, CIGAR-HMBC (constant time inverse-detected gradient accordion rescaled long-range heteronuclear multiple bond correlation), was developed to provide this flexibility. The constant time variable delay from the IMPEACH-MBC experiment was further modified as follows:

$$(D/2 + \Delta2/2) - 180^{\circ}\,{}^{13}\mathrm{C} - (D/2 + \Delta2/2) - \mathrm{Vd} \qquad (8.7)$$

The range of optimization is defined as in the previous experiments; Vd is decremented and D is incremented as in the IMPEACH-MBC experiment [144]. The interval $\Delta2$ is used to provide user-defined F_1 skew. The CIGAR-HMBC experiment uses a new parameter J_{scale} to control the extent of F_1 skew introduced [145]. The duration of $\Delta2$ is incremented by the interval $(J_{scale} - 1)t_1$. There are three possible conditions: $J_{scale} = 0$, 1, >1. When $J_{scale} = 0$, the interval $\Delta2$ will actually be decremented as the evolution time, t_1 is incremented, keeping the total duration of the experiment completely constant. This results in the suppression of homonuclear coupling modulation occurring during the incremented evolution period and gives the highest possible F_1 resolution as in the CT-HMBC experiment described by Furihata and Seto [142]. When $J_{scale} = 1$, results identical to an IMPEACH-MBC experiment are obtained. Finally, and most interestingly, when $J_{scale} > 1$, the overall duration of the modified constant time variable delay becomes ''non-constant'' in a user-defined manner. Incrementation of the $\Delta2/2$ intervals in the experiment reintroduces F_1 skew to a user-determined extent. The degree of F_1 skew is determined by the setting of the parameter J_{scale} as illustrated in Figure 8.27.

8.3.7.4 ^{2}J,^{3}J-HMBC

The most sophisticated accordion-optimized long-range shift correlation experiment to be developed to date is the ^{2}J,^{3}J-HMBC experiment [146]. For the first time in an inverse-detected experiment, it is possible to differentiate two-bond from three-bond long-range correlations to protonated carbon or nitrogen resonances. This

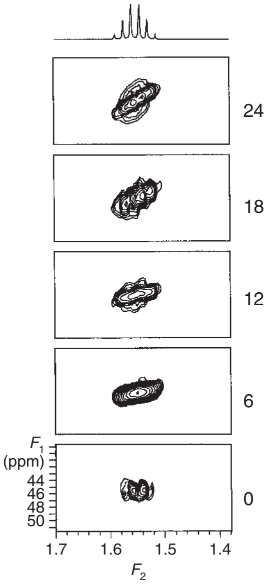

Figure 8.27 F_1 skew inherent to responses in ACCORD-HMBC spectra is only partially user controllable. These properties prompted the development of the IMPEACH-MBC experiment [144], which suppresses F_1 skew. Further modification to re-introduce user-controlled F_1 skew was incorporated into the CIGAR-HMBC experiment using a parameter called J_{scale} [145]. The effect of adjusting the J_{scale} parameter in the CIGAR-HMBC experiment is shown for the 3-methylene group of 2-pentanone over a range of J_{scale} settings from 0 to 24.

capability was last available for protonated carbons *via* the heteronucleus-detected XCORFE sequence pioneered by Reynolds and co-workers in 1985 [129].

Selective manipulation of the various components of magnetization to allow the differentiation of two-bond from three-bond long-range correlations is through the application of a new pulse sequence operator given the acronym STAR (selectively tailored accordion F_1 refocusing) shown schematically in Figure 8.28a while the full ${}^2J,{}^3J$-HMBC pulse sequence is shown in Figure 8.28b. Homonuclear couplings evolve through the D interval, while heteronuclear couplings are refocused by the 180° ^{13}C pulse prior to the second $D/2$ segment. The interval $\Delta 1$ is incremented from zero by $J_{\mathrm{scale}} \times t_1$ $J_{\mathrm{scale}} \times t_{1\mathrm{max}}$ while conversely, the $\Delta 2$ delay is decremented from $J_{\mathrm{scale}} \times t_{1\mathrm{max}}$ to zero. Hence, the sum of the $\Delta 1 + \Delta 2$ intervals is constant. All homonuclear couplings evolve through $\Delta 1$; all long-range heteronuclear couplings

Figure 8.28 The ${}^2J,{}^3J$-HMBC experiment is the most sophisticated accordion-optimized long-range heteronuclear shift correlation experiment reported to date [146]. The experiment uses a pulse sequence operator known as a STAR (selectively tailored F_1 accordion refocusing) to selectively manipulate two-bond and three-bond long-range correlations to protonated carbon or nitrogen resonances. (a) STAR operator used in the ${}^2J,{}^3J$-HMBC experiment. The experiment takes advantage of the ability of a BIRD(*x*, *x*, *x*) pulse to refocus the one-bond heteronuclear coupling of a protonated carbon. By doing this, the ${}^2J_{\mathrm{CH}}$ coupling to this proton labeled "A" in **7** is effectively decoupled. Within the STAR operator, the consequence of this event is to cause the ${}^2J_{\mathrm{CH}}$ long-range coupling to evolve in variable time (see evolution bars above the operator schematic), leading this response to selectively exhibit F_1 skew. (b) Incorporation of the STAR operator into the ${}^2J,{}^3J$-HMBC pulse sequence. Some of the detail in the expansion of the operator in (a) is eliminated for clarity. The schematic representation of the expectation of the results of using the STAR operator in the ${}^2J,{}^3J$-HMBC experiment are shown in Figure 8.29.

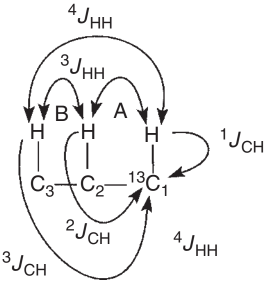
are refocused by the 180° ^{13}C pulse at $\Delta1/2$. The BIRD pulse located at $\Delta2/2$ serves as a 180° pulse for ^{1}H–^{13}C$_1$ and as a 360° pulse for other couplings. This results in a selective refocusing of the $^{3}J_{HH}$ coupling between H_2–$H_1{}^{13}C$. As a consequence of the incrementation of $\Delta1$ and the decrementation of $\Delta2$, the sum of the two intervals serves as a variable delay for this homonuclear coupling, causing the $^{2}J_{C1H2}$ coupling response to be selectively skewed in F_1 while other long-range correlations have the appearance of what would be the corresponding response in the IMPEACH-MBC experiment with $J_{scale} = 1$. The appearance of the long-range couplings from H11α–C12 ($^{2}J_{CH}$) and from H11α–C13 ($^{3}J_{CH}$) are shown schematically in Figure 8.29; experimental results are presented in Figure 8.30. The "staggered skew" exhibited by the two-bond H11α–C12 correlation response is typical of two-bond long-range correlations in the $^{2}J,^{3}J$-HMBC experiment. The setting for the parameter J_{scale} as in the predecessor CIGAR-HMBC experiment, [145] allows user control over the degree of staggered F_1 skew of two-bond responses in the experiment.



7

8.3.7.5 **Relative Sensitivity of Long-Range Heteronuclear Shift Correlation Experiments**

Relative to direct correlation experiments, the various long-range correlation experiments now available are all lower in sensitivity. It is generally accepted that the HMBC experiment ranges from one-fourth to one-eighth the sensitivity of a direct correlation experiment. While comparative data are not available for all of

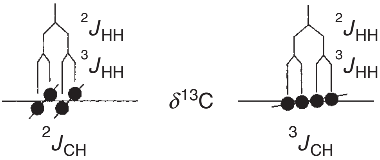


Figure 8.29 Schematic representation of expectations for two-bond (left, e.g., the H11α–C12) and three-bond long-range couplings (right, e.g., the H11α–C13) long-range couplings in strychnine (**2**). The staggered F_1 skew is typical of what would be expected from the function of the STAR operator. Experimental verification of these anticipated results is shown in Figure 8.30. (Reproduced with permission – Academic Press.)

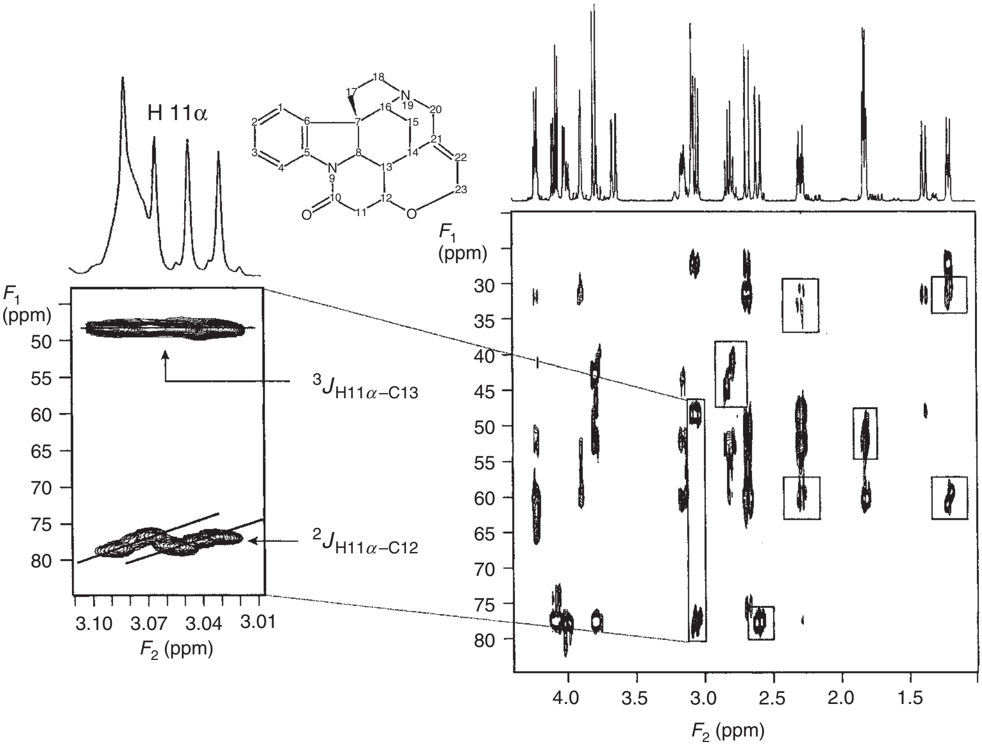

Figure 8.30 Results obtained with the $^2J,^3J$-HMBC using strychnine (**2**) as a model compound [146]. The aliphatic region is shown. The expanded region shows the two- and three-bond correlations from H11α to C12 and C13. The staggered F_1 skew exhibited for the H11α–C12 two-bond correlation is consistent with the schematic shown in Figure 8.29. The experiment utilizes an accordion-optimization range (6–10 Hz) as in predecessor experiments. The parameter J_{scale} is also employed to allow a user-selected degree of F_1 skew to be introduced into the two-bond correlation responses ($J_{scale} = 16$). (Reproduced with permission – Academic Press.)

the available long-range experiments, all of the accordion-optimized long-range experiments have been directly compared to the HMBC experiment in the recent description of the $^2J,^3J$-HMBC experiment [146]. It is likely that the other available experiments will range in sensitivity from that of HMBC downward, with the 3D-HMBC experiment of Furihata and Seto [139] likely to have the lowest sensitivity of any of the available experiments.

8.3.7.6 **Applications of Accordion-Optimized Long-Range Heteronuclear Shift Correlation Experiments**

To date, aside from the papers reporting the development of the accordion-optimized long-range experiments there have only been two reported applications, although more will doubtless follow. Two of the authors have reported a comparison of accordion-optimized experiments for long-range $^1H-^{15}N$ heteronuclear shift correlation at natural abundance to avoid problems inherent to the optimization of these experiments with more conventional experiments [147]. Zannger and Armitage [124] have also reported the utilization of an accordion-optimized HMQC experiment for the observation of the possible long-range $^1H-^{113}Cd$ couplings in a metalloprotein. Most recently, Sørensen and co-workers [148] have reported a method for measuring long-range $^1H-^{31}P$ coupling constants in nucleic acids which utilizes the accordion methods just described.

8.3.8
Hyphenated-2D NMR Experiments

The inverse-detected 2D NMR experiments that have been discussed to this point have all been discrete, single-purpose experiments, for example, correlating protons with their directly bound heteronuclide (typically ^{13}C or ^{15}N). There are another class of inverse-detected 2D NMR experiments that are generally referred to as *hyphenated* 2D experiments. These are experiments that first establish one type of correlation, followed by an additional experiment segment that then pursues a further spectroscopic task. Predecessors of the inverse-detected variants of these experiments were the HC-RELAY (proton–carbon heteronuclear relayed coherence transfer) experiments pioneered by Bolton [149–153]. Examples of these include, but are by no means limited to HSQC–COSY and –TOCSY [154–156], –NOESY [157], –ROESY [158], and more recent gradient variants [159], and so on, where X = S (single) or M (multiple) quantum variants of the experiments.

Hyphenated 2D NMR experiments utilize the obligatory three fundamental experiment segments (preparation, evolution, and detection) with a fourth period, for example, a mixing period, inserted between evolution and detection. Probably the most commonly encountered member of this class of experiments is HSQC– or HMQC–TOCSY (there are, of course, non-gradient predecessor versions of these experiments) [154–156]. Using the modern GHSQC–TOCSY experiment as an example, the experiment begins with the usual preparation period followed by an evolution period which labels amenable protons (the experiment does not work for protons on oxygen, or nitrogen, for example, if a proton–carbon correlation experiment is being performed) with the chemical shift of the directly bound heteronuclide. After magnetization is transferred back to the proton in question, homonuclear vicinal coupling is propagated between contiguous protons as in a homonuclear TOCSY experiment. The proton magnetization ultimately acquired provides homonuclear TOCSY correlated proton spin systems sorted by the chemical shift of the directly bound carbon(s) in question. In similar fashion, the –COSY, –NOESY, and –ROESY related experiments provide the corresponding homonuclear correlation data sorted by heteronuclide chemical shift.

Direct response-edited variants of the HSQC– and HMQC–TOCSY experiments and their gradient analogs have been developed following the initial, pioneering report of the HSQC–TOCSY experiment by Domke [160]. Possible choices include inverted direct response (IDR) and suppressed direct response (SDR) variants

[161] and gradient variants of the experiment [162], which can be quite useful when dealing with homonuclear spin systems that contain direct and relayed correlation responses with AB character. In the case of molecules with AB spin systems, the ability to either IDR or SDR increases the certainty of observing the relayed correlation response, which is not always true in the original version of the heteronuclear relayed coherence experiments. The GHSQC–TOCSY pulse sequence with multiplicity editing capability is presented in Figure 8.31.

Unfortunately, the relative sensitivity of the hyphenated 2D NMR experiments, as a group, is not high. The more sensitive experiments, for example, GHSQC–TOCSY, are lower in sensitivity than the long-range experiments such as GHMBC by at least a factor of 2 in the experience of the authors. The–NOESY and –ROESY hyphenated variants are much lower in sensitivity since the S/N ratio in the data set must be high enough to allow the observation of NOE or ROE responses with intensities of only a small percentage of the direct responses to be observed. Despite the inherent insensitivity of these techniques they have still found a number of useful applications. Examples include the application of IDR GHSQC–TOCSY in the total assignment of the proton and carbon NMR spectra of complex marine polyether toxins such as brevetoxin-2 (**8**) [163] (Figure 8.32); the observation of couplings between overlapped protons [164]; ROEs between "equivalent" protons in C2 symmetric molecules [158, 165–168]; and the unequivocal determination of the structure of complex polynuclear heteroaromatics [166, 167] to list a few of the applications contained in the literature.

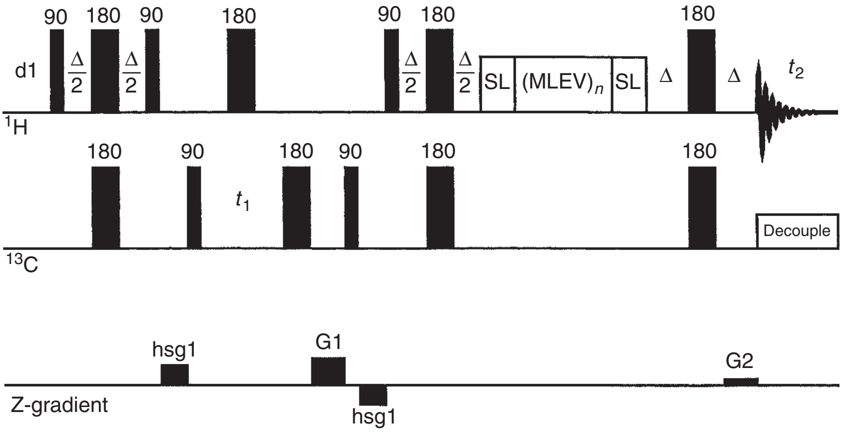

Figure 8.31 Pulse sequence schematic for the inverted direct response GHSQC–TOCSY experiment. After labeling protons with the respective, directly bound carbon chemical shifts, magnetization is propagated from a given proton to its vicinal and further removed neighboring protons through the isotropic mixing period. The number of bonds through which magnetization is propagated is a function of the duration of the mixing time.

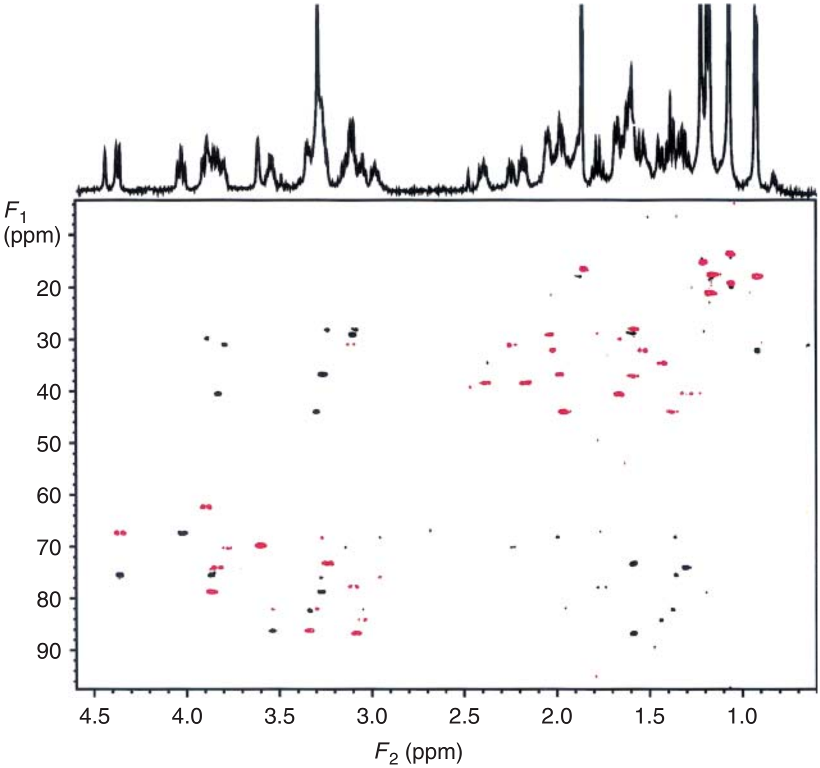

Figure 8.32 IDR GHSQC–TOCSY spectrum of a 500 µg sample of brevetoxin-2 (**8**) in 30 µl of d_6-benzene. Data were acquired at 600 MHz using a Varian INOVA spectrometer equipped with a Nalorac SMIDG-600-1.7 submicro gradient inverse detection probe. Data were acquired overnight. Direct responses are inverted and plotted in red; relayed responses have positive intensity and are denoted by black responses.

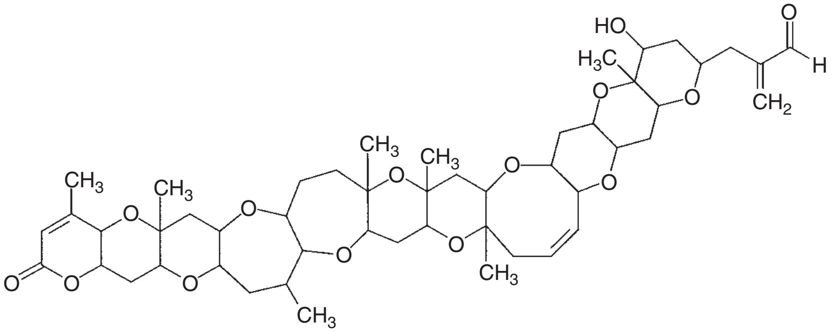

8

8.3.9
One-Dimensional Analogs of 2D NMR Experiments

Frequently, a single piece of correlation data such as an NOE or ROE, or a long-range heteronuclear coupling is sufficient to complete the structural characterization of a molecule. To provide these data, a number of selective, 1D analogs of 2D NMR experiments have been devised. Early work in this area has been reviewed by Kessler and co-workers in 1991 [169]. More recently, Parella [170] in 1996 and Berger [171] in 1997 have reviewed the combined use of selective pulses and gradients in NMR experiments. Specialized, shaped RF pulses frequently used in selective 1D NMR experiments have also been reviewed by Freeman [172]. At present, in the author's experience, the most frequently employed selective 1D NMR experiments are the gradient 1D NOESY experiment and selective 1D analogs of the HMBC experiment. These techniques are discussed in the following sections of this chapter.

8.3.9.1 **Gradient 1D NOESY**

Gradient selected experiments [104, 135, 173] are finding increased use in structural characterization. The gradient 1D NOESY experiment [173], in particular, is robust and has been very useful in the author's laboratory. The pulse sequence employs a DPFGSE (double pulsed field gradient spin echo) element to select the resonance for which NOEs will be developed and sampled in the experiment. The gradient 1D NOESY pulse sequence is shown in Figure 8.33. The selected resonance is refocused by the selective 180° pulses while other resonances are left in random orientations in the *xy*-plane. The resonance of interest is ultimately rotated to the $-z$-axis by the second 90° pulse. The NOE develops during the ensuing mixing delay, τ_m, and is sampled by the final 90° pulse. Results that can be obtained with the gradient 1D NOESY experiment are shown in Figure 8.34 and are compared to results from a conventional NOE difference experiment. Gradient 1D NOESY

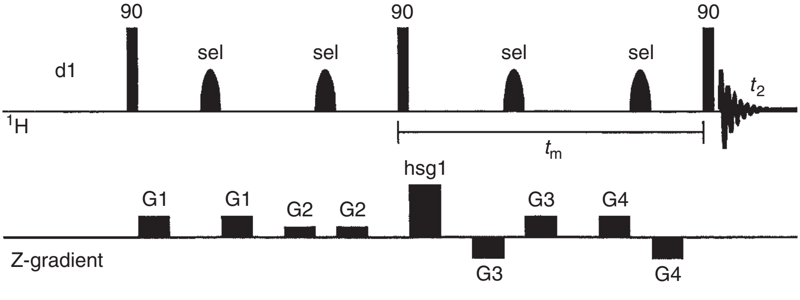

Figure 8.33 Pulse sequence schematic for the gradient 1D NOESY experiment. The double pulsed field gradient spin echo (DPFGSE) refocuses only for that resonance subject to the selective pulse. All other magnetization is left defocused in the *xy*-plane. Ultimately, a NOESY spectrum is recorded only for the selected resonance. In general 1D gradient NOESY data are substantially freer of subtraction artifacts, and so on, than the older 1D NOE difference experiment data (Figure 8.34). In essence, 1D gradient NOESY represents a selected "slice" of what would otherwise be a normal 2D NOESY experiment.

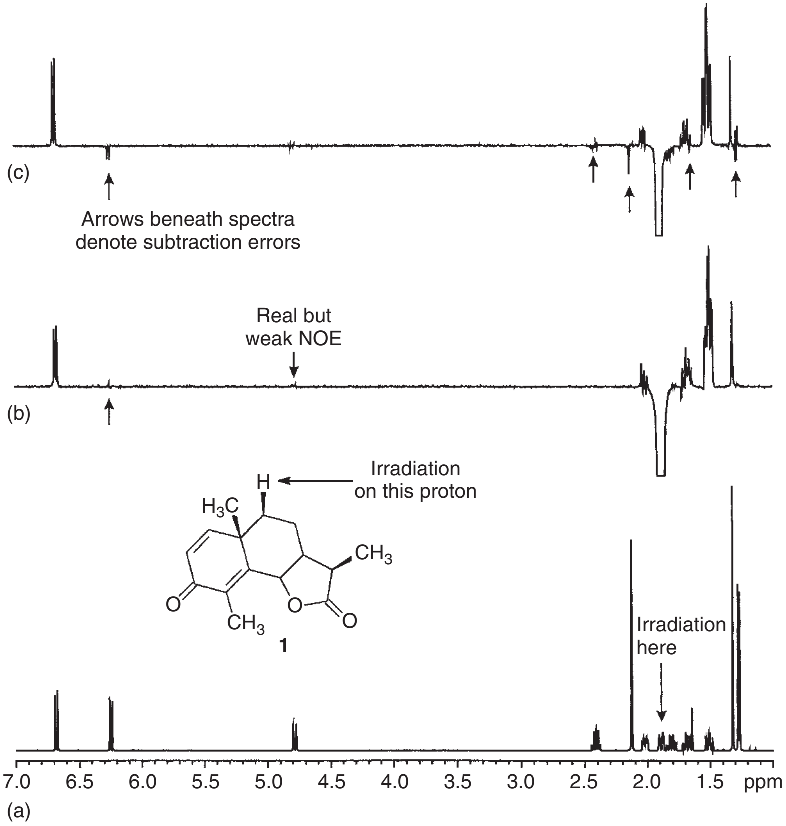

Figure 8.34 Application of the 1D gradient NOESY experiment to santonin (**1**). Comparison reference spectrum (a), 1D gradient NOESY (b), and 1D NOE difference (c) spectra. The proton shown on the structure inset was selected for both the 1D gradient NOESY data shown in trace (b) and the 1D NOE difference data shown in trace (c). The gradient 1D NOESY data shown in trace (b) is substantially free of artifacts with the exception of the one response denoted by an arrow below the trace and potential strong coupling effects for the geminal coupling partner of the selected resonance. In comparison, the 1D NOE difference data shown in trace (c) have a substantial number of subtraction artifacts, as denoted by arrows below the trace.

experiments are particularly useful in that they do not require the calculation of difference spectra to observe the NOE being sought and they cleanly remove signals not arising from NOEs making them more readily interpretable. These data are very useful for qualitative determinations of stereochemical orientation.

Unlike steady-state NOEs calculated from difference spectra, the transient NOEs determined using the 1D gradient NOESY technique have some attributes associated with responses that are worthy of mention. Responses are sensitive to mixing time choices and may vary markedly as a function of this parameter choice. The NOE enhancement will depend on the degree of inversion, which can be influenced by pulse calibration. This can lead to the absolute percentage enhancement that is observed being smaller than in a NOE difference experiment, necessitating a ''recalibration'' of what the spectroscopist may consider to be a reliable response. Despite the potential shortcomings just noted, gradient 1D NOESY experiments are extremely useful and will probably see more widespread use with time.

8.3.9.2 **Selective 1D Long-Range Heteronuclear Shift Correlation Experiments**

Situations frequently arise where one or a few heteronuclear correlations are all that is needed to complete the elucidation of a given structure. Often this missing information is a consequence of an inappropriate choice for the optimization of the long-range delay if HMBC/GHMBC experiments are being employed. In such situations, rather than acquiring another full, long-range 2D experiment, it is far more expedient to consider the acquisition of a selective long-range heteronuclear correlation experiment.

Following the description of the non-gradient SIMBA (selective inverse multiple bond analysis) experiment by one of the authors in 1991 [174], a number of reports describing related methods appeared [175–181]. There have been a few successful applications of SIMBA experiments reported in the literature [70, 182–184] used to establish specific correlations to complete structure assignments.

With the advent of gradient NMR methods, there have been several reports of gradient analogs of the SIMBA method [185–188]. Most recently, a double-selective *J*-HMBC method has been reported [189] and used to extract long-range couplings to the selectively excited resonances of the alkaloid harmane. Given the potential utility of SIMBA-type experiments augmented by PFGs, it is probable that this class of experiments will see expanded use in the future.

8.3.9.3 **Pulsed Field Gradients and Diffusion Ordered NMR Spectroscopy (DOSY)**

8.3.9.3.1 **Pulsed Field Gradients (PFGs)**

Markus Kramer

Many modern NMR experiments utilize PFGs to create or eliminate coherence. Field gradients are a defined linear disturbance of the static magnetic field and a function of the position. This disturbance can be applied to each direction, whereas most PFGs are applied along the B_0 field, that is, the z-direction. The resulting magnetic field (B_{res}) then consists of the B_0 field and the magnetic field of the gradient (B_{g}), which depends on the gradient strength (G_z) and its position along the z-axis:

$$B_{\text{res}}(z) = B_0 + B_{\text{g}} = B_0 + G_z \times z \tag{8.8}$$

For the sake of clarity one can imagine the sample to be cut in microscopically small slices along B_0. After application of a 90° pulse without succeeding z-gradient the magnetization vectors in every slice are aligned parallel in the xy-plane (Figure 8.35a). A field gradient along the z axis immediately after this excitation pulse results in a helical arrangement of the magnetization vectors because every

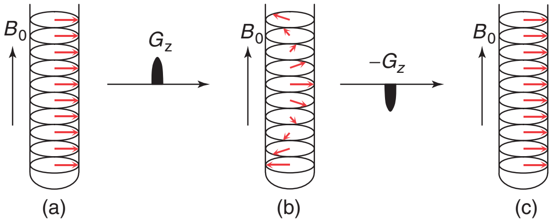

Figure 8.35 (a,b,c) The effect of a pulsed field gradient on the magnetization.

slice experiences a different magnetic field as a linear function of its position (Figure 8.35b). This change in the strength of the B_0-field causes a change of the Larmor frequency of the spins in each slice and thus a fanning out along the z axis.

$$\nu_L = \frac{\gamma \cdot B_{res}(z)}{2\pi} = \frac{\gamma \cdot (B_0 + G_z \times z)}{2\pi} \tag{8.9}$$

Starting the acquisition right now will result in a very low or no signal intensity, because all spin vectors of the sample will add up to zero. A second field gradient of the same strength and duration as the first one but of opposite sign will neutralize the effect of the first field gradient and the original magnetization is re-established (Figure 8.35c).

The field gradient causes the magnetization vector in a particular slice to be rotated about an angle Φ_z, which is a function of the coherence order (p), the gyromagnetic ratio of the observed nucleus (γ), the gradient field (B_g), and the duration of the field gradient (τ_g) [190]

$$\Phi_z = p \cdot \gamma \cdot B_g(z) \cdot \tau_g \tag{8.10}$$

Thus, for the same gradient strength the rotation angle of double quantum coherence is twice as large as that of single quantum coherence, while zero quantum coherence is not influenced by a field gradient. Consequently, with a combination of several field gradients and the correct choice of B_g and τ_g it is possible to select desired and to destroy unwanted coherence.

8.3.9.3.2 **Diffusion Ordered NMR Spectroscopy (DOSY)**

Diffusion ordered NMR spectroscopy (DOSY) [191, 192] is an NMR spectroscopic method which was developed to separate the signal sets of the substances in a mixture. This method is therefore often called *chromatographic NMR spectroscopy*. The separation is carried out by the different diffusion coefficients (D) of the single components. According to the Stokes Einstein equation (Eq. (8.11)) for spherical particles D is dependent upon the temperature (T), the viscosity of the mixture (η), and the hydrodynamic radius of the examined particle (r_H):

$$D = \frac{k_B \cdot T}{6\pi \cdot \eta \cdot r_H} \tag{8.11}$$

DOSY spectra are acquired utilizing NMR spectroscopic methods applying PFGs. The simplest pulse sequence for that purpose is called the *Carr–Purcell spin echo* (Figure 8.36).

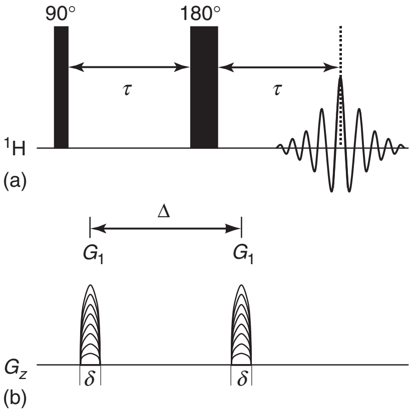

Figure 8.36 (a,b) The pulse sequence of the Carr–Purcell spin echo experiment.

The phase coherence of the individual spins produced by the initial 90° ^{1}H pulse is destroyed by the subsequent *z*-gradient G_1 leading to the same helical arrangement of the spins as shown in Figure 8.35b. During the diffusion time Δ the spins move owing to the self-diffusion of the molecules, while the 180° ^{1}H pulse causes an inversion of all spins. The following second *z*-gradient of the same strength and duration as the first one rephases all spins. In the absence of self-diffusion during the delay Δ the sequence $G_1{-}180^\circ{-}G_1$ would have no effect on the magnetization, because all dephased spins are rephased in the same way (without considering relaxation). Self-diffusion along the *z* axis of the sample during Δ leads to incomplete rephasing of the spins by the second gradient pulse, thus the overall sample magnetization is reduced. According to the following equation the resulting signal intensity is dependent on the diffusion coefficient D and the gradient strength

$$I = I_0 \cdot e^{-D\gamma^2 g^2 \delta^2 \left(\Delta - \frac{\delta}{3}\right)} \tag{8.12}$$

with D, diffusion coefficient; γ, gyromagnetic ratio; g, gradient strength; δ, gradient pulse duration; and Δ, diffusion time.

The two parameters δ and Δ have to be optimized at the beginning of the experiment and are then held constant, resulting in D being the only variable in the above mentioned equation. Repeating the experiment with linearly increasing gradient strength and plotting the signal intensity against g will result in a diagram as shown in Figure 8.37. Curve fitting with the aid of Eq. (8.12) finally yields in the diffusion coefficient D.

Performing this procedure for every signal in the spectrum and plotting the D values against the chemical shift results in a DOSY spectrum (Figure 8.38). For the calculation of these spectra several algorithms which are implemented in every established NMR processing software are employed.

For studying the diffusion behavior of larger molecules, very strong gradients (up to 30 T m^{-1}) are necessary. Strong gradient pulses of this order cause eddy currents

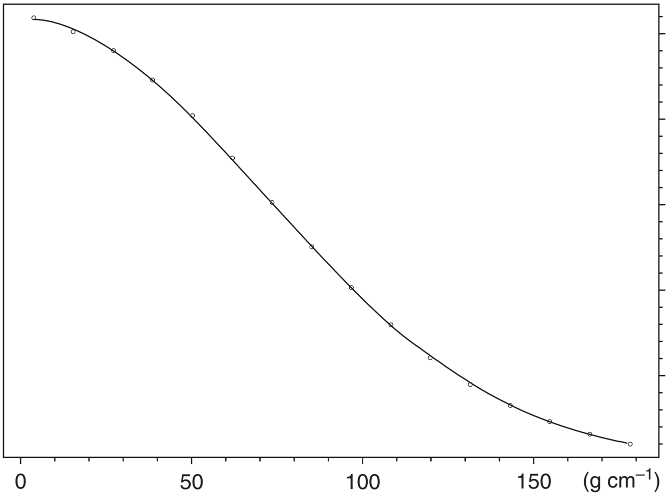

Figure 8.37 Attenuation of the signal intensity with increasing gradient strength.

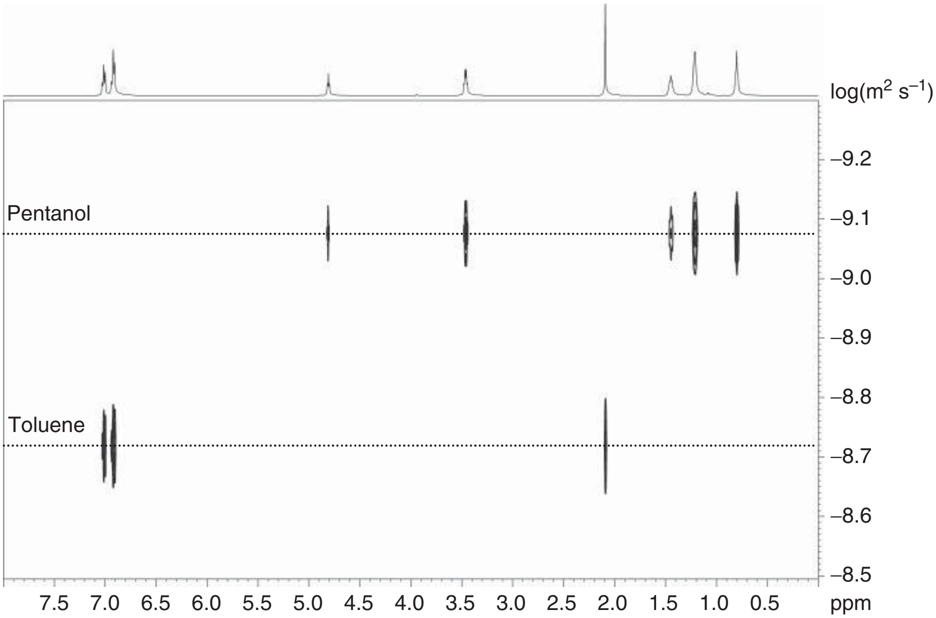

Figure 8.38 DOSY spectrum of a mixture of pentanol and toluene.

in the probehead which furthermore cause signal distortions. To minimize these eddy currents, nowadays alternatives of the presented pulse sequence are used. These modern sequences incorporate bipolar gradient pulses and contain a short delay, which allows the eddy currents to decay before the acquisition is started [192].

8.3.9.4 **Residual Dipolar Couplings (RDC) in Structural Analysis**

Markus Kramer

The dipolar or direct coupling between two spins I and S is mathematically given by the following equation (Eq. (8.13)) [193]:

$$D_{\mathrm{IS}} = -\left(\frac{\mu_0}{4\pi}\right)\frac{\gamma_{\mathrm{I}}\gamma_{\mathrm{S}}h}{2\pi^2\langle r_{\mathrm{IS}}^3\rangle}\left\langle\frac{3\cos^2\theta_{\mathrm{IS}}-1}{2}\right\rangle \tag{8.13}$$

with μ_0, magnetic field constant; γ_{I},γ_{S}, gyromagnetic ratio of the nuclei I and S; h, Planck's constant; r_{IS}, distance between the investigated nuclei; θ, angle formed by the internuclear vector and the static magnetic field B_0 (Figure 8.39).

The arrow brackets depict an ensemble average over all existing molecular motions. In solution, the dipolar interaction of two nuclei is only indirectly measurable via cross relaxation processes as nuclear Overhauser effect because the θ-dependent term averages to zero.

The molecular alignment in the static magnetic field leads to a measurable direct interaction. In perfect oriented samples, the absolute values of the dipolar couplings are much greater than that of the scalar couplings (e.g., 60.42 kHz compared to ~150 Hz for a CH group with $r = 1$Å and $\theta_{\mathrm{IS}} = 0°$). By lowering the degree of order, the dipolar interaction can be reduced to a value that is usually smaller than the scalar interaction and, in addition, the high resolution of the NMR spectra is retained. For that purpose, different liquid crystalline alignment media or gels have been investigated, which only align about 0.05% of the solute molecules at the same time. For a detailed description of several alignment media and suitable solvents refer to [194, 195].

Owing to the unknown molecular orientation of partially oriented samples, the Eq. (8.13) given in that form as shown above is not useful for the structural analysis. To allow an evaluation of the measurable dipolar couplings, an arbitrary molecular frame (M_x, M_y, M_z in Figure 8.40) is chosen, where the position of the internuclear vector of two spins (here: C–H) can be described by the three angles ϕ_x, ϕ_y, and ϕ_z.

The orientation of the molecular frame toward the static magnetic field can then be determined by calculating an order matrix S_{kl} [197]. Therefore, the equation is

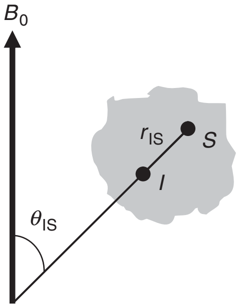

Figure 8.39 Graphical representation of the variables used in Eq. (8.13).

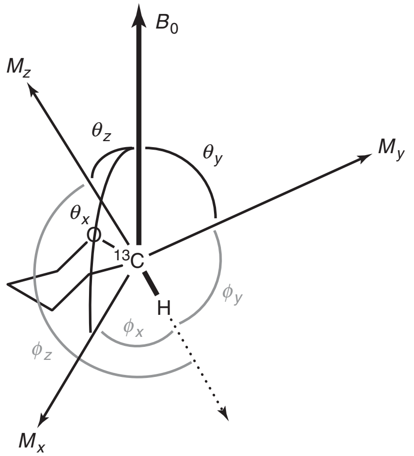

Figure 8.40 The position of a CH group in the arbitrary molecular frame and its orientation in the external magnetic field (after [196]).

recasted in a matrix form resulting in the following equation [198]

$$D_{\mathrm{IS}} = \frac{D_{\max \mathrm{IS}}}{r_{\mathrm{IS}}^3} \sum_{k,l} S_{kl} \cos \phi_k \cos \phi_l \tag{8.14}$$

with $D_{\max \mathrm{IS}}$, maximum possible D_{IS}-value at a distance of I and S (r_{IS}) of 1 Å and the internuclear vector oriented along B_0; k, l, x, y, z; $s_{kl} = \begin{bmatrix} s_{xx} & s_{yx} & s_{zx} \\ s_{xy} & s_{yy} & s_{zy} \\ s_{xz} & s_{yz} & s_{zz} \end{bmatrix}$; and ϕ_k, ϕ_l, angle between the internuclear vector and the k- and l-axis, respectively, of the arbitrary molecular frame.

The elements of the order matrix S_{kl} are given by Eq. (8.15)

$$S_{kl} = \left\langle \frac{3 \cos \theta_k \cos \theta_l - \delta_{kl}}{2} \right\rangle \tag{8.15}$$

where θ_k, θ_l, angle between the k- and l-axis, respectively, of the arbitrary molecular frame and the B_0 field; δ_{kl}, 0 if $k \neq l$, otherwise 1 (Kronecker delta).

For each D_{IS} value the order matrix has five linear-independent elements, because it is symmetric and has a zero trace. With at least five independent D_{IS} values the resulting system of equations can be solved and thus the elements of the order matrix can be determined. For additional structural information six independent D_{IS} values are necessary. The correctness of a calculated structure can now be confirmed by comparing experimental residual dipolar couplings (RDC) values with those obtained theoretically by back-calculation with the aid of the order matrix. The structure has to be evaluated as correct if the theoretical and experimental D values lie in between a certain error range. In flexible molecules the D values are averaged due to several possible conformers present in solution. Modern programs for the analysis of D values allow a consideration of intramolecular dynamic during the calculations.

8.3.9.4.1 **The Experimental Determination of RDC Values** By far, the most used RDCs are the $^1D_{C,H}$ or $^1D_{N,H}$ values, that is, the one-bond heteronuclear residual dipolar coupling constant for a CH or NH group (henceforth referred to as $^1D_{X,H}$). Depending on the degree of order these residual dipolar couplings are usually much smaller than the scalar couplings and lead to an additional splitting of the corresponding signals. The heteronuclear scalar interaction of two spins is usually detected by the HSQC experiment. Owing to decoupling the hetero-nucleus during the data acquisition and refocusing the proton scalar couplings by a 180° pulse it is impossible to extract a coupling constant from the standard HSQC experiment. Removing either this decoupling sequence or the refocusing pulse will result in a signal splitting in the direct (ω_2, t_2, F_2) and indirect (ω_1, t_1, F_1) dimension, respectively (Figure 8.41). Performing an coupled HQSC experiment on an oriented sample (with alignment medium) results in a signal splitting that is produced by the sum of $^1J_{X,H}$ and $^1D_{X,H}$. For the isotropic case (without alignment medium) the contribution of $^1D_{X,H}$ is missing. The difference in the splitting of corresponding signals for the anisotropic and isotropic case reveals the $^1D_{X,H}$ value for a certain CH and NH group, respectively.

Enthart *et al.* [199] showed, that the presence of antiphase magnetization during the data acquisition in an F_2-coupled HSQC experiment leads to a phase distortion

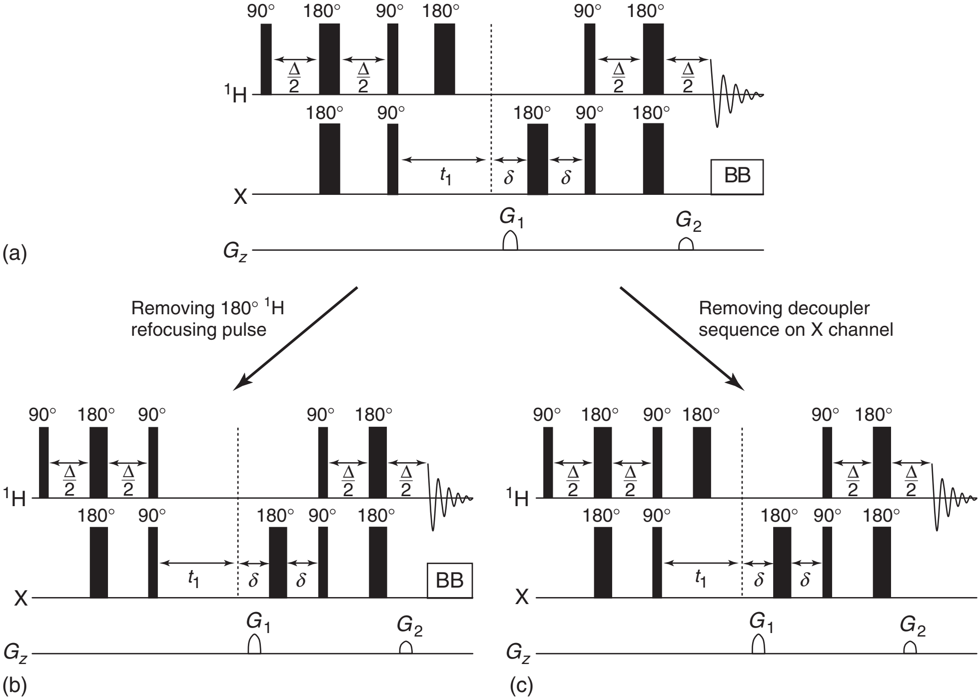

Figure 8.41 Modification of a standard HSQC sequence (a) to obtain either the F_1-coupled (b) or the F_2-coupled (c) HSQC pulse sequence. BB, broad band decoupling.

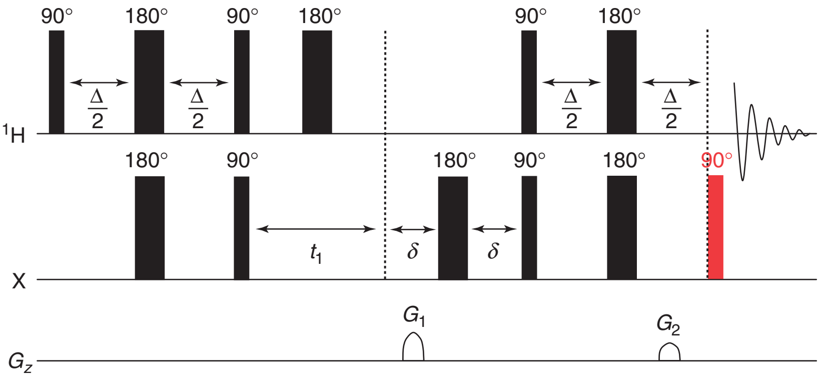

Figure 8.42 One of three possible pulse sequences for the CLIP-HSQC experiment.

of the signals and therefore presents erroneous RDC values. To remove this antiphase magnetization they proposed a modified version of the HSQC experiment, which they called CLIP-HSQC (clean in-phase heteronuclear single quantum coherence). This modification is made up of additional pulses inserted in the pulse sequence on the ^{1}H or X channel right before the acquisition is started. One of these modified pulse sequences is shown in Figure 8.42. Here, the inserted 90° pulse (red bar in Figure 8.42) on the X channel converts the antiphase magnetization to double quantum coherence, which cannot be detected directly and consequently produces pure in-phase signals.

Other RDC values often used for structural analysis are the $^nD_{\mathrm{H,H}}$, $^nD_{\mathrm{C,H}}$, $^1D_{\mathrm{C,C}}$, and $^nD_{\mathrm{C,C}}$ coupling constants [194, 195].

8.3.9.5 Small Sample NMR Studies

All NMR experiments detect signals from the sample being studied using some form of probe. Conventionally, NMR spectrometers have generally utilized 5 mm probes. There have, however, been a number of early reports of studies utilizing small sample NMR probes. A number of pioneering reports by Shoolery [200–202] using 1.7 mm probe designs were reported in the late 1970s. Following these studies, there was a hiatus of more than a decade before interest in small volume NMR probes was rekindled. In 1992, the collaborative development of 3 mm “micro” NMR probes was reported by one of the authors; comparative evaluation of 3 mm probes relative to 5 mm probes with identical quantities of material showed that the former achieved a given S/N ratio in roughly a quarter the time required for a conventional 5 mm probe [203, 204]. There followed a number of natural product studies utilizing 3 mm probes through the mid 1990s [204–213].

The development of the magic angle, liquid Nano-probe™ by Varian was reported in the mid 1990s [214–217]. A number of studies utilizing this probe technology have been reported and there have been a few comparative comments made regarding 3 mm micro-probes versus the nano-probe design [209, 210]. At about the same time, Sweedler and colleagues [218] began to report the results of their development of what they referred to as *μ-coil NMR probes* [219]. A number of subsequent studies have been reported by these authors including the development of μ-coil inverse probe designs [220, 221] and probes with multiple μ-coils contained in a single probehead [222]. The 1.7 mm probe format was revisited in 1998 by one of the authors when the development of the submicro inverse-detection gradient or SMIDG probe design was reported [223, 224]. A number of small sample $^1H-^{13}C$ and $^1H-^{15}N$ studies utilizing this probe design have also been reported [224–230]. To illustrate the capabilities of the 1.7 mm submicro NMR probe, GHSQC spectra of a 750 μg sample of the alkaloid cryptospirolepine (**9**) (MW 505 Da) recorded in 34 s and <5 min are shown in Figure 8.43a,b, respectively [218]. The trace

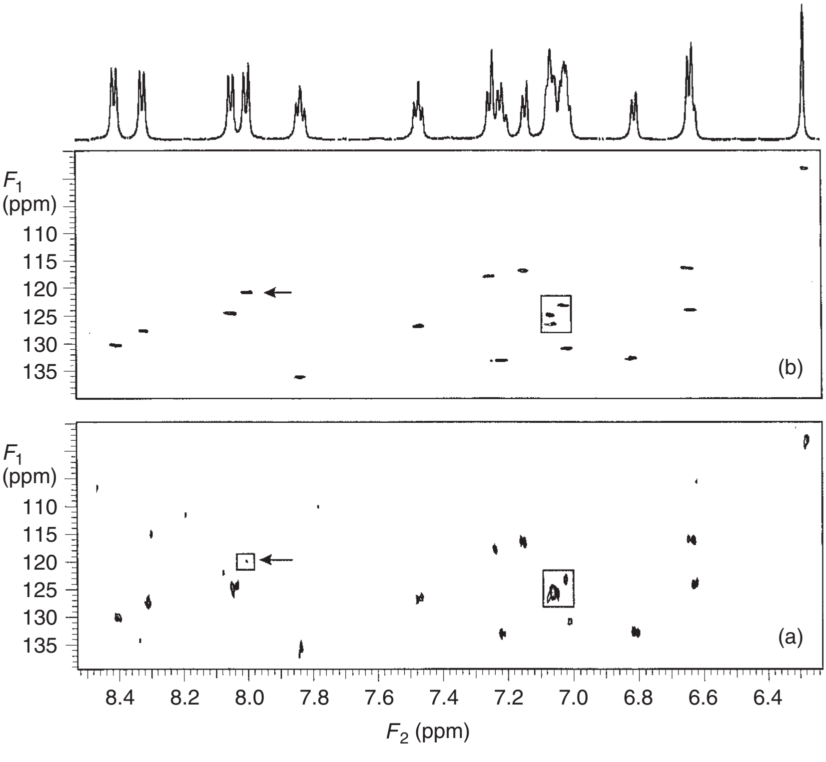

Figure 8.43 GHSQC spectra obtained using a 750 μg sample (~1.5 μmol) of cryptospirolepine (**9**) in 30 μl of DMSO-d_6 [229]. The data shown in (a) were acquired in a scant 34 s as 16 × 2 hypercomplex files with one transient accumulated/t_1 increment. The weak, boxed response denoted by the arrow is the weakest correlation in the spectrum (Figure 8.44). The other boxed region of the spectrum that is not well resolved under the data acquisitions used to acquire the 34 s spectrum shown should contain responses for three correlations. (b) GHSQC spectrum acquired in approximately 5 min with 48 × 2 hypercomplex files with two transients accumulated/t_1 increment. The weak boxed response in (a) is now clearly identifiable as a legitimate correlation and the three responses in the boxed region of (a) are now clearly resolved. (Reproduced with permission – HeteroCorp.)

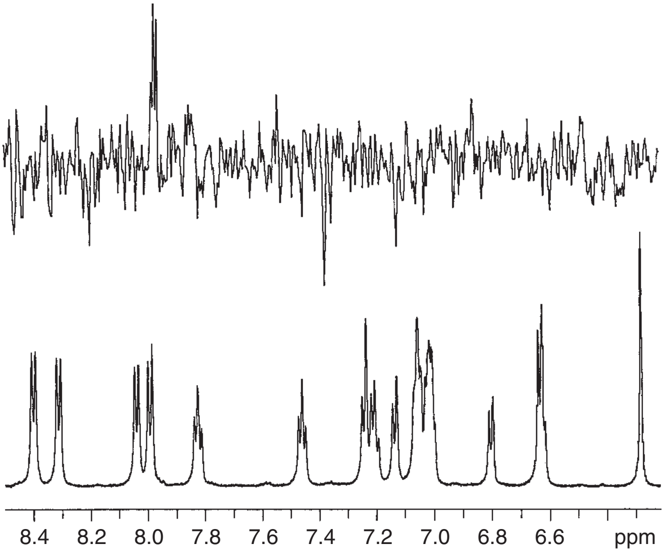

Figure 8.44 Proton reference spectrum and trace from the 2D GHSQC spectrum shown in Figure 8.34a of the weakest response in the 34 s spectrum of **9**. Despite the extremely short acquisition time for the GHSQC spectrum, the S/N ratio of the weakest peak is still ~3 : 1, which when coupled with the multiplet appearance, makes it easy to validate this as a real response from the examination of the slice. (Reproduced with permission – HeteroCorp.)

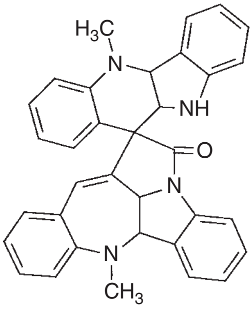
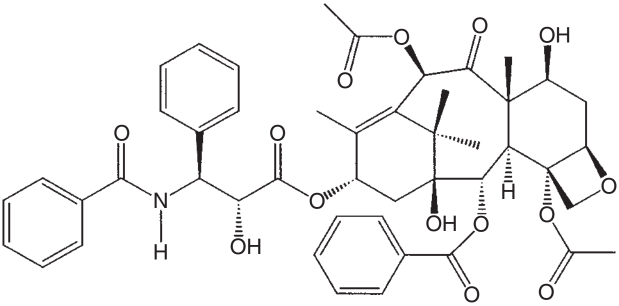
containing weakest response in the 34 s GHSQC spectrum of the alkaloid is plotted above a proton reference spectrum in Figure 8.44. Despite the extremely short acquisition time, the S/N ratio even for the weakest response is adequate. Work in the area of small sample NMR is the subject of a recent review by Sweedler and co-workers [231].



9

What will undoubtedly have the greatest impact on small sample NMR studies will be the development of small volume cold metal NMR probes. Probes of this type have RF coils designed to operate in the range of about 8–25 K [232–235]. Efforts in this area have only begun to be reported within the past year [236], but the initial results are quite promising. Sensitivity for 2.5 or 3 mm versions of these probes have reported gains of as much as fourfold relative to conventional probes operating at ambient magnet bore temperatures [237, 228]. To illustrate the potential of cold metal NMR probes, two examples are shown. The 45 min COSY spectrum of a 2.9 μg sample of paclitaxel (**10**, Taxol™) acquired using a 3 mm cryogenic NMR probe is shown in Figure 8.45 (D.J. Russell *et al.*, unpublished results). An HSQC spectrum of the aliphatic region of strychnine (**2**) acquired using a 3 mm cryogenic NMR probe is shown for a 40 μg (0.12 μmol) sample. The data, shown in Figure 8.46 were acquired in <2 h [239]. Comparable data acquired in a conventional 3 mm micro NMR probe required a 17 h acquisition. Full characterization of a sample of this size, if it required the acquisition of an HMBC or GHMBC spectrum in addition to the HSQC spectrum, would consume approximately 100 h of spectrometer time. In contrast, using a 3 mm cryogenic NMR probe, it should be possible to acquire all of the necessary data in approximately 10 h. Consequently, it is likely that the use of small volume cryogenic NMR probes will be an area of intense research in the coming years.



10

8.4
Conclusions

NMR experiments performed in the solution state are capable of providing a wealth of chemical structure information both through bonds and through space. The array of experiments available to the spectroscopist with which to probe chemical structure is vast. Many of the issues relating to the inherent insensitivity of the NMR experiment have been addressed through increases in magnetic field strength, with 600 MHz instruments now frequently available for the determination of small molecule structures. Sample limitations have been largely circumvented by small volume NMR probes, specialized NMR cells, and by the very recent availability of 3 mm cryogenic NMR probes. When the available technology is used in concert and in conjunction with data from other analytical spectroscopic techniques such as mass spectrometry and vibrational methods, most chemical structures can be

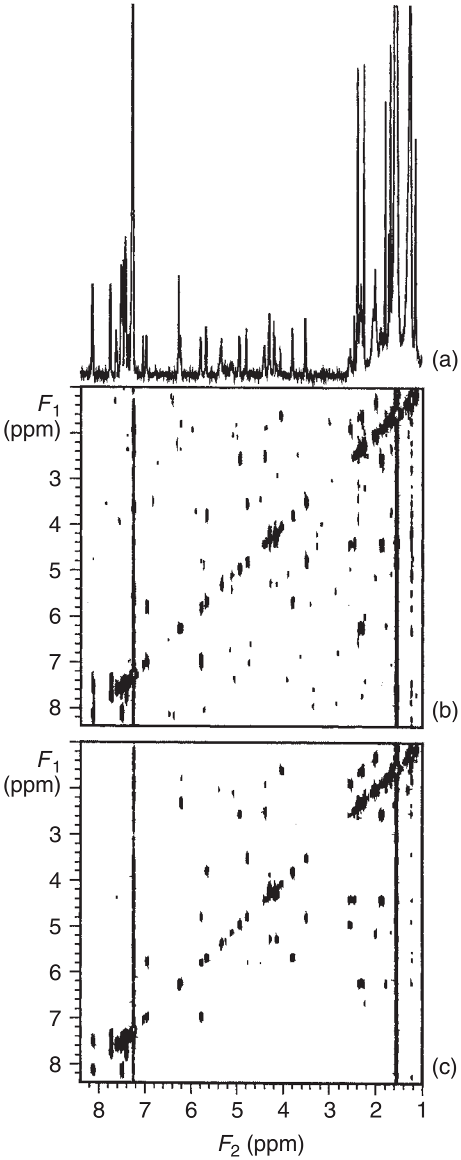


Figure 8.45 Spectra recorded with a 2.9 μg sample of paclitaxel (Taxol™, **10**, ~3.4 nmol) dissolved in 165 μl $CDCl_3$ [227]. (a) Proton reference spectrum recorded in 32 transients. (b) COSY spectrum recorded in 46 min as a 2048 × 128 point file accumulating 12 transients/t_1 increment. All of the expected correlations are observable in the spectrum and are discernible from the noise. (c) COSY spectrum recorded in 3 h 4 min as a 2048 × 192 point file accumulating 32 transients/t_1 increment. The spectrum is essentially noise-free.

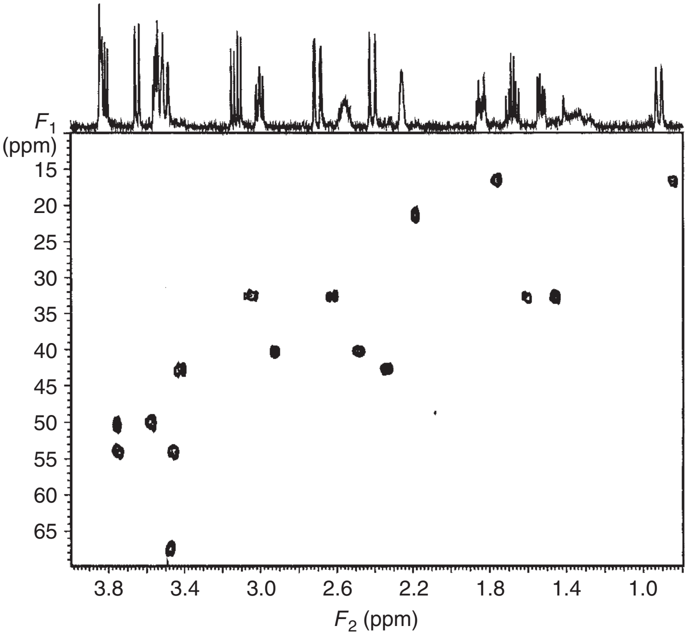

Figure 8.46 HSQC spectrum of a 40 µg sample (120 nmol) of strychnine (**2**) dissolved in 160 µl benzene-d_6 in a 3 mm NMR tube. The data were acquired in 90 min using a Varian INOVA 500 MHz instrument equipped with a Nalorac 3 mm Cryo•Spec® NMR probe. The acquisition of an HSQC spectrum with comparable signal-to-noise using a conventional 3 mm NMR probe required 17 h [239].

solved in reasonable periods of time even if only submicromole quantities of material are available for analysis.

Suspended-State NMR Spectroscopy (High-Resolution Magic Angle Spinning (HR-MAS) NMR Spectroscopy)

Markus Kramer and Klaus Albert

Structural assignment and ligand–receptor interactions [1, 2] have been studied recently in solution and also in suspension using methods of high-resolution (HR) nuclear magnetic resonance (NMR) spectroscopy, employing routine 5 mm NMR tubes.

Suspended solid- or gel-like samples cannot be investigated with conventional HR NMR spectroscopy. Owing to the inhomogeneity of the sample strong susceptibility distortions are present, leading to severe signal broadening. These susceptibility distortions can be eliminated by the application of high-resolution magic-angle spinning (HR-MAS) NMR spectroscopy. Here, the sample is rotated in a 4 mm ZrO_2 rotor at the "magic angle" of 54.7° at a rotation speed between 3000 and 5000 Hz. Under MAS conditions, spectral resolution can approach the typical values obtainable in the liquid state. Thus, an insoluble sample swollen in an appropriate solvent can be rapidly characterized by HR-MAS ^1H NMR spectroscopy [3–5].

Figure 9.1 shows the ^1H NMR spectrum of a cosmetic emulsion recorded in a conventional 5 mm NMR tube. The same sample is recorded under MAS conditions. The effect of MAS is clearly visible. Because of the increased resolution, coupling constants can be depicted and all essential information characterizing a ^1H NMR spectrum can be obtained [6].

Other examples of the application of HR-MAS NMR spectroscopy deal with the characterization of other emulsions such as milk, the reaction monitoring of peptide synthesis on a polymeric support [7] and the investigation of interactions between analytes and chromatographic supports in the presence of a mobile phase [8–21].

10
Solid-State NMR

Steven P. Brown and Lyndon Emsley

10.1
Introduction

For the chemist today, the importance of solution-state NMR is well established. Individual nuclei within a molecule are differentiated on account of their chemical shift, while connectivities, which permit spectral assignment, are identified by through-bond *J*-couplings. Through-space proximities, which yield information about three-dimensional structure, are accessible by experiments which exploit the nuclear Overhauser effect (NOE). Moreover, a host of multidimensional experiments have been developed which further enhance the information content [1, 2]. In many cases, however, the most appropriate sample to study molecular structure and dynamics is the solid. The purpose of this chapter is to give an overview of the different solid-state NMR methods which are available in such cases. Our focus is on the structural and dynamic information which a particular method can deliver, and, at most, only a simple qualitative explanation of how the experiment works will be given, although the relevant literature will always be cited, such that the interested reader can find details about, for example, the experimental implementation.

Firstly, it is necessary to consider how and why NMR of solid samples differs from the solution-state case. High-resolution solution-state spectra are a result of fast isotropic molecular tumbling. In the solid-state, this motion is (usually) absent, and anisotropic interactions, that is, the chemical shift anisotropy (CSA), and the dipolar and quadrupolar couplings, lead to a broadening, see Section 10.2, of the resonances [3–5] These anisotropic interactions, on the one hand, have the significant disadvantage of hindering the resolution of distinct sites, but, on the other hand, contain valuable structural and dynamic information. Specifically, the CSA and quadrupolar interactions provide insight into electronic structure and bonding, while the dipolar coupling offers direct access to internuclear distances. Moreover, all three anisotropic interactions are formidable probes of dynamics. As is demonstrated in this chapter, a number of ingenious experimental approaches have been developed which provide access to the information inherent to the anisotropic

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

Table 10.1 The properties of the NMR-active nuclei of most relevance for organic solids [6].

Nucleus	I	γ (10^7 rad T^{-1} s^{-1})	Natural abundance (%)
^1H	1/2	26.8	99.99
^2H	1	4.1	0.02
^{13}C	1/2	6.7	1.10
^{14}N	1	1.9	99.63
^{15}N	1/2	−2.7	0.37
^{17}O	5/2	−3.6	0.04
^{19}F	1/2	25.2	100.00

interactions particular to the solid state, while retaining the site specificity associated with high-resolution NMR.

Tables 10.1 and 10.2 list the NMR-active nuclei (i.e., those with $I > 0$) of most relevance for organic and inorganic solids, respectively, together with their nuclear spin quantum numbers, their magnetogyric ratios (γ), and natural abundances. (For a comprehensive listing of all NMR-active nuclei, the reader is referred to [6].) For spin $I = 1/2$ nuclei, the two most important anisotropic interactions are the anisotropy of the chemical shielding interaction and the dipolar coupling between the dipole moments of two or more spins. This is to be compared to the case of nuclei with $I \geq 1$, which possesses a quadrupole moment and whose spectra are dominated by the interaction of the quadrupole moment with the electric field gradient at the nucleus. Thus, a separate methodology exists for quadrupolar nuclei. Moreover, it is further necessary to distinguish between quadrupolar nuclei with integer (only $I = 1$) and half-integer ($I = 3/2$, $5/2$, $7/2$, $9/2$) spin, because in the latter case the presence of a "central transition," which is not broadened by the quadrupolar interaction to a first-order approximation, modifies the experimental approach. Solid-state NMR methods suitable for half-integer quadrupolar nuclei, for example, ^{17}O, ^{23}Na, and ^{27}Al, which are of much importance in inorganic systems, are therefore discussed separately in Section 10.7.

Nuclei can be further classified as to their natural abundance: nuclei with 99+% natural abundance, for example, ^1H, ^{19}F, and ^{31}P, are referred to as *being abundant*, while nuclei with low natural abundances, for example, ^2H, ^{13}C, and ^{15}N, are termed *dilute* or *rare*. For dilute nuclei, there exists the possibility of achieving site selectivity by means of selective isotopic labeling. In an NMR experiment, the sensitivity, that is, the signal-to-noise ratio (S/N), depends on the natural abundance, that is, the number of NMR-active nuclei in the sample, as well as the magnetogyric ratio, which determines the Larmor frequency of the nucleus at a particular magnetic field. Of all the naturally occurring nuclei, the proton, ^1H, thus, has the best sensitivity. However, unlike in solution-state NMR where ^1H NMR is of central importance, in the solid-state, there exists a major complication with ^1H NMR primarily due to its high natural abundance; namely, the abundance of protons in organic solids means that there exist strongly dipolar-coupled proton networks,

Table 10.2 The properties of the NMR-active nuclei of most relevance for inorganic solids [6].

Nucleus	I	γ (10^7 rad T^{-1} s^{-1})	Natural abundance (%)
^{6}Li	1	3.9	7.50
^{7}Li	3/2	10.4	92.50
^{11}B	3/2	8.6	80.10
^{17}O	5/2	−3.6	0.04
^{23}Na	3/2	7.1	100.00
^{25}Mg	5/2	−1.6	10.00

^{133}Cs	7/2	3.5	100.00
^{195}Pt	1/2	5.8	33.80
^{207}Pb	1/2	5.6	22.10

which lead to static line broadenings of the order of 50 kHz. As a consequence, as far as organic solids are concerned, attention has rather focused on dilute spin $I = 1/2$ nuclei, for example, ^{13}C and ^{15}N. However, as will be discussed briefly in this chapter, new high-resolution ^{1}H solid-state NMR methods have recently been developed [7], such that the importance of ^{1}H solid-state NMR is expected to increase significantly in the coming years.

In this chapter, we will first illustrate how anisotropic interactions lead to a broadening of the NMR resonances (Section 10.2), and then describe the principal line-narrowing method in solid-state NMR, namely magic-angle spinning (MAS), in Section 10.3. As stated above, achieving high-resolution is not the only goal in solid-state NMR, and ideally the spectroscopist would like to combine this with the retention of the structural and dynamic information inherent to the anisotropic interactions responsible for the line broadening. Recoupling methods [8, 9] are the subject of Section 10.4. As in solution-state NMR, the extension of the experiment to a second (and higher) dimension is of much importance in solid-state NMR;

homonuclear and heteronuclear multidimensional experiments are discussed in Sections 10.5 and 10.6, respectively. Finally, methods applicable to half-integer quadrupolar nuclei are introduced in Section 10.7.

10.2
Solid-State NMR Lineshapes

10.2.1
The Orientational Dependence of the NMR Resonance Frequency

In solid-state NMR, a very important concept is that *the resonance frequency of a given nucleus within a particular crystallite depends on the orientation of the crystallite* [3–5]. Considering the example of the CSA of a ^{13}C nucleus in a carboxyl group, Figure 10.1 illustrates how the resonance frequency varies for three particular orientations of the molecule with respect to the static magnetic field, B_0. At this point, we note that the orientation dependence of the CSA, dipolar, and first-order quadrupolar interactions can all be represented by what are referred

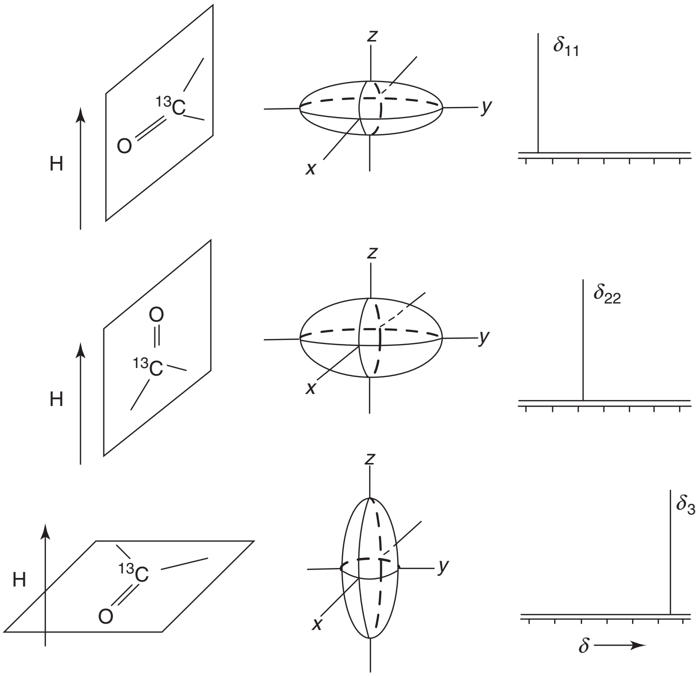

Figure 10.1 The dependence of the resonance frequency upon orientation for an anisotropic interaction, namely the CSA of a ^{13}C nucleus in a carboxyl group. The orientations illustrated correspond to the alignment of the three principal axes of the chemical shift tensor with the axis defined by B_0. (Reproduced by permission of the Società Italiana di Fisica from [5].)

to as *second-rank tensors*. This simply means that the interaction can be described mathematically in Cartesian space by a 3×3 matrix (this is to be compared with scalar and vector quantities, which are actually zero- and first-rank tensors, and are specified by a single element and a 3×1 matrix, respectively). For such a second-rank tensor, there exists a principal axes system (PAS) in which only the diagonal elements of the matrix are nonzero. Indeed, the orientations illustrated in Figure 10.1 correspond to the orientation of the three principal axes of the chemical shift tensor with respect to the axis defined by B_0.

To fully characterize the CSA and the first-order quadrupolar coupling, it is necessary to determine the three principal values (corresponding to the diagonal elements in the PAS) as well as the two angles (referred to as *Euler angles*) which describe the rotation of the PAS onto a fixed reference frame, for example, that are specified by B_0. The mathematical expression for the dependence of the resonance frequency of a given nucleus in a crystallite on these parameters is given in Appendix. It should be noted that the dipolar coupling between a pair of spins is always axially symmetric, and is fully specified by a single principal value and a single angle (see also Appendix). As the principal values and Euler angles for a given anisotropic interaction contain valuable chemical information, for example, about the electronic environment, one of the principal aims of solid-state NMR is the development of methods by which these parameters can be determined.

10.2.2
Single-Crystal NMR

One approach by means of which the principal values and orientations of the different anisotropic interactions can be determined involves the measurement of the change in the observed resonance frequencies upon rotating a single crystal in a well-defined fashion [10]. This is illustrated in Figure 10.2 for the case of ^{2}H NMR of a single crystal of the peptide *N*-acetyl-D,L-valine (NAV) for which the exchangeable amide and carboxyl hydrogens were deuterated [11]. The quadrupolar coupling leads to an inequivalence of the two single-quantum (SQ) transitions associated with a spin $I = 1$ nucleus such that a doublet is observed for each distinct deuterium. There are two molecules in the unit cell of NAV, and thus two crystallographically distinct hydrogen positions for both the amide and carboxyl groups, yielding four different deuterons, and therefore eight separate lines are observed (Figure 10.2a).

The change in the resonance frequencies of these eight lines upon rotating the crystal in 10° steps around two orthogonal axes is shown in Figure 10.2b,c. These results can then be analyzed to yield the principal values and orientations of both the ^{2}H CSA and quadrupolar tensors for both the amide and carboxyl hydrogens in NAV. As described in [11], it was found that, while the eigenvectors corresponding to the largest and intermediate principal values of the quadrupolar interaction are aligned (within experimental error) with the NH bond direction and the normal to the peptide plane, respectively, small but significant deviations are observed for the orientation of the CSA tensor.

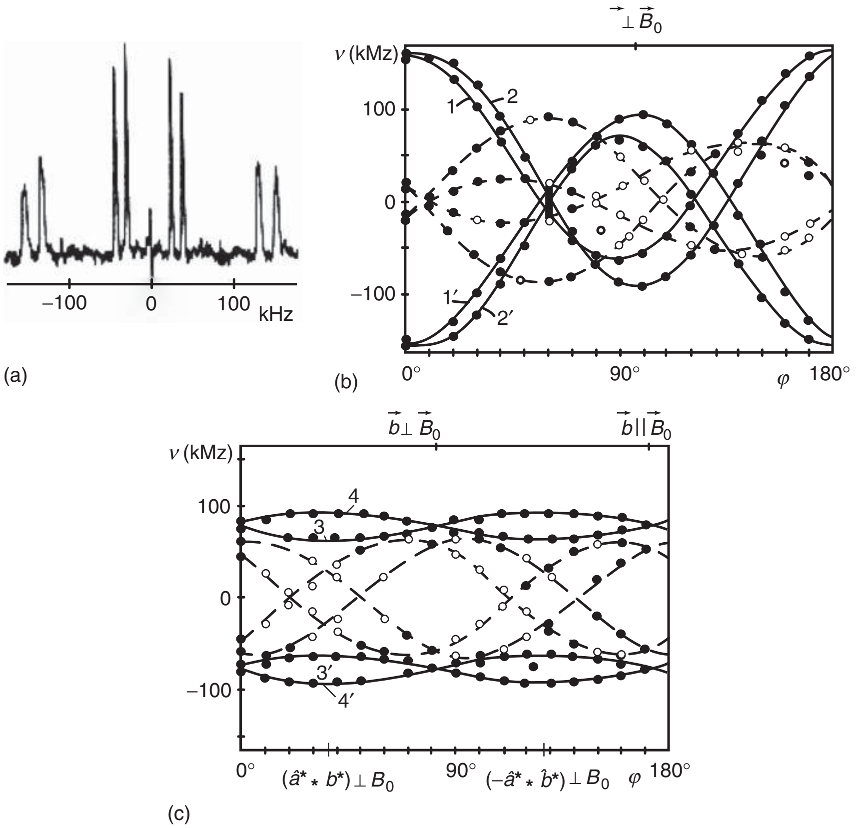

Figure 10.2 (a) ^{2}H NMR spectrum for a particular orientation of a single crystal of the peptide *N*-acetyl-D,L-valine (NAV) for which the exchangeable amide and carboxyl hydrogens were deuterated. (b,c) The change in the resonance frequencies of the eight lines upon rotating the crystal in 10° steps around two orthogonal axes. (Reproduced by permission of the American Chemical Society from [11].)

Although the power of the single-crystal method is evident, it suffers from a couple of significant limitations. First, a single crystal of sufficient size, several mm in each dimension, with a typical volume of $50\,\text{mm}^3$, is necessary. Second, a specialized NMR probe incorporating a goniometer is required for the well-defined rotation of the sample, and such equipment is available in only a handful of laboratories worldwide. If, however, both the crystal and the equipment are available, this kind of study yields very precise measurements of parameters that are not available from diffraction techniques.

At this point, we mention a related class of sample, namely oriented samples. In the case of a perfect macroscopic ordering, each equivalent nucleus is oriented identically, and the situation is the same as that in a single crystal. Specific oriented samples of relevance (with varying degrees of ordering) include polymer fibers [4], liquid crystals (LCs) [12, 13], and membrane proteins in oriented lipid bilayers [14].

We will return to the latter two cases in the discussion of two-dimensional experiments in Sections 10.5 and 10.6.

10.2.3
Powder Spectra

In solid-state NMR, it is more usual to deal with a powdered sample, where there is a uniform distribution of molecular orientations over three-dimensional space. The NMR spectrum for a powdered sample, therefore, consists of a superposition of many lines, corresponding to all the possible resonance frequencies, where each line originates from a given nucleus in a particular crystallite. Examples of powder spectra are shown in Figures 10.3 and 10.4. In Figure 10.3, the anisotropic

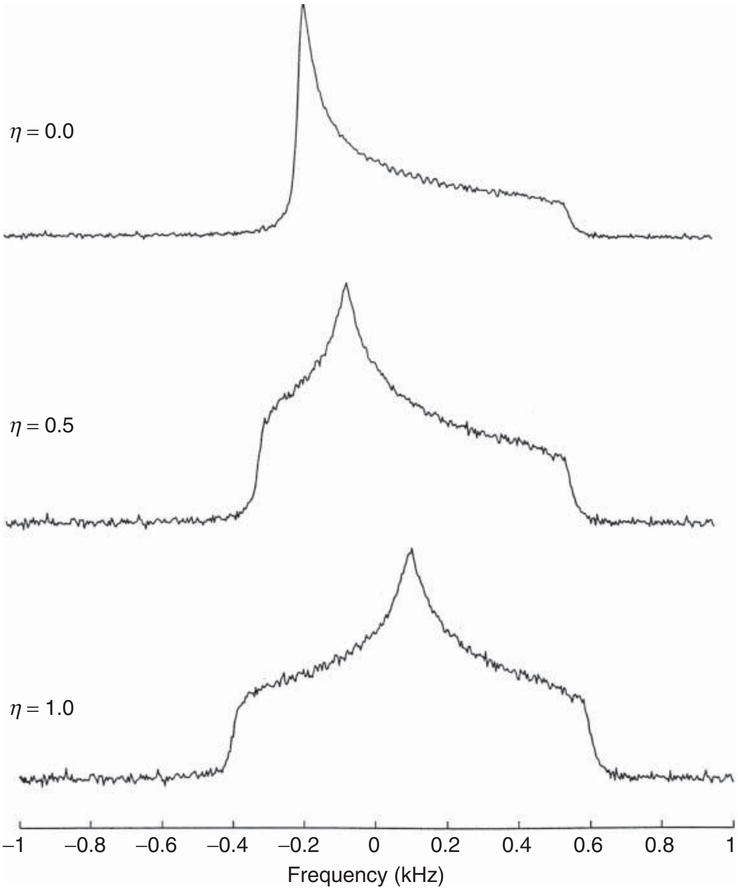

Figure 10.3 Simulated static powder spectra (with added noise) for the anisotropic broadening due to the CSA of a spin $I = 1/2$ nucleus, for example, ^{13}C. Spectra are shown for three different values of the asymmetry parameter, η (Appendix). (Reproduced by permission of the Società Italiana di Fisica from [5].)

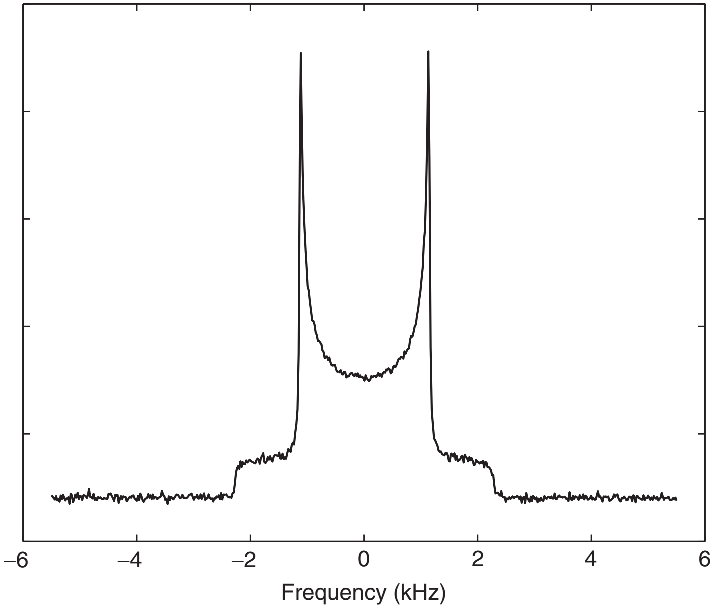

Figure 10.4 Simulated static powder spectrum (with added noise) for the anisotropic broadening due either to a dipolar coupling between an isolated pair of spin $I = 1/2$ nuclei or to the first-order quadrupolar coupling of a spin $I = 1$ nucleus, for example, ^{2}H. (Reproduced by permission of the Società Italiana di Fisica from [5].)

broadening is due to the CSA of a spin $I = 1/2$ nucleus, for example, ^{13}C (for three different values of the asymmetry parameter, η (Appendix)) while Figure 10.4 corresponds either to a dipolar coupling between an isolated pair of spin $I = 1/2$ nuclei or to the first-order quadrupolar coupling of a spin $I = 1$ nucleus, for example, ^{2}H.

If powder spectra of the type shown in Figure 10.3 and Figure 10.4 can be obtained experimentally, the principal values of the anisotropic interaction in question (though *not* the orientation of the PAS with respect to a fixed frame) can be obtained by a straightforward lineshape analysis. However, to obtain such spectra, it is necessary that there is only one distinct nucleus, and that one anisotropic interaction dominates. Usually, the static NMR lineshape is a ''broad featureless hump'' due to the overlapping of many powder patterns as well as the interplay of the different broadening mechanisms. As an example of this, Figure 10.5 presents a ^{1}H NMR spectrum of a representative organic solid, together with, for comparison, the corresponding solution-state ^{1}H spectrum. It is to be noted that the problem in such a case is not a lack of information, but rather there is essentially an overload, such that the net effect is the virtual loss of all information. In the remainder of this chapter, solid-state NMR approaches by which this information can be recovered will be demonstrated.

10.2.4
One-Dimensional ^{2}H NMR

One notable case where it is possible to obtain powder spectra due to a single resonance for the case where one broadening mechanism dominates is ^{2}H NMR. As the natural abundance of deuterium is very low (Table 10.1), the ^{2}H NMR spectrum of a sample which has been selectively deuterated at a particular hydrogen position contains, to an extremely good approximation, only the response of that particular ^{2}H nucleus. Moreover, ^{2}H is a spin $I = 1$ nucleus, and it, therefore, possesses a quadrupole moment. Although the ^{2}H quadrupolar coupling ($\sim$200 kHz) is relatively small compared to other quadrupolar nuclei, it still dominates the other anisotropic interactions in diamagnetic compounds, for example, the CSA and the dipolar coupling.

The applications of ^{2}H NMR usually relate to the investigation of dynamic processes [4]. Indeed, one of the most important facets of solid-state NMR, in general, is its ability to probe molecular dynamics with atomic site selectively. This ability to probe dynamics is a direct consequence of the orientational dependence of the NMR resonance frequency: a given motional process leads to a particular crystallite experiencing a range of different orientations and hence a range of different frequencies. The motion is thus reflected in a marked change in the NMR spectrum as compared to the static case, with an extreme example of this phenomenon being the complete removal of anisotropic broadening as a consequence of isotropic molecular tumbling in solution. Notably, solid-state NMR spectra are not only sensitive to the *rates* of dynamic processes but also the *geometry*.

In ^{2}H NMR of a selectively labeled molecule, the one-dimensional (1D) powder spectrum depends only on the quadrupolar interaction for a single resonance. Moreover, the quadrupolar interaction for a deuteron bonded to a carbon atom is invariably axially symmetric and aligned with the bond direction. By recording a series of spectra at different temperatures, it is therefore possible, by means of a relatively straightforward lineshape analysis based on computer simulations, to determine the kinetic parameters, that is, the rate constants and the activation energy, as well as the motional mechanism for the dynamic process under investigation. Moreover, such investigations are aided by the fact that the experiment can be performed over a very wide temperature range, because the sample is static and in the solid-state (i.e., there is no problem with a solvent freezing or evaporating). It should be noted that it is usual practice to record ^{2}H powder spectra using the quadrupolar (or solid) echo technique [15].

As a specific example, consider the ^{2}H NMR spectra shown in Figure 10.6, which were recorded for a sample of [18-CD_3]-6-*s*-*cis*-retinoic acid, such that the motion of the methyl hydrogens could be investigated [16]. Marked changes in the spectra are apparent on increasing the temperature. In particular, as well as changing its shape, the linewidth is observed to narrow by approximately a factor of 2, when comparing the spectra for the lowest (top) and highest (bottom) temperatures. The rate constant for a model invoking a three-site jump motion was determined at each temperature by means of a lineshape analysis, and in Figure 10.6, the best-fit simulated spectra are shown to the right of the corresponding experimental spectra. For the lowest (top) and highest (bottom) temperatures investigated, the rate constant was determined to be 2.3×10^4 and $1.5 \times 10^{10}\,s^{-1}$, respectively. These two temperatures, therefore, correspond to a motion which is, respectively, ‘‘slow’’ and ‘‘fast’’ compared to the relevant timescale of this NMR experiment (corresponding, in this case, to the time required to record the free-induction decay (FID)). From the knowledge of the rate constant for each temperature, it was possible to determine an activation energy of $14.5\,kJ\,mol^{-1}$. By additionally investigating the methyl group jump motion in the corresponding trans model

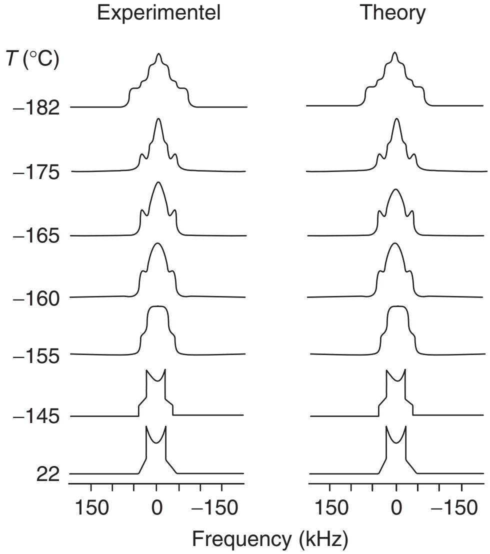

Figure 10.6 Variable-temperature ^{2}H NMR spectra recorded for a sample of [18-CD$_3$]-6-*s*-*cis*-retinoic acid. compound as well as in the membrane protein bacteriorhodopsin, Copié *et al.* [16] were able to postulate the existence of a 6-*s*-*trans* chromophore in the protein.

10.3
Magic-Angle Spinning

The above example of the effect of dynamics on a ^{2}H NMR powder spectrum illustrates that motion leads to line narrowing. Moreover, as noted above, in solution, fast isotropic tumbling of the molecules causes the averaging *to zero* of the line broadening due to the anisotropic interactions. To achieve high resolution, the solid-state NMR spectroscopist would like to mimic this averaging process. Rather than requiring random isotropic motion of each molecule, it can be shown that a physical rotation of the whole sample around an axis inclined at an angle of $\arctan(\surd 2) = 54.7^\circ$ (referred to as the *magic angle*) to B_0 suffices to average any second-rank tensor interaction to zero [17, 18].

To understand why so-called magic-angle spinning (MAS) is so successful as a means of line narrowing, it is first necessary to recognize that the CSA, dipolar, and first-order quadrupolar interaction all have basically the same orientational dependence: for an axially symmetric tensor (this is always the case for the dipolar interaction, and corresponds to a CSA or first-order quadrupolar interaction with a zero asymmetry parameter), the orientationally dependent part of the frequency of a particular crystallite can be expressed in the form

$$\omega \propto \frac{1}{2}(3\cos^2\theta - 1) \tag{10.1}$$

where θ denotes the angle between the tensor PAS direction and B_0 (see Appendix for the full mathematical expressions). For a static sample, there is thus no anisotropic frequency shift for those crystallites with $\theta = 54.7^\circ$.

To illustrate the effect of MAS, we consider in Figure 10.7 the specific example of a dipolar coupling between two spins. The four cones represent the range of positions adopted over the course of one rotor period for four different orientations of the internuclear vector relative to the rotor axis. In each case, the sample rotation leads to those components *perpendicular* to the rotation axis being zero on average, and only the component *parallel* to the rotation axis remains nonzero on average. Thus, for any original orientation, rotation around an axis yields an ‘‘average orientation’’ parallel to the axis of rotation. If the rotation axis is inclined at the magic angle to B_0, this parallel component has an anisotropic frequency shift equal to zero for all cases. Thus, under MAS, the anisotropic broadening is averaged to zero by the sample rotation for all crystallite orientations.

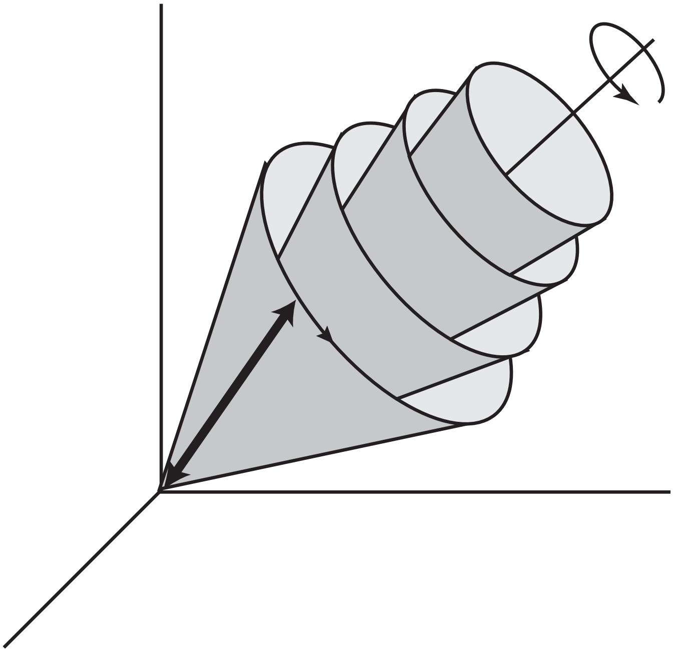

Figure 10.7 The effect of MAS for the specific example of a dipolar coupling between two spins. The four cones represent the range of positions adopted over the course of one rotor period for four different orientations of the internuclear vector relative to the rotor axis. The double-headed arrow represents an arbitrary position of one of the internuclear vectors.

10.3.1
Cross Polarization Magic-Angle Spinning Nuclear Magnetic Resonance CP MAS NMR

For solid-state NMR of a dilute spin $I = 1/2$ nucleus, for example, ^{13}C or ^{29}Si, MAS is usually combined with the method of cross polarization (CP) [19, 20], whereby a sensitivity enhancement results as a consequence of the transfer of polarization from an abundant nucleus with a high magnetogyric ratio, usually ^{1}H; the approach is referred to as *CP MAS NMR* [21]. High-power proton decoupling is normally applied during the acquisition of the FID to remove broadenings due to dipolar couplings involving the protons, such that the dominant anisotropic broadening is the CSA.

The simulated spectra in Figure 10.8 illustrate the effect of MAS for the case of a CSA interaction. On rotating the sample, the static lineshape is seen to break up into a centerband and spinning sidebands, separated by the rotor frequency. At a low MAS frequency, ν_R, the sideband manifold is observed to map out the shape of the static pattern. As the ν_R is increased, the signal intensity is increasingly concentrated at the centerband position, which corresponds to the isotropic chemical shift. It is to be noted that the linewidths are narrow and independent of ν_R [22].

In principle, it is possible to extract the anisotropy and asymmetry of the CSA by fitting the observed MAS sideband intensities. This is referred to as a *Herzfeld–Berger analysis* [24]. Such an approach is restricted to relatively small molecules, as it is necessary to be able to resolve, at a low ν_R, the sidebands of different resonances. As the number of distinct resonances increases, the 1D spectrum becomes increasingly more crowded; the advantage of extending the experiment to a second dimension in such cases will be discussed in Section 10.5.

The main interest of the CP MAS technique is that it can provide high-resolution purely isotropic spectra. As is apparent from Figure 10.8, as ν_R is increased such that it becomes large as compared to the static linewidth, the signal is increasingly concentrated in the centerband position. The spectrum is obviously much simplified if there is only one narrow resonance line, at the isotropic chemical shift, for each distinct nucleus. As an example, Figure 10.9 presents a ^{13}C CP MAS spectrum of powdered cyclosporin A, a cyclic 11-residue peptide. In this case, the isotropic spectrum is obtained by employing a ν_R of 33.3 kHz, and there are virtually no spinning sidebands. (MAS probes capable of supporting such a ν_R have only become available in the past 2–3 years. It is to be noted that at such a fast ν_R, it is necessary to employ a modified CP procedure, which is referred to as *ramped CP* [25, 26].) An alternative means by which a purely isotropic spectrum without spinning sidebands can be achieved for the case of a moderate ν_R is to employ a specially designed sequence of radio frequency (RF) pulses to suppress the spinning sidebands; the classic example is the TOSS (total suppression of sidebands) sequence [27, 28] which involves the application of four (or $2n + 2$) appropriately spaced 180° pulses before the start of acquisition.

In solid-state NMR experiments, a central theme is that of resolution. For ^{13}C CP MAS NMR, a critical factor in this respect is the efficiency of ^{1}H decoupling.

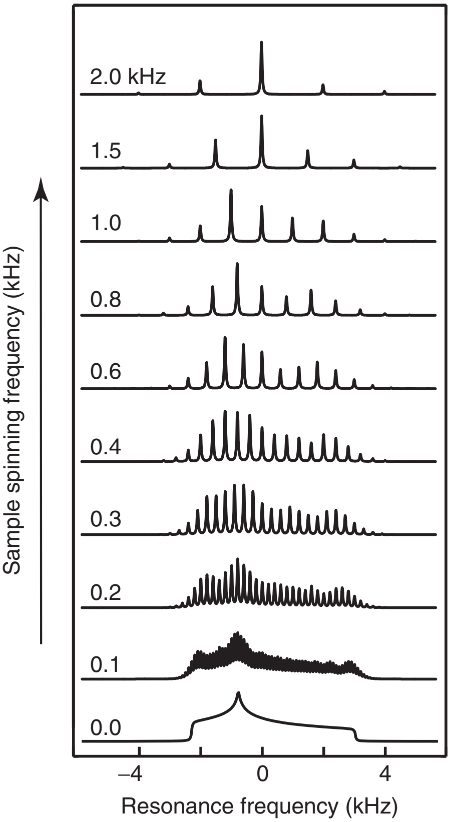

Figure 10.8 Simulated spectra showing the effect of MAS on the anisotropic lineshape due to a CSA interaction. (Reproduced by permission of the American Institute of Physics from [23].)

The simplest method, which is termed continuous wave (CW) decoupling, involves the application of a continuous RF pulse of fixed phase for the duration of the acquisition of the FID [29]. Recently, more sophisticated decoupling methods, such as two-pulse phase-modulation TPPM [30] or other sequences possessing a RN_n^ν symmetry [31], have been introduced; an explanation of why these methods yield narrower ^{13}C linewidths than conventional CW decoupling is given in [31, 32]. In simple terms, the efficiency of ^{1}H decoupling increases as the RF field strength increases (note that NMR literature usually refers to the inherent nutation frequency of the pulse, $|\omega_1| = |\gamma B_1|$, where B_1 is the RF field strength). Experimentally, care must of course be taken to find the power level which gives the optimum decoupling performance without damaging the probe. In Figure 10.9, it is shown that current state of the art ^{1}H decoupling, namely TPPM at a ω_1 of 200 kHz, yields a ^{13}C linewidth (full-width at half-maximum height, FWHMH) of 14 Hz (see the inset for a methyl carbon in cyclosporin A). The spectrum in Figure 10.9 was recorded at a B_0 of 11.8 T (corresponding to ^{1}H and ^{13}C Larmor frequencies of 500 and

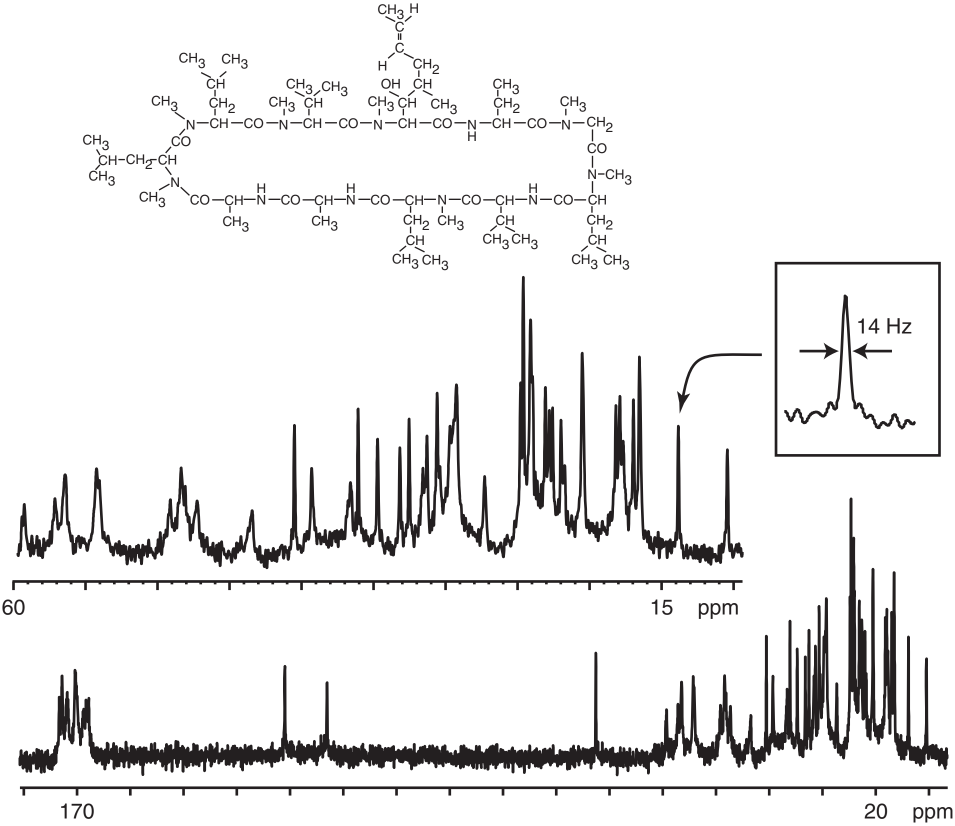

Figure 10.9 A ^{13}C CP MAS ($\nu_R = 33.3$ kHz) spectrum of powdered cyclosporin A, a cyclic 11-residue peptide, at natural abundance. (Courtesy of A. Lesage and P. Charmont.)

125 MHz). Today, solid-state NMR is being performed at B_0 fields approaching 20 T; provided that the same or narrower linewidths (in Hertz) can be achieved at the higher B_0, and this can certainly not be taken for granted in solid-state NMR, the resolution of resonances with different chemical shifts will be further improved at higher B_0.

For small molecules, some of the ^{13}C resonances can usually be assigned by reference to an assigned solution-state spectrum, as ^{13}C chemical shifts are relatively insensitive to the through-space effects of importance in the solid phase. As the molecular size increases, however, this is no longer the case. To assign a complicated ^{13}C CP MAS spectrum, such as that in Figure 10.9, spectral editing methods which can distinguish between CH_3, CH_2, CH, and quaternary carbons are of much help [33–36]. As a specific example, Figure 10.10 shows a 1D ^{13}C spectrum of L-histidine monohydrochloride monohydrate recorded using the SS-APT (solid-state attached proton test) method [34]: resonances due to carbons with an even (i.e., quaternary and CH_2 moieties) or odd (i.e., CH and CH_3 moieties)

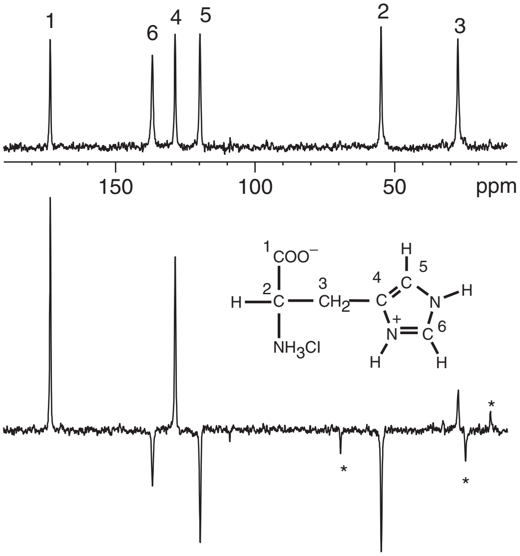

Figure 10.10 One-dimensional ^{13}C spectrum of L-histidine monohydrochloride monohydrate recorded using the SS-APT method. Resonances due to carbons with an even (i.e., quaternary and CH_2 moieties) or odd (i.e., CH and CH_3 moieties) number of attached protons are positive or negative, respectively. Spinning sidebands are labeled by asterisks. For comparison, the ^{13}C CP MAS spectrum is shown at the top. (Reproduced by permission of the American Chemical Society from [34].)

number of attached protons are positive or negative, respectively. It is to be noted that the SS-APT method is based on through-bond *J*-couplings, and thus has the advantage of being unaffected by molecular motion, which can lead to the erroneous interpretation of spectra obtained with the other spectral editing methods which exploit through-space dipolar couplings.

1D CP MAS is the workhorse solid-state NMR experiment, a fact which is apparent from the very wide range of applications, with specific examples including fossil fuels [37], that is, coals [38], and cokes [39], food science, for example, polysaccharides [40], pharmaceuticals [41], polymer blends [42], and soil science [43]. In addition to ^{13}C and, to a lesser extent, ^{15}N, another much investigated nucleus is ^{29}Si, with ^{29}Si solid-state NMR being of much importance in materials science and geology [44, 45]. Although ^{31}P has a 100% natural abundance, the relatively large separation between phosphorus atoms in a typical solid means that ^{31}P often has the characteristics of a rare spin. ^{31}P CP MAS NMR is of importance in, for example, the investigation of glasses [46].

Valuable information can often be obtained by simple experiments which determine the relaxation times, in particular the spin–lattice (or longitudinal) relaxation times in the laboratory or rotating frame, namely the ^{13}C T_1 and the ^{1}H $T_{1\rho}$, respectively, for the different resolved resonances in a 1D CP MAS spectrum. In simple terms, a faster relaxation time is due to an increase in molecular mobility.

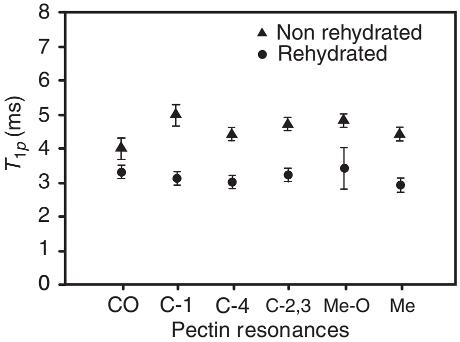

Figure 10.11 Fitted ^{1}H $T_{1\rho}$ relaxation time constants as read out at the various assigned ^{13}C resonances for 10% hydrated (triangles) and 35% hydrated (circles) onion cell-wall material. The difference directly reflects the increased mobility in the hydrated sample. (Reproduced by permission of Elsevier Science Publishers from [47].)

As a specific example, Figure 10.11 shows the ^{1}H $T_{1\rho}$ relaxation time constants, as read out at the ^{13}C resonances, for the pectin resonances in onion cell-wall material [47]. It is apparent that increasing the sample hydration from 10% to 35% leads to a clearly faster relaxation.

10.3.2
^{1}H Solid-State NMR

In the discussion of Figure 10.8, it was noted that the linewidths of the centerband and spinning sidebands are narrow and independent of ν_R. This is a general feature of *rare spin* spectra. A different situation is usually encountered in ^{1}H solid-state NMR. Figure 10.12 shows the effect of increasing ν_R upon the centerband in the ^{1}H MAS NMR spectrum of a medium-sized organic solid. In particular, it is apparent that the linewidth is dependent on ν_R, with a line narrowing being observed on increasing ν_R. Even at 35 kHz, the linewidths (FWHMH ≈ 750 Hz) are, however, much larger than those observed in ^{13}C MAS spectra.

The different effect of MAS in ^{1}H and ^{13}C NMR is a consequence of the central importance and relative insignificance of homonuclear (i.e., between like spins) dipolar couplings in the respective two cases. The homonuclear dipolar coupling between a pair of protons is approximately 16 times larger than that between two ^{13}C nuclei at the same internuclear separation. Moreover, the natural abundance of ^{13}C is only 1% as opposed to nearly 100% for ^{1}H, such that (except for the case of isotopically enriched samples) very few ^{13}C nuclei have a nearby ^{13}C neighbor.

For a typical organic solid, there exists a strongly dipolar-coupled multiproton network, and the effect of MAS is quite different as compared to the case of the CSA interaction. This difference is explained in a classic paper by Maricq and Waugh [22]. The CSA is an example of an interaction where the anisotropic broadening is perfectly refocused at the end of each rotor period, τ_R, (in the language of quantum mechanics, the corresponding Hamiltonian for a given

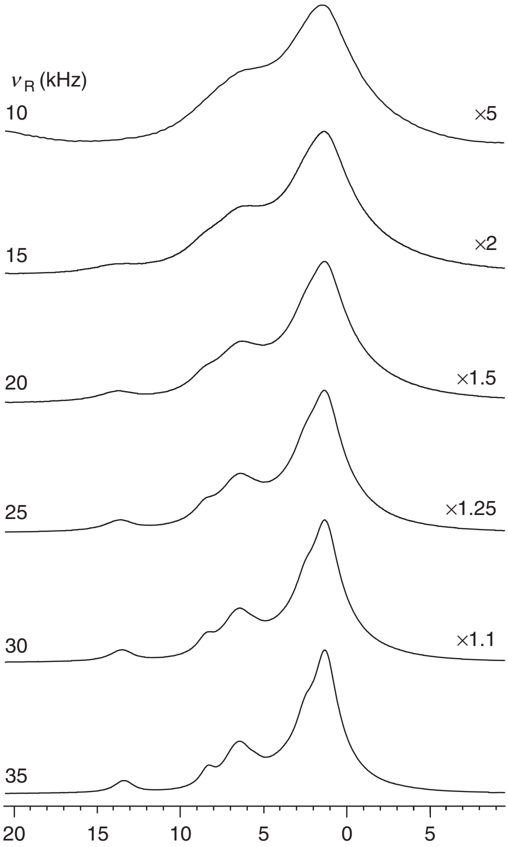

Figure 10.12 The effect of increasing the MAS frequency, ν_R, on the centerband of a ^{1}H MAS spectrum of a typical organic compound. (Reproduced by permission of the American Chemical Society from [48].)

crystallite commutes with itself at all times). By comparison, when there are three or more dipolar-coupled protons, the perturbing influence of the other dipolar-coupled protons on a particular dipolar-coupled pair means that the Hamiltonian does not commute with itself at all times, and the evolution under the dipolar coupling of a particular pair is no longer refocused at the end of each τ_R.

It was noted in the previous section, that a ν_R in excess of 20 kHz has only become possible in the past 2–3 years. The advantage in terms of the enhanced line narrowing in a ^{1}H MAS NMR spectrum is evident in Figure 10.12. Indeed, it has been shown that a ν_R of 30+ kHz at a ^{1}H Larmor frequency of 500+ MHz is sufficient to allow some ^{1}H resonances due to particular chemically distinct protons to be resolved in ^{1}H MAS NMR spectra of small to moderately sized organic solids [48–51]. The line narrowing achieved by MAS alone at a ν_R equal to 30 kHz is, however, still far from the limiting case, where all residual dipolar broadening has been removed.

Brute-force fast MAS is not the only means by which line narrowing can be achieved in solid-state NMR. A particularly ingenious alternative approach, first presented over 30 years ago by Waugh and coworkers [52, 53], involves the removal of the dipolar broadening by specific multiple-pulse techniques, where RF pulses achieve rotations in spin space. These rotations can complement the effect of the physical rotation of the sample; combined rotation and multiple-pulse spectroscopy (CRAMPS) [54–56] yields well-resolved ^{1}H spectra [57]. We will discuss the CRAMPS approach in more detail in Section 10.5.3.

An inspection of Table 10.1 reveals that ^{19}F has similar NMR properties to ^{1}H. Thus, methods which deal with the residual broadening owing to homonuclear dipolar couplings are also of much relevance in ^{19}F solid-state NMR [58]. Although fluorine is much less commonly encountered in chemistry than the omnipresent hydrogen, ^{19}F solid-state NMR has found a number of important applications, with recent examples including fluoropolymers [59] and biomembranes [60].

10.4
Recoupling Methods

Anisotropic interactions present both problems and opportunities. On the one hand, there is the significant disadvantage of hindering the resolution of distinct sites, and methods, such as MAS, which remove the line broadening due to the anisotropic interactions are essential to allow the recovery of the isotropic chemical shift information. On the other hand, they contain valuable structural and dynamic information. This information can be accessed while maintaining high resolution by employing the so-called recoupling method [8, 9] to recover the anisotropic interaction during part of the NMR experiment. In simple terms, recoupling involves the application of RF pulses to counteract the effect of the physical rotation. The conceptually most simple technique to illustrate the principle is rotational-echo double resonance (REDOR).

10.4.1
Heteronuclear Dipolar-Coupled Spins: REDOR

In the REDOR [61–63] technique, the distance between two heteronuclei is determined by comparing the signal intensity in two closely related experiments. The interpretation of the experimental results assumes the existence of isolated spin pairs, and there is thus usually a requirement for selective isotopic labeling at the two sites, the distance between which is of interest.

In a reference experiment, an echo corresponding to the refocusing of the evolution under both the chemical shift and the heteronuclear dipolar coupling is formed. The echo intensity in the reference experiment, S_0, is then compared to that in a second experiment where the application of 180° pulses at intervals of $\tau_R/2$ on the channel where there is no transverse magnetization interferes with the refocusing by MAS of the evolution due to the heteronuclear dipolar coupling,

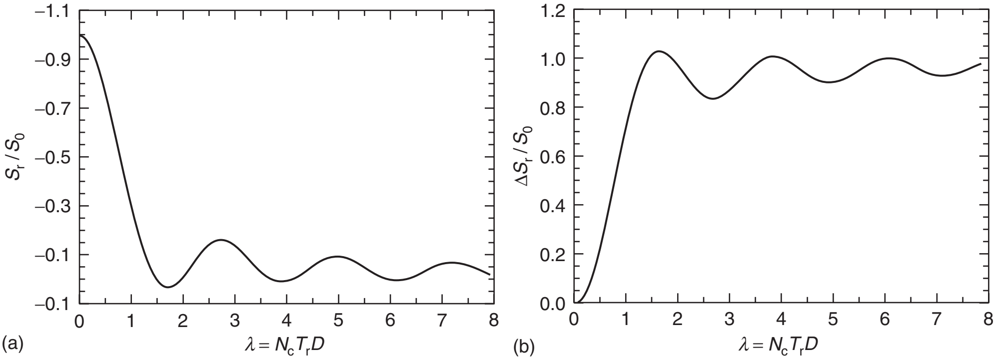

Figure 10.13 (a,b) REDOR master curves for an isolated dipolar-coupled spin pair showing the dependence of the ratios S_r/S_0 and $\Delta S/S_0$ upon the product of the evolution time and the heteronuclear dipolar coupling. (Reproduced from [63].)

and hence results in a reduced signal intensity, S_r. For an isolated spin pair, the ratio S_r/S_0 depends solely and in a straightforward manner on the product of the evolution time and the heteronuclear dipolar coupling. The REDOR master curve applicable to all heteronuclear spin pairs is plotted in Figure 10.13. Note that it is common to see the REDOR literature referring to the difference, $\Delta S = S_0 - S_r$. By simple reference to this master curve, it is possible to determine the heteronuclear dipolar coupling between the spin pair under consideration. It is of course advisable to determine two or more S_r values to ensure the reliability of the analysis. As the dipolar coupling depends on the internuclear distance to the inverse cubed power (Appendix), this method allows the determination of internuclear distances for heteronuclear spin pairs.

A number of interesting applications of the REDOR method have been presented (see Table 10.1 of [9]), with a particular emphasis on samples of biological relevance. A specific example is shown in Figure 10.14, where the distance between the specific spin labels in [1-^{13}C,^{15}N]acetyl-L-carnitine is determined to be 0.496 nm [63]. In this particular case, a distance determination was possible even though the C1 resonance is not resolved from that of the indicated C8 carbon. As well as ^{13}C and ^{15}N, other spin $I = 1/2$ nuclei studied by REDOR include ^{19}F, ^{29}Si, and ^{31}P. For example, Holl *et al.* [64] have demonstrated the measurement of a 0.8 nm ^{13}C–^{19}F internuclear distance in a nine-residue fragment of the peptide antibiotic emerimicin. Extensions of the REDOR method to measure distances where one or even both of the nuclei are quadrupolar have also been proposed. For quadrupolar nuclei, the large quadrupolar interactions present significant problems, in particular a simple 180° pulse does not achieve a uniform inversion for all crystallites for the case of a broad quadrupolar lineshape. Various methods, for example, TRAPDOR [65] and rotational-echo adiabatic passage double resonance (REAPDOR) [66], have been introduced which attempt to address this problem.

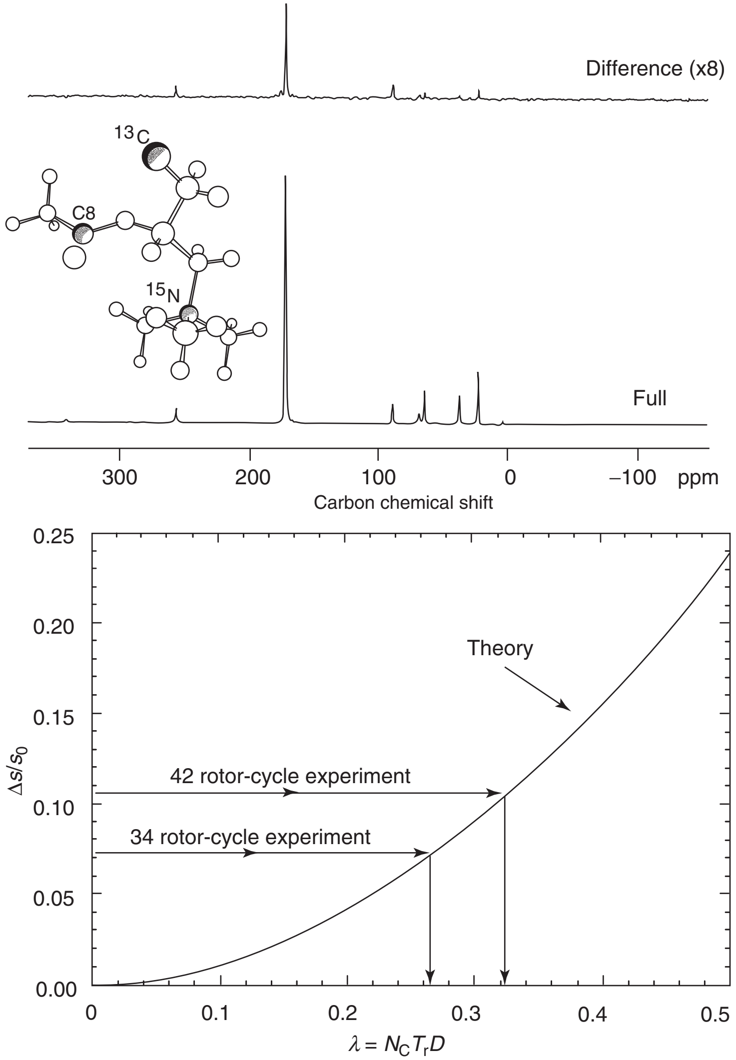

Figure 10.14 The determination of the distance between the specific spin labels in [1-^{13}C, ^{15}N]acetyl-L-carnitine by the REDOR technique. The difference, ΔS, and reference, S_0, REDOR spectra are shown for the 34-τ_R experiment. (Reproduced from [63].)

10.4.2
Homonuclear Dipolar-Coupled Spins

There are small but important differences between the evolution of a given spin under a homonuclear as opposed to a heteronuclear dipolar coupling [3–5]. As a consequence, a different methodology is required for the determination of the internuclear distance between a homonuclear dipolar-coupled pair of spins.

Rotational resonance (RR) is an intriguing phenomenon which is observed when ν_R is equal to a small integer multiple of the difference in the isotropic chemical shift frequencies of two resonances in the spectrum [67, 68]. The most apparent effect of RR is that the normally narrow spectral peaks acquire splittings and broadenings, the nature of which depends on the dipolar coupling between the two spins. As a specific example, experimental spectra (together with best-fit simulations) corresponding to the $n = 1$, 2, and 3 RR conditions for all-E-[11,20-$^{13}C_2$]-retinal are shown in Figure 10.15 [69]. In this case, it was possible to determine that the internuclear distance between the two ^{13}C labels is 0.301 ± 0.008 nm.

In the last decade, a large number of methods for recoupling the homonuclear dipolar coupling have been developed, with specific examples including DRAMA

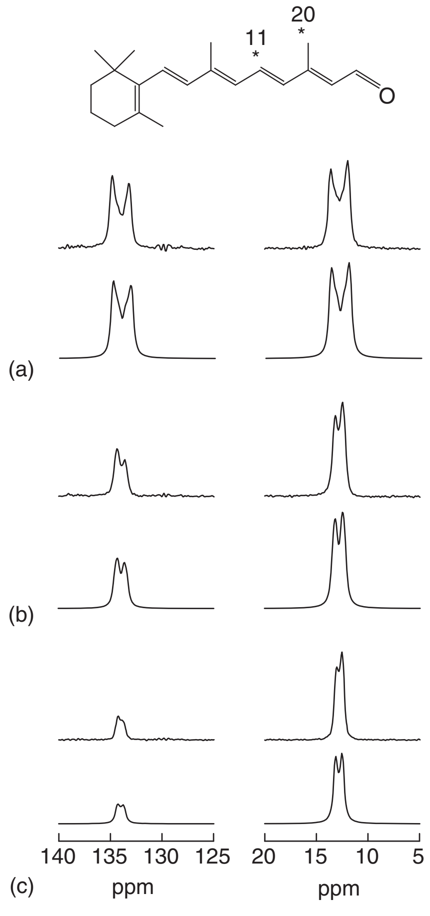

Figure 10.15 ^{13}C rotational-resonance experimental spectra (top), together with best-fit simulations (bottom), corresponding to the $n =$ (a) 1, (b) 2, and (c) 3 RR conditions for all-E-[11,20-$^{13}C_2$]-retinal. (Reproduced by permission of Elsevier Science Publishers from [69].)

[70], radio-frequency-driven recoupling (RFDR) [71], HORROR [72], C7 [73], BABA [74], DRAWS [75], and DREAM [76] (for a comprehensive account, see [8, 9]). We note that Levitt and coworkers have recently introduced a very helpful classification system, based on symmetry principles, which explains how many of these sequences work and provides a framework for generating other sequences [31, 77]. Rather than allowing the accurate determination of internuclear distances, these sequences, as will be illustrated in Section 10.5, are usually employed to establish correlations or to select dipolar-coupled spin pairs in multidimensional homonuclear experiments.

10.4.3

The CSA: CODEX

It was stated above that MAS causes the evolution under the CSA to be refocused at the end of each τ_R. If a 180° pulse is applied every $\tau_R/2$, the refocusing of the CSA evolution is prevented (the same principle applies for the case of the heteronuclear dipolar coupling in the REDOR experiment (Section 10.4.1) or the homonuclear dipolar coupling in the RFDR [71] sequence). Recently, de Azevedo *et al.* [78, 79] have shown how an experiment incorporating two periods of such CSA recoupling separated by a mixing time, τ_m, allows the detection of slow dynamic processes. The method is applicable at fast MAS, and is termed centerband-only detection of exchange (CODEX). The principle of the experiment is that a loss of signal intensity is observed if the orientation of the CSA tensor for a particular carbon changes during τ_m. By subtracting the signal intensity from that measured in a reference experiment, a pure-exchange CODEX spectrum is obtained.

As a specific example, Figure 10.16 shows pure-exchange CODEX ^{13}C NMR spectra, recorded for a sample of amorphous poly(methyl methacrylate), PMMA (at natural abundance in ^{13}C), at 300 K with different τ_m [78]. For the very small mixing time, τ_m, of 1 ms, no intensity is observed, indicating the absence of dynamics on this timescale. For a longer τ_m, intensity is seen to build up at the COO and OCH_3 positions as well at the quaternary C position due to side group and backbone motion, respectively, in the polymer. From a series of CODEX experiments, it is possible to determine the reorientation angle, the correlation time, as well as the fraction of mobile segments.

10.5

Homonuclear Two-Dimensional Experiments

The importance of solution-state NMR today owes much to the extension of the experiment to a second (and higher) dimension [1]. Two-dimensional (2D) NMR spectroscopy is also of much significance in solid-state NMR. In attempting to classify the many important different 2D solid-state NMR experiments which have been proposed to date, we make, in this chapter, a distinction between homonuclear (i.e., those involving only one kind of nucleus) and heteronuclear experiments.

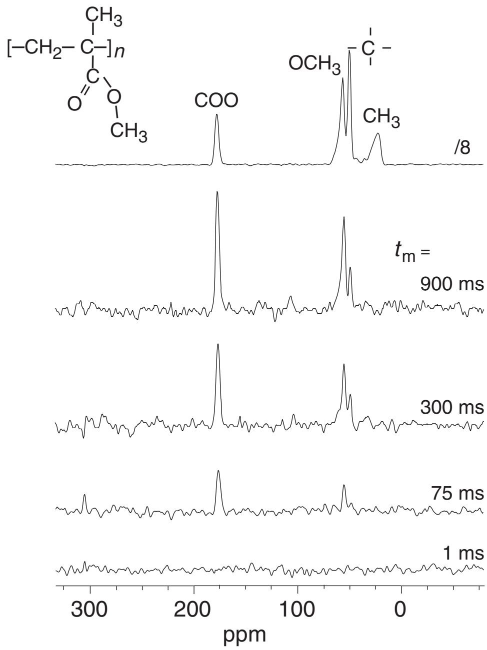

Figure 10.16 Pure-exchange CODEX ^{13}C NMR spectra, recorded for a sample of amorphous PMMA, (at natural abundance in ^{13}C) at 300 K with different τ_m. A ^{13}C CP MAS spectrum is shown at the top. (Reproduced by permission of the American Chemical Society from [78].)

10.5.1
Establishing the Backbone Connectivity in an Organic Molecule

In Section 10.3.1, the problem of assigning the many resolved ^{13}C resonances in a 1D MAS spectrum was mentioned, and 1D spectral editing methods were introduced. In this section, we describe homonuclear ^{13}C–^{13}C 2D correlation experiments in which a selection is usually made such that 2D peaks are only observed for pairs of directly bonded carbons (or at least these peaks are significantly more intense). In this way, it is possible to trace out the connectivity along the backbone of the organic molecule, and thus assign the ^{13}C resonances. As a consequence of the significant sensitivity problems associated with the very low probability of finding a pair of directly bonded ^{13}C nuclei in a sample at natural abundance, these experiments are usually performed on fully or partially ^{13}C-enriched (normally globally, i.e., at all carbon positions) samples.

In the first class of ^{13}C–^{13}C 2D correlation experiments described here, single-quantum coherence (SQC), that which is detected in a conventional 1D NMR experiment, evolves in both dimensions of the NMR experiment. A mixing time is inserted between the two evolution periods during which a pulse sequence is applied which recouples the homonuclear dipolar coupling (Section 10.4.2), such that coherence transfer occurs between ^{13}C nuclei which are close together in space. As a specific example, Figure 10.17 shows the region corresponding to the C_α and aliphatic side-chain carbons of a ^{13}C–^{13}C SQ–SQ correlation spectrum of ^{13}C globally labeled antanamide (a cyclic decapeptide), recorded using the DREAM [76] recoupling sequence. The indicated negative off-diagonal peaks are due to one-bond correlations among the aliphatic side-chains.

By using very high magnetic fields, even larger biopolymers are becoming accessible to solid-state NMR. As an example, Figure 10.18 presents a ^{13}C–^{13}C SQ–SQ correlation spectrum of a solid 62 residue ^{13}C and ^{15}N globally labeled protein containing the α-spectrin SH3 domain, recorded at 17.6 T [80]. In this case, mixing was achieved using proton-driven spin diffusion; a long mixing time of 15 ms was employed such that longer-range correlations are also observed. Using this and other experiments, it was possible to assign all the ^{13}C and ^{15}N resonances.

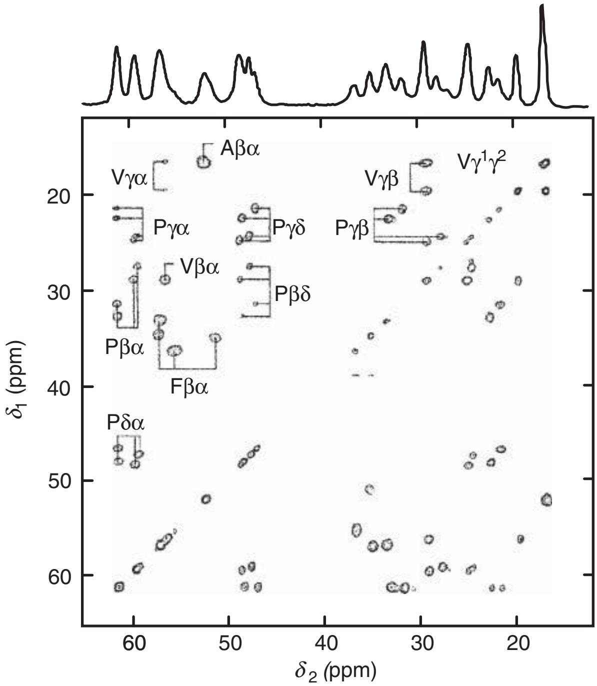

Figure 10.17 The region corresponding to the C_α and aliphatic side-chain carbons of a ^{13}C–^{13}C SQ–SQ correlation spectrum of ^{13}C globally labeled antanamide (Val-Pro-Pro-Ala-Phe-Phe-Pro-Pro-Phe-Phe), recorded at a magnetic field of 14.1 T and $\nu_R = 30$ kHz. Mixing was achieved using a DREAM [76] recoupling sequence of duration 7 ms. Positive and negative peaks are shown as dark- and light-shaded lines, respectively. The indicated negative off-diagonal peaks are due to one-bond correlations among the aliphatic side-chains. (Courtesy of B.H. Meier.)

Mixing was achieved using proton-driven spin diffusion; a long mixing time of 15 ms was employed such that longer-range correlations are also observed. (Reproduced from [80].)

Emsley and coworkers have recently suggested an alternative approach for establishing carbon–carbon connectivities, namely the solid-state INADEQUATE experiment [81]. It is so termed because of the analogy to the solution-state experiment of the same name [82]. Unlike the experiments described above which utilize through-space dipolar couplings, this approach is based on the through-bond *J*-coupling. A further important difference is that double-quantum coherence (DQC) as opposed to SQC evolves during the t_1 (or indirect) dimension of the experiment. Experiments involving the creation of DQC and multiple-quantum coherence (MQC) in general are of much importance in both solution-state and solid-state NMR. For example, in pioneering work, Pines and coworkers have shown that the analysis by so-called spin-counting experiments of the very high MQC orders excitable in static ^{1}H solid-state NMR provides valuable information about large clusters (often up to 100 nuclei) of dipolar-coupled protons [83, 84].

For a detailed discussion of the concept of MQC, the reader is referred to, for example, [1, 85]. Here, we simply note two relevant features: first, a MQC cannot be directly detected in an NMR experiment, that is, an experiment involving a multiple-quantum (MQ) evolution period is inherently at least 2D, since the MQC must be converted into detectable SQC; and, second, for spin $I = 1/2$ nuclei, MQC can only be created for coupled nuclei. As illustrated by the specific example of L-tyrosine in Figure 10.19, an advantage over the SQ–SQ correlation spectra in Figure 10.17 and Figure 10.18 is the absence of signal along the diagonal. Furthermore, by using the *J*-coupling, the observation of a pair of correlated peaks can only be due to directly bonded ^{13}C nuclei. However, S/N of the *J*-coupled INADEQUATE experiment is invariably worse than that of the dipolar-based experiments used for Figure 10.17 and Figure 10.18, although refocused INADEQUATE experiments [86, 87] reduce the signal loss and are applicable to disordered systems.

10.5.2
Dipolar-Mediated Double-Quantum Spectroscopy

Double-quantum (DQ) spectroscopy is not only useful for homonuclear ^{13}C–^{13}C correlation experiments which allow the identification of the backbone connectivity. In this section, the utility of other 2D DQ experiments which provide insight into, for example, through-space proximities will be illustrated. As opposed to the solid-state INADEQUATE experiment introduced in the previous section, the experiments described in this section are based on the dipolar as opposed to the *J*-coupling of spins.

A ^{1}H 2D DQ MAS spectrum [88] recorded in a rotor-synchronized fashion in t_1 (i.e., the t_1 increment is set equal to one rotor period such that all spinning sidebands in the DQ dimension (F_1) fold back onto the centerband position) is shown in Figure 10.20a. To create DQC as well as to allow its conversion into

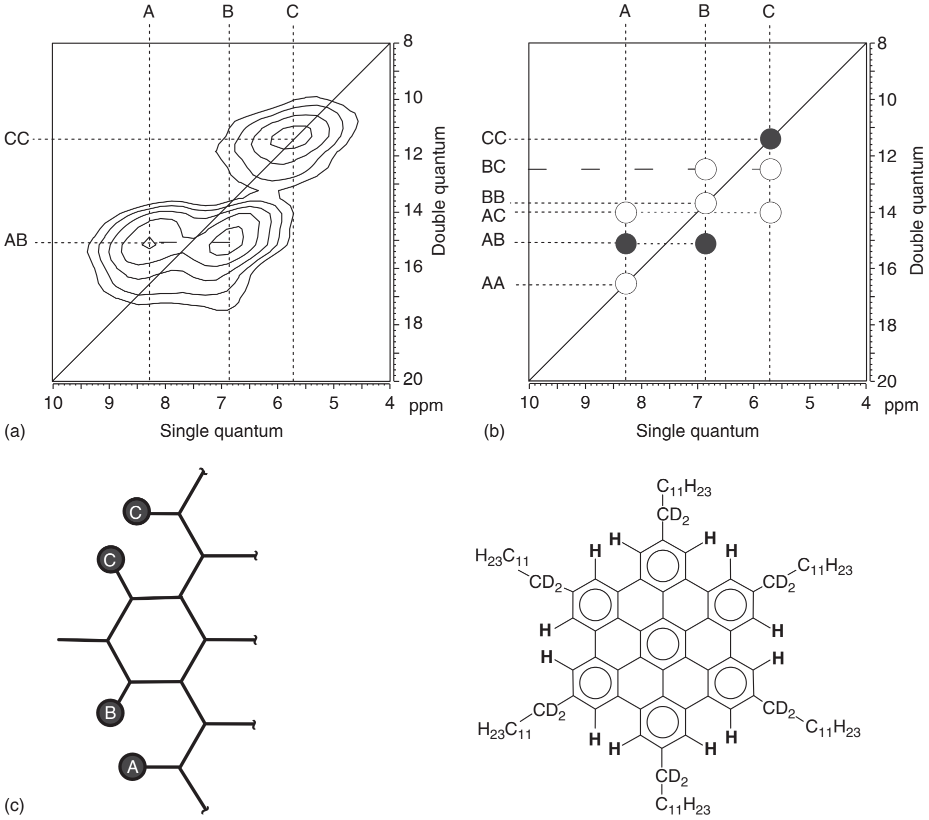

Figure 10.20 (a) A representative rotor-synchronized ^{1}H DQ MAS spectrum, corresponding to the aromatic protons in HBC-C_{12}. (b) A schematic representation showing the positions of the six possible DQ peaks; the observed AB and CC peaks (filled circles) imply the proton–proton proximities indicated in (c). (Reproduced by permission of Elsevier Science Publishers from [50].)

observable SQC, the BABA [74] recoupling sequence (Section 10.4.2) was used. This is a robust sequence which is suitable for the fast ν_R of 35 kHz employed. The ability of the ^{1}H DQ MAS experiment to identify proton–proton proximities lies in the fact that both the excitation and subsequent reconversion of DQC relies on the presence of a dipolar coupling between a particular two spins. As the dipolar coupling is proportional to the internuclear distance to the inverse cubed power, a peak is, hence, only observed in the DQ MAS spectrum if the corresponding two protons are close together in space. As a rule of thumb, the presence of a peak in a ^{1}H DQ MAS spectrum implies a proton–proton proximity of under 0.35 nm.

For this particular example, which corresponds to the aromatic protons of an alkyl-substituted polycyclic aromatic system (HBC-C_{12}) [49], three resonances (labeled A, B, and C) can be identified in the corresponding 1D ^{1}H (500 MHz) MAS spectrum, which is shown at the top of Figure 10.20a. The six possible DQ peaks in this case are shown in Figure 10.20b. As the DQ frequency corresponding to a given DQC is simply the sum of the two SQ frequencies, DQCs between like (AA), and unlike (AB) spins can, in general, be distinguished in that, in the former case, a single peak at $(2\nu_A, \nu_A)$ is observed, while, in the latter case, two peaks at $(\nu_A + \nu_B, \nu_A)$ and $(\nu_A + \nu_B, \nu_B)$ are observed. (The notation (ν_1, ν_2) refers to a DQ peak centered at ν_1 and ν_2 in the F_1 and F_2 dimensions, respectively.) Note that for the anisotropic dipolar coupling, it is, unlike for the isotropic J-coupling, possible to observe an auto peak for a DQC between two like spins. It should be noted that an advantage of the DQ approach over a spin diffusion experiment [4, 89] in which a mixing time is inserted between two SQ evolution periods is that an auto peak is only observed if there is a close proximity of two protons. By contrast, in the spin diffusion experiment, strong auto peaks are seen for all resonances, regardless of whether there is a close proximity.

Of the six possible DQ peaks, only two, namely AB and CC, are observed in the experimental spectrum in Figure 10.20a. For this system, the aromatic protons are arranged into well-isolated pairs of "bay protons;" the observed DQ peaks thus correspond to these bay protons pairs. As discussed in [49], the implied presence of only two types of pairs of aromatic protons, H_A–H_B and H_C–H_C (Figure 10.20c) is a consequence of intermolecular ring current effects; for an isolated molecule, the sixfold symmetry leads to all aromatic protons being equivalent. Using quantum-chemical calculations of ^{1}H chemical shifts, the experimental data could be assigned in a fully quantitative manner to a particular structural model [90]. Such effects of ring currents on NMR chemical shifts are, of course, well established [91]; however, it is only recently, with the development of solid-state NMR methods allowing the resolution of ^{1}H resonances, that the widespread importance of these effects in organic solids is gaining attention; other clear examples of the phenomenon can be found in, for example, [92, 93]. It is to be noted that, although the absolute shifts due to ring currents are similar for both ^{1}H and ^{13}C, the much smaller range of chemical shifts ($\sim$20 ppm as opposed to 200 ppm) means that the influence is much more evident in ^{1}H NMR. In addition, protons are normally located at the more exposed parts of the structure.

^{1}H NMR is well suited for the investigation of hydrogen bonding, with it being well-known that hydrogen bonding leads to a marked lowfield (to a high parts per million value) chemical shift. For example, for a general hydrogen bond O–H$\cdots$O, a clear correlation between the ^{1}H isotropic chemical shift and the hydrogen-bond strength as given by the O$\cdots$H and O$\cdots$O distances determined by single-crystal diffraction studies has been established [94–96]. By identifying specific proton–proton proximities, rotor-synchronized 2D ^{1}H DQ MAS spectra have been shown to differentiate between distinct hydrogen-bonded structures [48].

Applications of dipolar-mediated DQ spectroscopy are not limited to ^{1}H NMR. For example, ^{31}P–^{31}P DQ MAS spectra have provided valuable insight into the structure of inorganic phosphates [97] and glasses [98]. In addition, Nielsen *et al.* [99] and Hong [100] have presented dipolar analogs of the *J*-coupled ^{13}C–^{13}C DQ MAS correlation experiment described in Section 10.5.1. Finally, we note that Schmidt-Rohr and coworkers [101] have elegantly demonstrated that 2D ^{13}C–^{13}C DQ spectra recorded for static samples can identify the chain conformation statistics for ^{13}C-labeled polymer samples. Remembering that the frequency of a given ^{13}C resonance depends on the orientation of the CSA tensor (Section 10.2.1), the method relies on the fact that the adoption of a particular torsional angle along the chain results in DQ peaks for only specific pairs of ^{13}C frequencies. As illustrated in Figure 10.21, trans and gauche conformations lead to very different 2D DQ powder

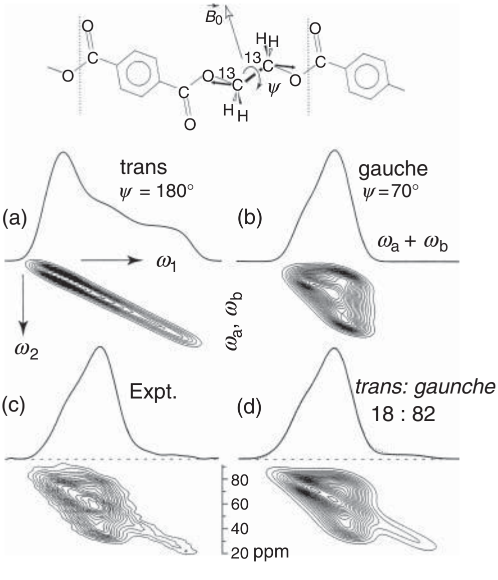

Figure 10.21 Two-dimensional ^{13}C–^{13}C DQ static spectra allow the determination of the chain conformation statistics for ^{13}C-labeled polymer samples. The simulated spectra show that (a) trans and (b) gauche conformations lead to very different 2D DQ powder spectra. For the experimental spectrum (c) obtained for amorphous PET, a best-fit simulation (d) revealed a 18 : 82 trans : gauche distribution. (Reproduced by permission of the American Association for the Advancement of Science from [101].)

spectra, and it was thus possible to quantitatively determine the conformation statistics for a sample of amorphous poly(ethylene terephthalate) (PET).

10.5.3
High-Resolution ^{1}H Solid-State NMR

The previous section has illustrated that the resolution in a ^{1}H DQ MAS spectrum provided by a combination of very-fast MAS and a high magnetic field as well as the extension to a second frequency dimension is sufficient to allow the differentiation of some particular ^{1}H resonances. However, as noted in Section 10.3.2, the line narrowing achieved by MAS alone at a ν_R equal to 30 kHz is still far from the limiting case, where all residual dipolar broadening has been removed. Section 10.3.2 also briefly introduced experiments which provide homonuclear ^{1}H decoupling by combining multiple (RF) pulse sequences with MAS. In this section, we demonstrate that a marked line narrowing as compared to MAS alone can be achieved by this CRAMPS approach.

In this section, we consider ‘‘windowless’’ homonuclear decoupling sequences. Specific examples are the Lee–Goldburg (LG) technique [102] and refinements, namely the frequency switched and phase-modulated LG (frequency switched Lee–Goldburg, FSLG [103, 104] and phase-modulated Lee–Goldburg, PMLG [105]) sequences, as well as the computer-optimized sequence, DUMBO-1 [106]. For a discussion of these different decoupling sequences, the interested reader is referred to, for example, [7]. Such sequences are so-called because no windows during which acquisition of the FID would be possible are built into the sequence. NMR experiments incorporating evolution under the application of a windowless homonuclear decoupling are thus inherently multidimensional. For example, Vinogradov, *et al.* [105] have presented a 2D experiment in which a high-resolution ^{1}H dimension, incorporating PMLG homonuclear decoupling, is correlated with ^{1}H acquisition, with only moderate MAS (10–15 kHz) providing line narrowing in the direct dimension.

Using LG-based decoupling methods, a FWHMH of 150–170 Hz has been reported for the aliphatic ^{1}H resonances in L-alanine [107]; this is demonstrated in Figure 10.22c, where, for comparison, the Figure 10.22a static and Figure 10.22b MAS ($\nu_R = 30$ kHz) spectra are also shown. Lesage *et al.* [107] have further shown that the frontiers of high-resolution ^{1}H solid-state NMR can be pushed back yet further; using the constant-time (CT) CRAMPS experiment a FWHMH as low as 60 Hz can be obtained for the aliphatic resonances in L-alanine (Figure 10.22d).

10.5.4
Anisotropic–Isotropic Correlation: the Measurement of CSAs

In Section 10.3.1, it was stated that it is possible to extract the anisotropy and asymmetry of the CSA by fitting the observed MAS sideband intensities. It is, however, necessary to be able to resolve, at a low ν_R, the sidebands of the different resonances. The problem of the 1D spectrum becoming increasingly more crowded

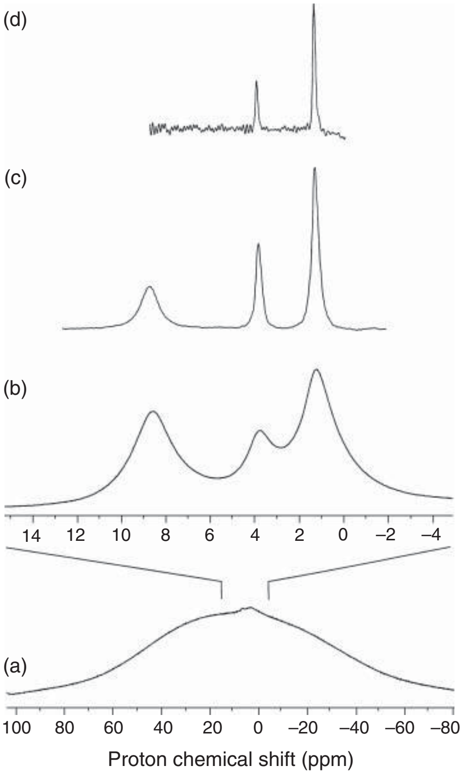

Figure 10.22 ^{1}H (500 MHz) NMR spectra of natural abundance powdered L-alanine, recorded with (a and b) a one-pulse experiment for (a) a static sample and (b) under MAS at a $\nu_R = 30$ kHz, (c) the 2D FSLG ($\nu_R = 12.5$ kHz) experiment, and (d) the CT-CRAMPS ($\nu_R = 12.5$ kHz) experiment using FSLG decoupling. (Reproduced by permission of the American Chemical Society from [107].)

as the number of distinct resonances increases can be overcome by extending the NMR experiment to a second dimension.

In a first class of experiment, a 2D spectrum is obtained in which a separate anisotropic powder lineshape (corresponding to either the static case or a slow spinning frequency) is associated with each resolved resonance in an isotropic dimension. Two elegant approaches have been presented by which this can be achieved, namely magic-angle hopping (MAH) [108] and magic-angle turning (MAT) [109]. In the MAH experiment, t_1 consists of the sample making three hops of 120° about an axis inclined at the magic angle to B_0, with a period of evolution of the same incremented duration (during which the sample is static) before each hop. In this way, the evolution periods correspond to each crystallite adopting three orthogonal positions relative to B_0; for this case, it can be shown that the average chemical shift evolution equates to the isotropic chemical shift. The same effect is achieved in the MAT experiment under conditions of very slow (typically <100 Hz) continuous sample rotation by rotations in spin space, that is, by the application of RF pulses. Moreover, related experiments such as switched angle sample spinning (SASS) [110, 111] and variable angle correlation spectroscopy (VACSY) [112], which involve a change in the orientation of the rotor axis with respect to B_0, have also been presented.

For the original MAH and MAT techniques, a significant drawback was the long measuring time (1–2 days) that was required even when up to 5 g of sample was used. However, modified versions of the MAT approach employing 180° rather than 90° pulses and using a faster ν_R have been presented, which offer a better experimental sensitivity [113, 114] For example, Figure 10.23 shows the anisotropic CSA patterns for each resolved resonance in a selected region of the isotropic ^{13}C spectrum of the terpene verbenol [115]. Six resonance lines are resolved for both the C2 and C3 carbons, with the CSA tensor spinning-sideband patterns being remarkably similar. Supported by quantum-chemical calculations of the ^{13}C CSA tensors, the solid-state NMR analysis demonstrated that verbenol exhibits polymorphism, with, however, only minor conformational variations in the distinct solid-state environments. It is to be noted that single crystals suitable for an X-ray diffraction analysis could only be obtained for the major crystalline form.

An alternative means by which the isotropic and anisotropic chemical shift interactions can be separated is the 2D PASSs (phase-adjusted spinning-sidebands) experiment due to Levitt and coworkers [116]. By changing the timings of the application of five π pulses in the t_1 dimension, it is possible to separate the spinning sidebands by order. As a specific example, Figure 10.24 shows the 2D ^{13}C PASS spectrum for the antibiotic, penicillin-V [117]. An analysis of this spectrum allowed the determination of the CSA principal values for all the ^{13}C resonances. A distinct advantage of this approach is that only very few (typically 16) increments must be made in the indirect dimension.

10.5.5
The Investigation of Slow Dynamics: 2D Exchange

The basic principle of 2D exchange NMR involves the measurement of the frequency of the same molecular segment at two different times. A slow dynamic process is detected on account of the change, during a mixing time between the two evolution periods, in the NMR frequency caused by a reorientation of the molecular segment. In this section, we describe ^{2}H static and ^{13}C MAS 2D exchange experiments [4].

In static ^{2}H 2D exchange NMR, advantage is taken of the simplification resulting from both the presence of a single ^{2}H resonance and the fact that the quadrupolar interaction dominates (Section 10.2.4). Without any slow dynamics in the mixing time, the frequency of each molecular segment remains unchanged, and the intensity in the 2D frequency-domain spectrum is restricted to a ridge along the $\nu_1 = \nu_2$ diagonal. If a reorientation occurs, off-diagonal intensity is observed as a consequence of the frequency change. In particular, a

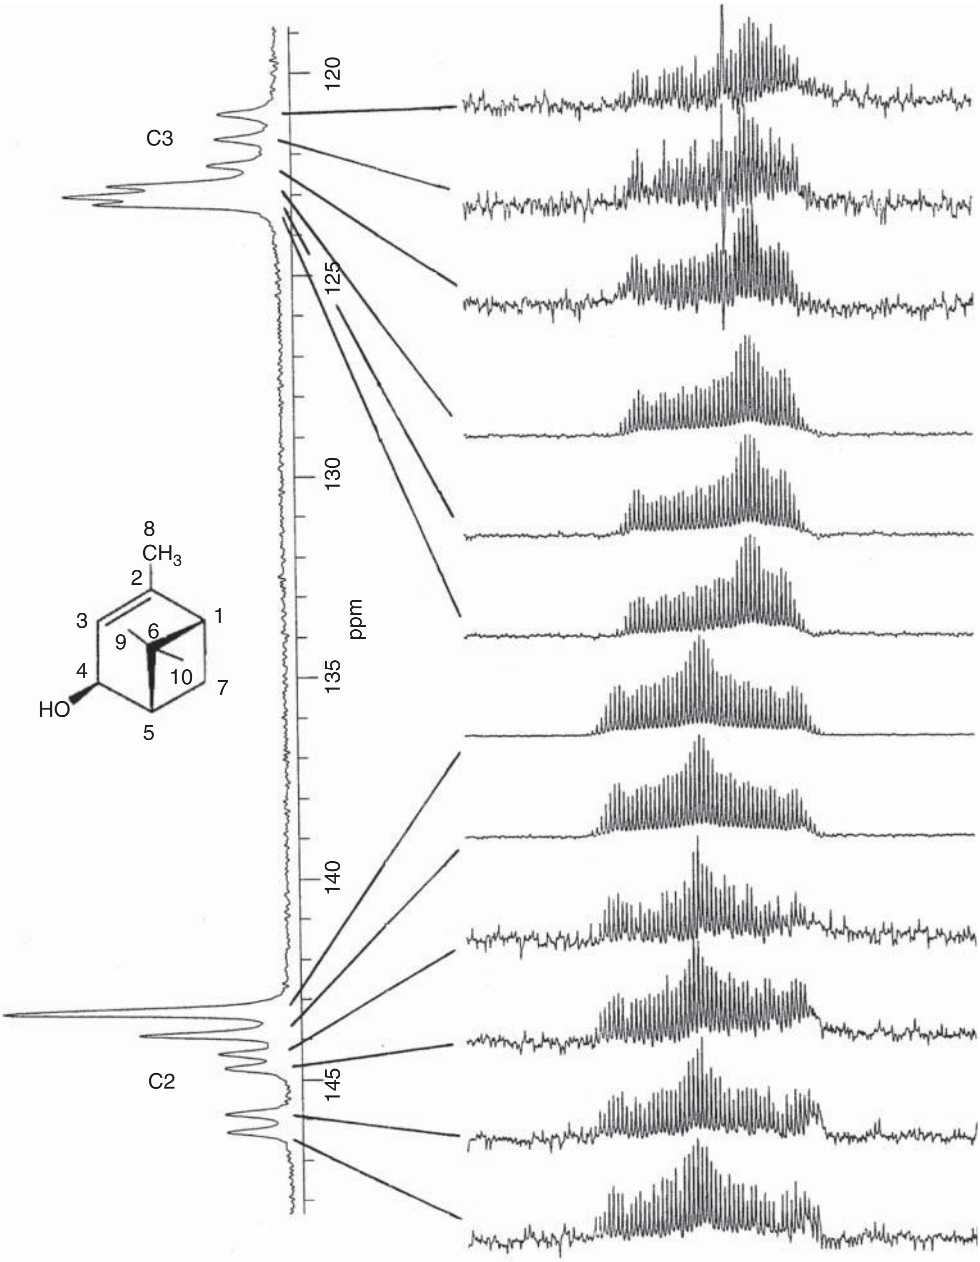

Figure 10.23 The anisotropic CSA patterns for each resolved resonance in a selected region of the isotropic ^{13}C spectrum as obtained from a FIREMAT (five π replicated magic-angle turning) experiment recorded for a sample of the terpene verbenol. (Reproduced by permission of the American Chemical Society from [115].)

well-defined motion yields an elliptical off-diagonal pattern which is characteristic of the reorientation angle. The beauty of the static ^{2}H exchange experiment is illustrated in Figure 10.25, which shows a spectrum recorded for a sample of methyl-deuterated isotactic polypropylene (iPP) [118]. The observed elliptical ridges are characteristic of the helical chain reorientation illustrated in the inset.

A 2D exchange experiment can also be recorded under MAS, although care must be taken to ensure that pure absorption-mode spinning sidebands are obtained. As compared to a static experiment, both the resolution and sensitivity are improved, which is of much importance for ^{13}C NMR. These gains are, however, at the expense of the ease with which information about the reorientation process can be accessed. As in the static case, a reorientation is associated with the observation of off-diagonal intensity. As a specific example, Figure 10.26 presents a ^{13}C 2D MAS exchange spectrum recorded for polyoxymethylene (POM) [119]. In addition to

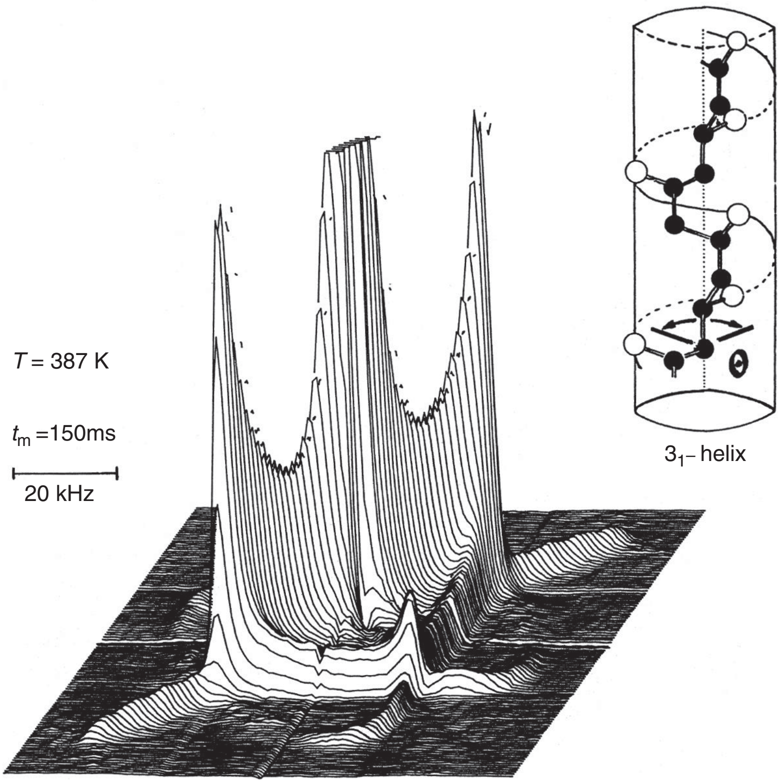

Figure 10.25 A static ^{2}H exchange experiment recorded for a sample of methyl-deuterated isotactic polypropylene (iPP) at $T = 387$ K. Figure 10.26 (a) Experimental and (b) theoretical ^{13}C 2D MAS pure absorption-mode exchange spectra recorded for polyoxymethylene (POM). The experimental spectrum corresponded to $T = 360$ K and a mixing time of 1.5 s. (Reproduced by permission of Academic Press from [119].)

probing the motion of a particular molecular moiety, 2D exchange experiments are well suited to the investigation of slow chemical exchange processes; for example, Titman *et al.* have studied the hydrogen shift and/or π flip which occurs in solid tropolone.

10.5.6
^{1}H–^{1}H DQ MAS Spinning-Sideband Patterns

In Section 10.5.2, a rotor-synchronized ^{1}H–^{1}H DQ MAS spectrum was presented (Figure 10.20). The 2D DQ MAS can be performed in an alternative fashion; if the t_1 increment is reduced, which corresponds to an increase in the DQ spectral width, a DQ MAS spinning-sideband pattern is observed [121, 122]. Such DQ MAS sideband patterns exhibit characteristic unusual features. In particular, the observed patterns are very sensitive to the product of the dipolar coupling constant, D, and the recoupling time, τ_{rcpl}, with an increase in this product leading to the appearance of higher-order spinning sidebands.

Importantly, since τ_{rcpl} is known, the absolute value of D can be extracted by an analysis of DQ MAS spinning-sideband patterns. As a specific example, Figure 10.27 presents experimental ^{1}H–^{1}H DQ MAS spinning-sideband patterns for the aromatic protons in (i) the crystalline and (ii) the LC phases of the same alkyl-substituted polycyclic aromatic system, HBC-C$_{12}$, discussed in Section 10.5.2 [49]. The dotted lines represent best-fit spectra simulated using the analytical time-domain expression for an isolated spin pair. As is evident from the insets on the right of Figure 10.27, the DQ MAS spinning-sideband patterns are very sensitive to the product of D and τ_{rcpl}. The best-fit spectra for the solid and LC phases then correspond to $D/(2\pi)$s equal to 15.0 ± 0.9 and 6.0 ± 0.5 kHz, respectively.

Comparing the evaluated D values for the crystalline and LC phases, a reduction of D by a factor of 0.40 ± 0.04 is observed, corresponding to an order parameter [123] of 0.80 ± 0.08. This could be explained by postulating the presence of out-of-plane motion in addition to the axial rotation of the molecule about an axis perpendicular

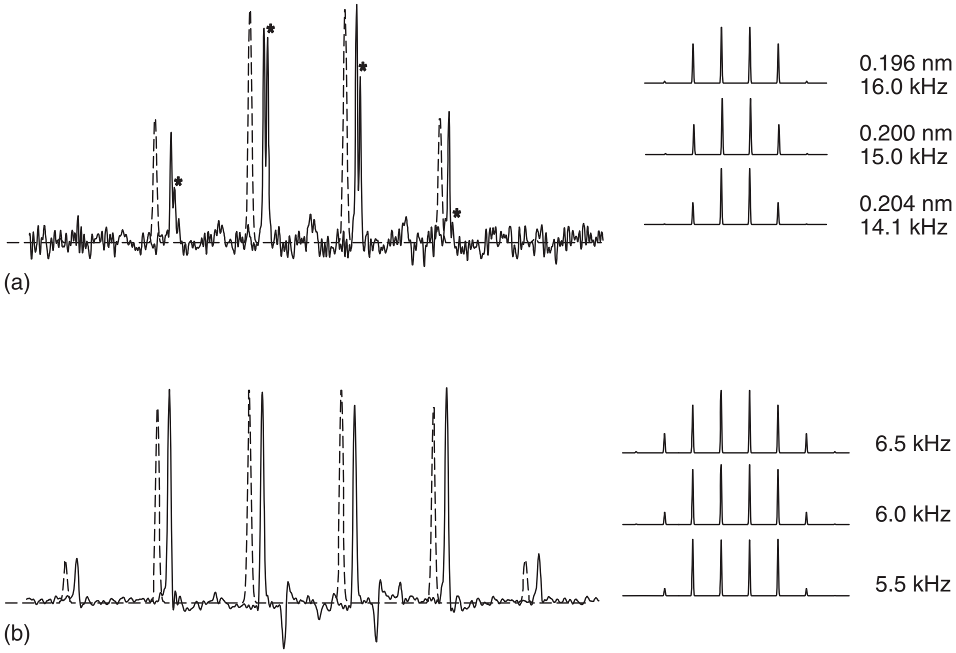

Figure 10.27 Extracted columns from ^{1}H (500.1 MHz) DQ MAS spectra of HBC-C_{12}, showing the DQ spinning-sideband patterns for (a) the aromatic protons at 8.3 ppm in the solid phase ($T = 333$ K) and (b) the aromatic protons at 6.2 ppm in the LC phase ($T = 386$ K). In each case, best-fit spectra, generated according to the analytical expression for a spin pair, are shown (shifted to the left to allow a better comparison) as dotted lines. A spinning frequency, ν_R, equal to 35 and 10 kHz was used for the solid and LC phases, respectively, with the two rotor period compensated BABA recoupling sequence being used for the excitation and reconversion of DQCs in both cases. In (a), additional peaks corresponding to DQCs between aromatic and residual undeuterated α-carbon protons are marked by *. The insets to the right of the experimental spectra show the sensitivity of the spinning-sideband patterns to the product $D\tau_{\mathrm{rcpl}}$. (Reproduced by permission of the American Chemical Society from [49].)

to the ring. The good agreement with the value of 0.84 obtained from an analysis of ^{2}H 1D NMR lineshapes is to be noted [124]. It is to be emphasized, however, that the ^{1}H DQ MAS method is applicable to as-synthesized samples, that is, there is no reliance on isotopic labeling.

As well as the investigation of dynamics, an analysis of ^{1}H DQ MAS spinning-sideband patterns can be used to determine proton–proton distances. For example, it was possible to determine that the distance between the lactam and pyrrole NH protons in the complex hydrogen-bonding arrangement in the biologically important molecule bilirubin is 0.186 ± 0.002 nm [125]. In this respect, it is to be noted that structure determination by single-crystal X-ray diffraction methods, being based on the diffraction of X-rays by electrons, is not well suited to the localization of lighter atoms. This is of particular relevance with regards to the localization of hydrogen-bonded protons, in which case a neutron diffraction study is to be preferred [126]. Moreover, neutron diffraction is not the perfect solution: as well as the requirement for both larger crystals and very expensive facilities, the investigation of protons is complicated by their large incoherent cross section, such that deuteration, which may cause a change in the hydrogen-bonding arrangement, is often required. Thus, solid-state NMR methods which can provide interproton and proton–heteroatom distance constraints, by means of which the localization of the important protons in the single crystal structure can be refined, are of much value.

Finally, we note that 1D DQ-filtered MAS experiments (corresponding to setting $t_1 = 0$) can also provide insight into dynamic processes. The principle, in this case, is that signal is only observed for pairs of protons which remain dipolar-coupled for the timescale of the experiment, which in this case is the time required to excite and reconvert the DQC. For example, in [127], the kinetics of hydrogen-bond breaking and formation is quantitatively analyzed for a carboxylic acid dimer on the basis of the fall off in the DQ intensity with increasing temperature.

10.6
Heteronuclear Two-Dimensional Experiments

10.6.1
Heteronuclear Correlation

In a 2D heteronuclear correlation (HETCOR) experiment, the t_1 and t_2 periods correspond to the evolution of SQC of two different nuclei, for example, ^{1}H and ^{13}C. A number of different HETCOR experiments have been proposed which differ with respect to, for example, the means by which coherence transfer is achieved, the type of coherence which evolves during t_1, as well as the application of homonuclear decoupling sequences.

One of the simplest HETCOR experiments is the ^{1}H–^{13}C WISE (wideline separation) experiment [128]. After the t_1 period, during which ^{1}H transverse magnetization created by a 90° pulse evolves, coherence transfer to ^{13}C SQC, which is detected in t_2, is achieved by a simple CP step. The experiment is performed under MAS. At a low to moderate ν_R, a wide dipolar-broadened ^{1}H lineshape in F_1 (Section 10.3.2) is correlated with a narrow resonance line in a well-resolved isotropic ^{13}C dimension (F_2). Remembering that motion leads to a narrowing of the ^{1}H resonance due to the reduction in the dipolar broadening, the WISE experiment has found a number of applications in polymer chemistry on account of its ability to distinguish between rigid and mobile chemical moieties [4]. For example, in Figure 10.28, narrow and broad lines in the ^{1}H dimension are observed for the resonances due to the mobile spoly(butyl methacrylate) (PbuA) and the rigid PMMA, respectively, in a core–shell system [129]. Furthermore, as illustrated by the investigation of onion cell-wall material in Ref. [47], the information provided

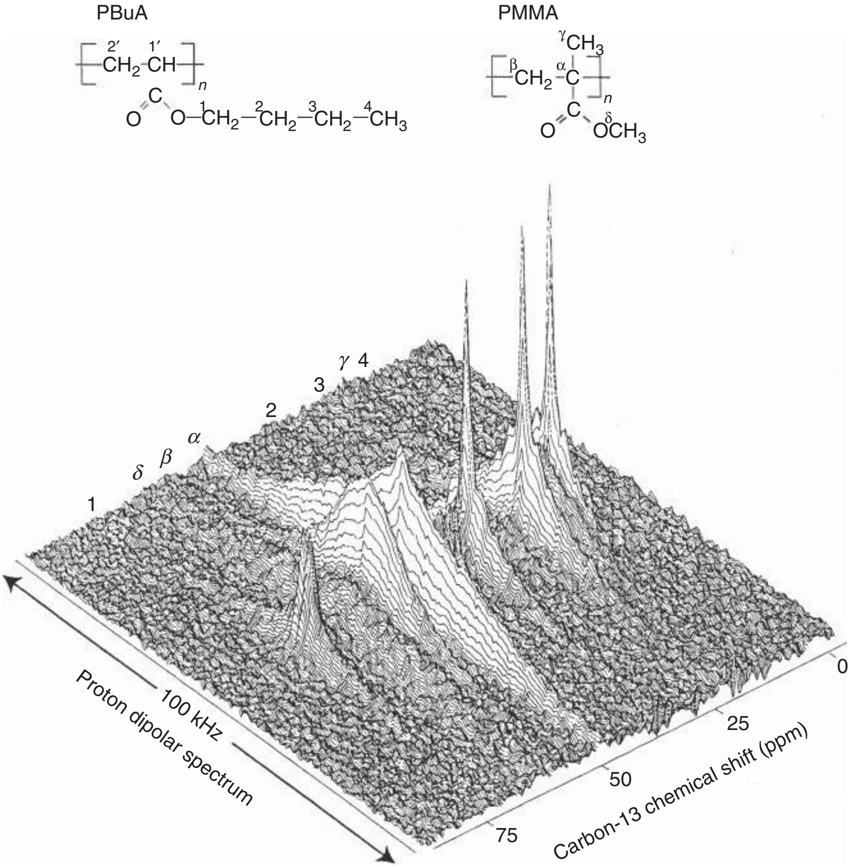

Figure 10.28 A ^{1}H–^{13}C WISE experiment recorded for a core–shell system comprising mobile poly(butyl methacrylate) (PbuA) and rigid PMMA. (Reproduced by permission of the American Chemical Society from [129].)

by WISE spectra complements that yielded by an analysis of ^{13}C T_1 and the ^{1}H $T_{1\rho}$ relaxation times.

^{1}H–^{13}C HETCOR spectra incorporating a high-resolution ^{1}H dimension can be achieved. As early as 1982, Caravatti *et al.* presented an experiment which employed a multiple-pulse sequence at a low ν_R (as in the conventional CRAMPS approach) to achieve homonuclear decoupling in t_1 [130, 131]. Recently, various alternative high-resolution HETCOR experiments applicable at a fast or a very-fast ν_R have been proposed. Two methods which utilize the through-space dipolar coupling to achieve coherence transfer are those due to van Rossum *et al.* [132] and Saalwächter, *et al.* [133, 134]. In the former case, coherence transfer occurs via CP, while FSLG ^{1}H homonuclear decoupling (Section 10.5.3) is applied during the evolution of transverse ^{1}H magnetization in t_1. This is to be compared with the latter recoupled polarization transfer (REPT) methods, which employ REDOR recoupling under very-fast MAS (Section 10.4.1) to create a heteronuclear single-quantum coherence (HSQC) or a heteronuclear multiple-quantum coherence (HMQC), the evolution of which is followed during t_1. The analogy to the well-known solution-state HSQC [135] and HMQC [136] experiments (dilute spin, e.g., ^{13}C, detected) is to be noted.

Alternatively, the MAS-*J*-HMQC [137, 138] and MAS-*J*-HSQC experiments [139] utilize the isotropic through-bond *J*-coupling. The primary aim of recording a ^{1}H–^{13}C correlation spectrum is usually the establishing of one-bond correlations, such that the ^{1}H chemical shifts can be identified. For correlation methods based on the dipolar coupling, it is necessary to ensure that the observed peaks are then not due to close through-space proximities. This problem is obviously avoided by utilizing through-bond *J*-couplings. As an example, Figure 10.29 presents ^{1}H–^{13}C and ^{1}H–^{15}N MAS-*J*-HMQC spectra recorded for 20 mg of a tripeptide sample at natural abundance [138]. The recording of ^{1}H–^{13}C MAS-*J*-HMQC spectra which reveal one- and multiple-bond connectivities allowed the complete assignment of the ^{1}H, ^{13}C, and ^{15}N resonances for the tripeptide.

It should be noted that the existence of methods based on both dipolar and *J*-couplings opens up the possibility of distinguishing through-bond connectivities and through-space proximities on a medium to long range, such that insight into intermolecular packing arrangements is provided. In this way, the two approaches are complimentary in a similar way to the case of the correlation spectroscopy (COSY) and nuclear Overhauser spectroscopy (NOESY) [1, 2] solution-state NMR experiments.

10.6.2
The Quantitative Determination of Heteronuclear Dipolar Couplings

As described in Section 10.4.1, the REDOR experiment, by allowing the quantitative determination of dipolar couplings, accurately yields the distance between two heteronuclei. Indeed, REDOR is currently the workhorse experiment for structure determination. The method does, however, rely on selective isotopic labeling. As well as measuring internuclear distances, Section 10.5.6 showed how probing the change in the dipolar coupling provides insight into a dynamic process. In this section, 2D experiments which have the aim of measuring multiple heteronuclear dipolar couplings (as opposed to only one in the REDOR experiment) are described.

In a separated local field (SLF) experiment [140–143] the basic principle is that a spinning-sideband pattern, from which the heteronuclear dipolar coupling can be extracted, is obtained in the indirect dimension for each resolved resonance in the direct dimension, that is, the dipolar interaction is separated from the chemical shift interaction (the experiment is sometimes referred to as the *DIPSHIFT experiment*). In the original SLF articles, a homonuclear decoupling method is applied in t_1, but recently McElheny *et al.* [144] have shown that fast MAS alone at a ν_R of at least 12 kHz (much faster MAS should be avoided as the higher-order spinning sidebands become too weak to allow a reliable fitting) provides sufficient proton

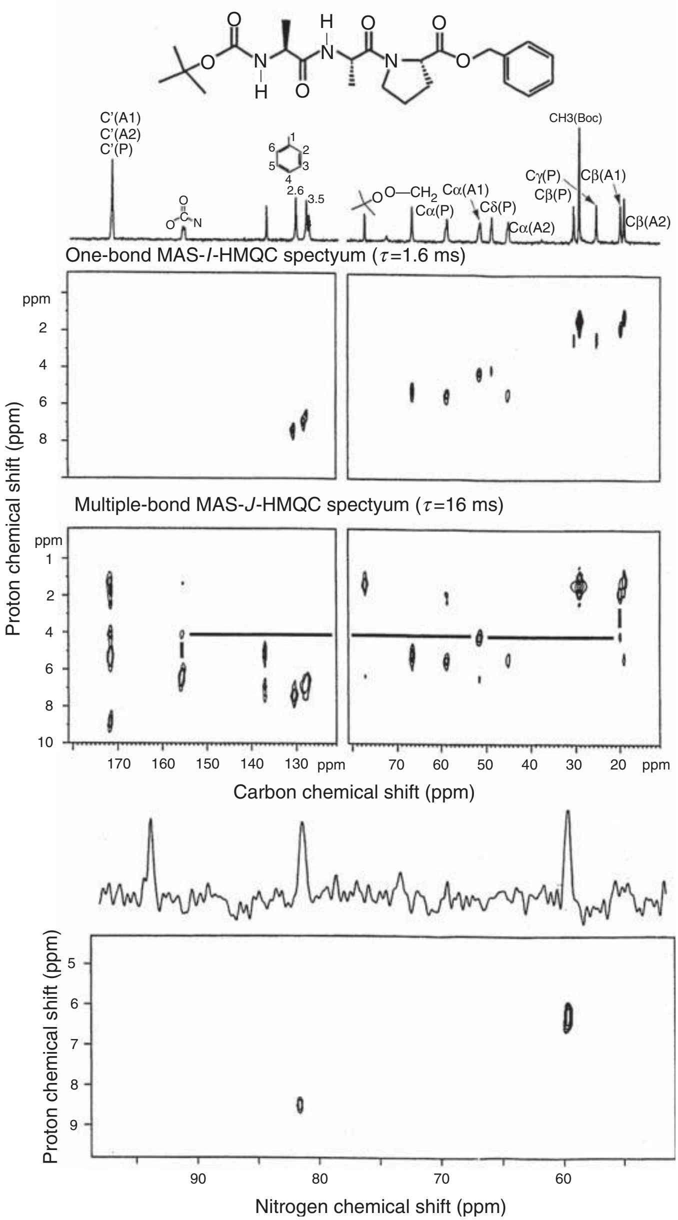

Figure 10.29 $^1H-^{13}C$ and $^1H-^{15}N$ MAS-*J*-HMQC spectra recorded for a tripeptide sample at natural abundance. Two different $^1H-^{13}C$ experiments were performed, with the use of a short ($\tau = 1.6$ ms) and a long ($\tau = 16$ ms) evolution period selecting in the former case one-bond correlations, while the latter case allowed the identification of multiple-bond correlations. ^{13}C and ^{15}N CP MAS spectra are presented above the relevant 2D spectra. (Reproduced by permission of the American Chemical Society from [138].)

dipolar decoupling such that relatively reliable $^1H-^{13}C$ dipolar couplings can be extracted.

Alternatively, in a modification of the original SLF method, Hohwy *et al.* [145] have presented a sophisticated experiment in which a pulse sequence is applied during t_1 which actively recouples the weak heteronuclear dipolar coupling while decoupling the homonuclear $^1H-^1H$ dipolar coupling. Instead of giving a spinning-sideband pattern, a powder line shape is obtained in the indirect dimension. It is shown that this experimental approach allows the accurate determination of both N–H distances as well as the H–N–H bond angle in an NH_2 group. Another state-of-the-art method which has recently been proposed involves performing CP from ^1H to ^{13}C with the RF pulse on the ^1H channel fulfiling the LG condition mentioned in Section 10.5.3 [146]. The suppression of the homonuclear ^1H dipolar couplings means that a LG–CP signal builds up in an oscillatory manner, reflecting coherent heteronuclear transfer. The Fourier transformation of such build-up curves yields powder spectra with marked singularities from the separation of which the heteronuclear dipolar coupling can be determined. Alternatively, it is to be noted that an analysis of a standard CP build-up curve under fast MAS can, in some cases, allow the determination of the heteronuclear dipolar coupling [147].

In direct analogy to the homonuclear DQ MAS experiment (Section 10.5.6), if the t_1 increment in the REPT pulse sequences (Section 10.6.1) is not set equal to τ_R, a spinning-sideband pattern rotor-encoded by the heteronuclear dipolar coupling is obtained [133, 134, 148]. An advantage of the heteronuclear $^1H-^{13}C$ approach is that it benefits from the better resolution in a ^{13}C SQ dimension. An example of this is provided by the hexa(*para*-*n*-dodecylphenyl)-substituted HBC (henceforth referred to as *HBC-PhC$_{12}$*) [148]. In this case, ^1H solid-state NMR is unable to distinguish the core and *exo*-phenyl protons. By comparison, as shown in the ^{13}C CP MAS spectrum at the top right of Figure 10.30, the corresponding ^{13}C resonances are well resolved. It is, thus, possible to use the heteronuclear approach to probe separately the dynamics of the core and the outer phenyl rings. For example, the right-hand side of Figure 10.30 presents $^1H-^{13}C$ spinning-sideband patterns obtained at the core aromatic CH ^{13}C resonance for the solid and LC phases of HBC-PhC$_{12}$, using the REPT–HMQC experiment.

A comparison of the spinning-sideband patterns obtained for the LC phases of HBC-C$_{12}$ and HBC-PhC$_{12}$ reveals that the third-order spinning sidebands are significantly higher in the latter case; they are of the same height as the first-order spinning sidebands for HBC-PhC$_{12}$. As the same experimental conditions were used in both cases, this result immediately indicates a larger dipolar coupling and, hence, a larger order parameter for HBC-PhC$_{12}$. Indeed, the order parameter is determined to be 0.93 ± 0.09, indicating less out-of-plane mesogen mobility. It is interesting that this NMR result is correlated with an improved intra- and inter-columnar packing as evidenced by powder X-ray diffraction patterns [148].

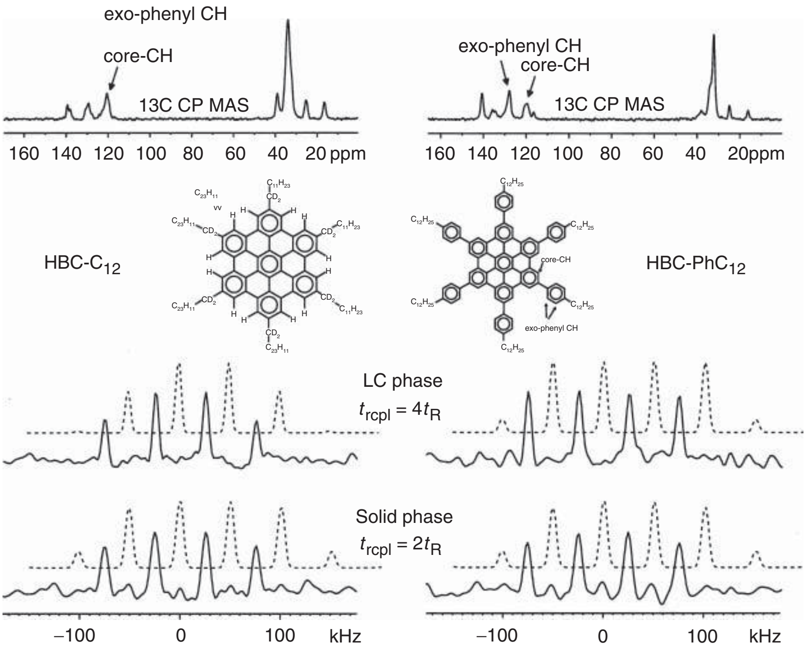

Figure 10.30 $^1H-^{13}C$ heteronuclear MQ MAS spinning-sideband patterns, obtained at a $\nu_R = 25$ kHz, using the REPT–HMQC experiment. The patterns correspond to the sum projections over the ^{13}C resonance due to the aromatic core CH in the 2D spectra of HBC-C_{12}, and HBC-PhC_{12}. The spectra for the room temperature (solid) and high temperature LC phases were recorded at 35 and 120 °C, respectively. The dashed traces represent simulated spectra, obtained by taking into account the best-fit *D*s for the CH groups. At the top, ^{13}C CP MAS ($\nu_R = 15$ kHz) spectra are presented, with the signal positions of the aromatic CH resonances being identified. (Reproduced from [148].

10.6.3
Torsional Angles

In an extension to experiments which measure internuclear distances, Levitt and coworkers and Griffin and coworkers have presented ingenious methods which allow the measurement of torsional angles [149, 150]. The methods involve the creation of MQC between a pair of nuclei (selective isotopic labeling is required), which may be homonuclear, for example, $^{13}C-^{13}C$, or heteronuclear, for example, $^{13}C-^{15}N$. A spinning-sideband pattern is observed as a result of the evolution of the two spins which make up the MQC under the dipolar couplings to the directly attached nuclei. As a specific example, consider the $H^N-N-C^{\alpha}-H^{\alpha}$ moiety in ^{15}N-labeled NAV [150]. By incrementing a period of ^1H homonuclear decoupling, a t_1 FID (Figure 10.31a) is obtained which depends on the evolution under the $N-H^N$ and $C^{\alpha}-H^{\alpha}$ dipolar coupling, and in particular the relative orientation of the two bonds. From the best-fit simulation (Figure 10.31c) of the experimental

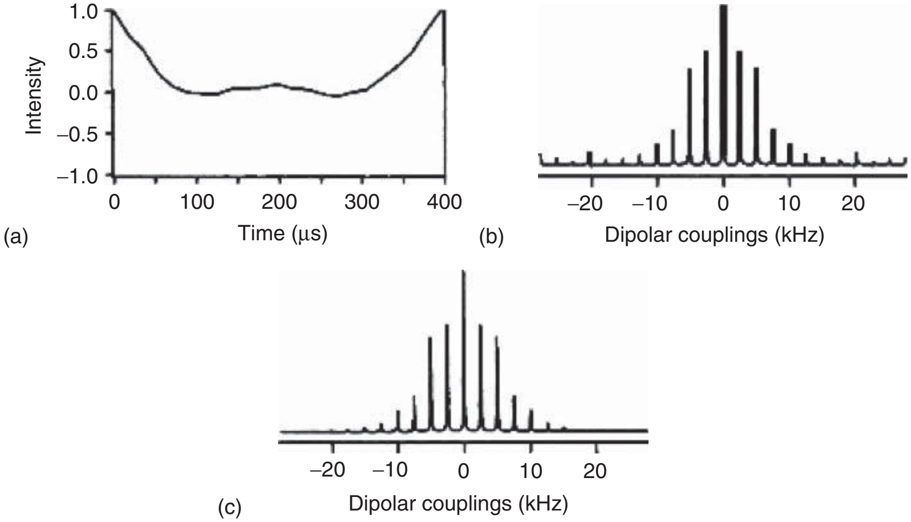

Figure 10.31 The measurement of the H^N–N–C^α–H^α torsional angle in ^{15}N-labeled NAV. The (a) t_1 FID and (b) frequency-domain spinning-sideband pattern depend on the evolution under the N–H^N and C^α–H^α dipolar coupling, and in particular the relative orientation of the two bonds. The (c) best-fit simulation corresponds to a torsional angle of -135°. (Reproduced by permission of the American Chemical Society from [150].)

frequency-domain spinning-sideband pattern (Figure 10.31b), the torsional angle was determined to be -135°.

10.6.4
Oriented Samples

The difficulties associated with the preparation of samples suitable for diffraction studies has led to much interest in the application of solid-state NMR to the investigation of the three-dimensional structure adopted by membrane proteins in their functional environment of phospholipid bilayers [14]. As an oriented sample, the NMR spectrum of a membrane protein is much simplified as compared to the case of a powder sample; for perfect ordering, all structurally equivalent nuclei have the same orientation with respect to B_0, and hence the same anisotropic resonance frequency (Section 10.2.1). This phenomenon is taken advantage of in the PISEMA (polarization inversion with spin exchange at the magic-angle) experiment [151]. This technique is closely related to the experiments described in Section 10.6.2, although it is to be noted that it is applied to static samples.

Figure 10.32a presents a 2D PISEMA spectrum of a uniformly ^{15}N-labeled polypeptide in an oriented lipid bilayer [152]. For each ^{15}N resonance, the ^{15}N chemical shift (horizontal axis) is correlated with the corresponding ^{15}N–^{1}H dipolar coupling, with both the chemical shift and the dipolar coupling depending on the orientation of the particular nitrogen containing moiety. Making the

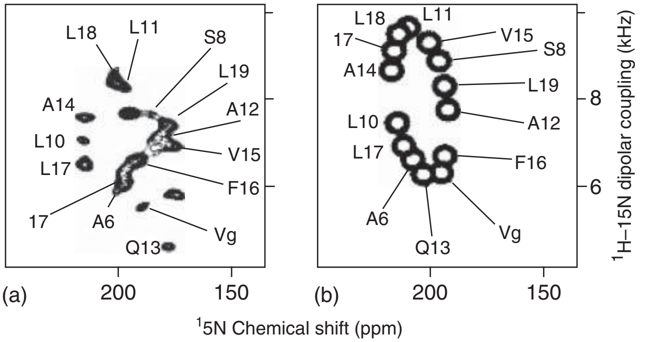

Figure 10.32 (a) A 2D PISEMA spectrum of a uniformly ^{15}N-labeled polypeptide in an oriented lipid bilayer. (b) The best-fit simulated spectrum corresponds to a helix tilt angle of 12°. (Reproduced by permission of Academic Press from [152].)

assumption that the local chemical environment leads to only slight variations in the principal values and orientations of the CSA and dipolar tensors, the observed PISEMA pattern allows the tilt angle of the polypeptide helix with respect to the bilayer normal to be determined. For example, the best-fit simulated spectrum in Figure 10.32b corresponds to a helix tilt angle of 12°.

PISEMA experiments yield the local dipolar field experienced by the ^{13}C or ^{15}N nucleus. Perhaps counter intuitively, it has been shown that better resolution is obtained by using experiments which detect the local dipolar field on protons [130, 153–155]. As specific examples, the ^{1}H detected local field experiment has recently successfully been applied to the characterization of LCs [156, 157] and membranes [158]. As illustrated by Figure 10.33, this approach has even been shown to yield sufficient resolution in 3D versions to allow the direct measurement of internuclear dipolar couplings between nuclei separated by up to five bonds in LCs, thereby providing very strong conformational constraints [159].

10.7
Half-Integer Quadrupole Nuclei

An inspection of Table 10.2 displays that many nuclei of relevance in inorganic systems, for example, ^{23}Na (spin $I = 3/2$), ^{27}Al (spin $I = 5/2$), and ^{17}O (spin $I = 5/2$), are quadrupolar with a half-integer nuclear spin. For such nuclei, an important result is that the $|m_I = +s\rangle \leftrightarrow |m_I = -s\rangle$ transitions are not broadened by the quadrupolar coupling to first-order (for a spin $I = 3/2$ nucleus, the energy levels are labeled −3/2, −1/2, +1/2, and +3/2). As a consequence, for the usual case that the quadrupolar coupling is large (typically of the order of megahertz), only the central transition, $|m_I = +1/2\rangle \leftrightarrow |m_I = -1/2\rangle$, is observed in the normal spectrum, because the broadened satellite transitions ($|m_I = +3/2\rangle \leftrightarrow |m_I = +1/2\rangle$ and $|m_I = -1/2\rangle \leftrightarrow |m_I = -3/2\rangle$ for a spin $I = 3/2$ nucleus) are lost in the baseline. It should be noted that various groups have presented ingenious methods which

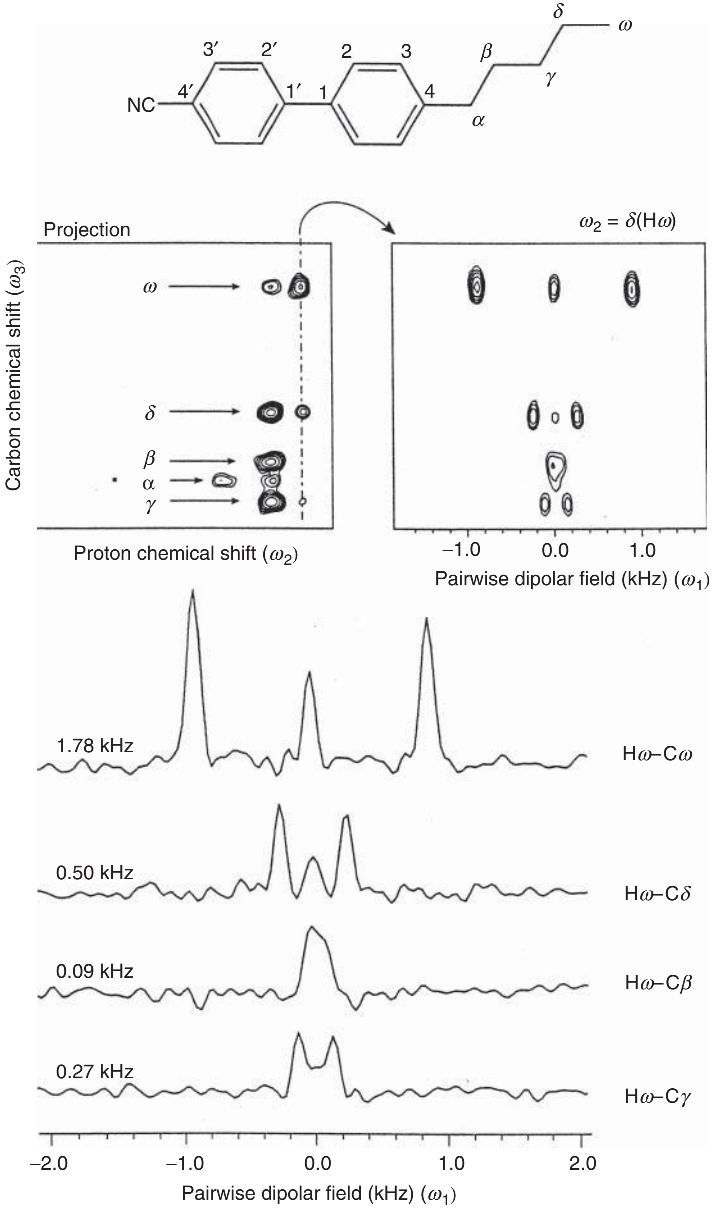

Figure 10.33 The aliphatic region of the 3D pairwise local field spectrum of the nematic LC, 5CB. A projection onto the $\omega_2 - \omega_3$ plane yields a $^1H-^{13}C$ correlation spectrum (upper left), and a plane taken perpendicular to this at a particular ^1H chemical shift yields a $\omega_3 - \omega_1$ slice (upper right) that contains a series of pairwise local fields for each carbon atom. The pairwise local fields obtained for H^{ω} are shown, which demonstrate that couplings to carbons all the way down the chain to C^{β} can be measured. (Reproduced by permission of the American Chemical Society from [159].)

use the satellite transitions to enhance the sensitivity of the central transition spectrum [160–162].

The central transition of a half-integer quadrupolar nucleus is, however, broadened to second order. In contrast to the CSA, and dipolar and first-order quadrupolar couplings, the orientation dependence of the broadening associated with second-order quadrupolar coupling is no longer purely a second-rank tensor. In particular, there is a fourth-rank tensor contribution, which is not fully removed by MAS (regardless of what ν_R is used). The residual second-order quadrupolar broadening of the central transition often prevents the resolution of resonances due to chemically or crystallographically distinct sites [163]. For example, Figure 10.34b shows the ^{87}Rb (spin $I = 3/2$) MAS spectrum of $RbNO_3$; the presence of residual second-order quadrupolar broadening precludes the resolution of the three crystallographically distinct sites.

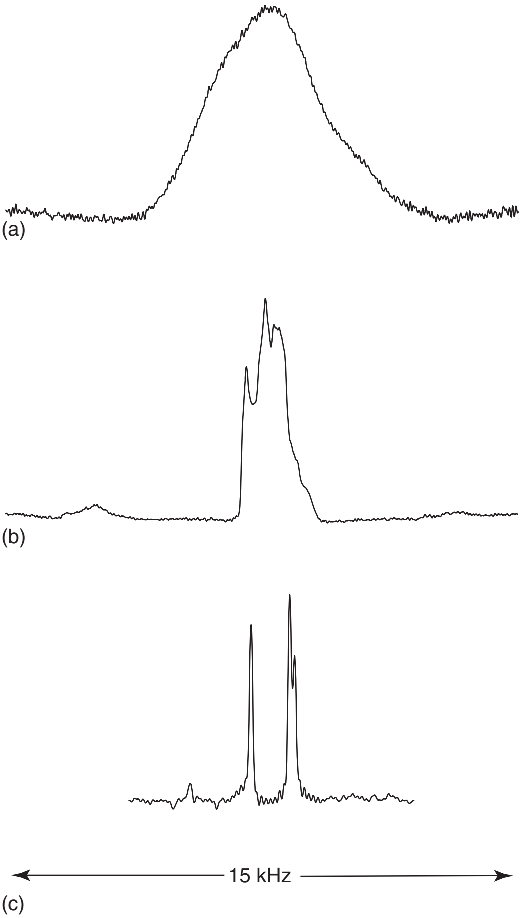

Figure 10.34 ^{87}Rb (130.9 MHz) (spin $I = 3/2$) (a) static, (b) MAS, and (c) isotropic MQ MAS spectra of $RbNO_3$.

As the fourth-rank anisotropic broadening can be removed by sample rotation at an angle of 30.6° or 70.1° with respect to B_0, high-resolution spectra corresponding to the removal of the residual second-rank quadrupolar broadening can be achieved by the methods of double rotation (DOR) [164] and dynamic-angle spinning (DAS) [165], which, respectively, involve the simultaneous and sequential rotation of the sample about two axes [166]. As a specific example, Figure 10.35a presents a ^{17}O

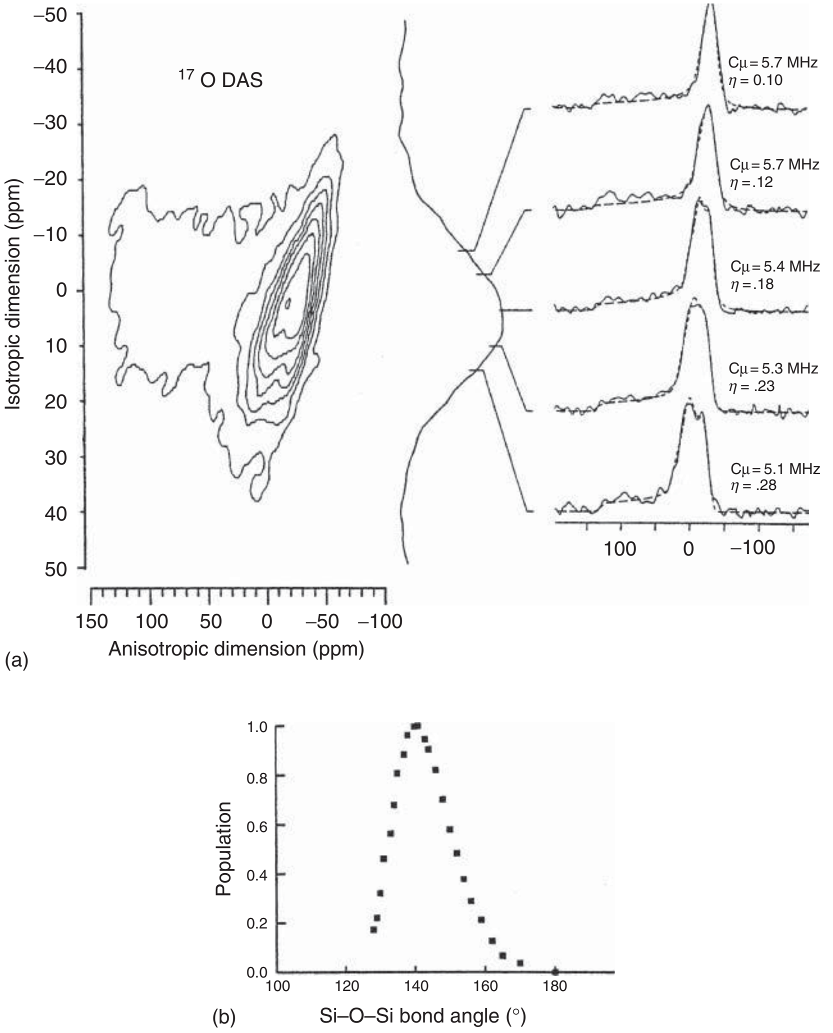

Figure 10.35 (a) A ^{17}O 2D DAS spectrum of the bridging oxygen (Si–O–Si) resonances in a $K_2Si_4O_9$ glass. Selected anisotropic cross sections corresponding to different ^{17}O isotropic frequencies are shown. (b) The Si–O–Si bond angle distribution in the glass, as determined by the use of quantum-chemical calculations to interpret the experimental information about the ^{17}O quadrupolar interactions. (Reproduced from [168].)

2D DAS spectrum of the bridging oxygen (Si–O–Si) resonances in a $K_2Si_4O_9$ glass [167, 168]. Residual second-order quadrupolar broadening is removed from the isotropic dimension such that the broadness of the isotropic lineshape reflects a continuous variation in the ^{17}O isotropic frequency. The selected anisotropic cross sections demonstrate that the quadrupolar coupling parameters vary as the isotropic frequency changes. In combination with quantum-chemical calculations, the information about the ^{17}O quadrupolar interactions allows the determination of the Si–O–Si bond angle distribution in the glass (Figure 10.35b). Although a number of impressive applications of both the DAS and DOR methods have been presented, the technical complexity of both experiments has meant that their use is not widespread.

In 1995, Frydman and Harwood [169] presented a 2D MQ MAS experiment, which, by means of the formation of an echo corresponding to the refocusing of the fourth-rank second-order quadrupolar broadening, yields 2D spectra in which anisotropically broadened ridges are resolved on the basis of their different isotropic shifts. The resolution of the three distinct Rb sites in $RbNO_3$ in an isotropic MQ MAS spectrum is demonstrated in Figure 10.34c. It is to be noted that the experiment is only applicable for odd MQ orders (e.g., 3Q or 5Q), for which there is no first-order quadrupolar broadening. Moreover, as compared to the spin $I = 1/2$ MQ methods described earlier in this chapter, MQC can be excited for a single isolated nucleus.

The MQ MAS technique has the big advantage of requiring only conventional MAS hardware. In the last five years, much attention has been devoted to the optimization of the technique, with respect to, for example, obtaining pure absorption-mode lineshapes, improving the sensitivity, and extending the applicability to nuclei with ever greater quadrupolar couplings; various groups have carried out studies to compare the different variants which have been proposed [170–172]. The development has been so rapid that MQ MAS NMR of nuclei such as ^{23}Na, ^{27}Al, and ^{17}O can now be considered to be routine, with many applications having been presented, which encompass, for example, glasses, minerals, and microporous materials [173–178].

As a specific example, Figure 10.36 shows ^{27}Al 5Q MAS spectra corresponding to the tetrahedral aluminum sites in the microporous aluminum methylphosphonates Figure 10.36a AlMePO-α and Figure 10.36b AlMePO-β [176]. In Figure 10.36b, three distinct sites can be distinguished in the isotropic (F_1) dimension. In a MAS experiment (this corresponds to the projection onto the F_2 dimension), only a single peak is observed in the tetrahedral region. AlMePO-β can be converted by a thermal transformation into AlMePO-α. As discussed in [176], insight into this process is provided by the subtle but significant differences between the 5Q MAS spectra for a physical mixture of the two forms (Figure 10.36c) and for a sample in which the thermal transformation was interrupted (Figure 10.36d).

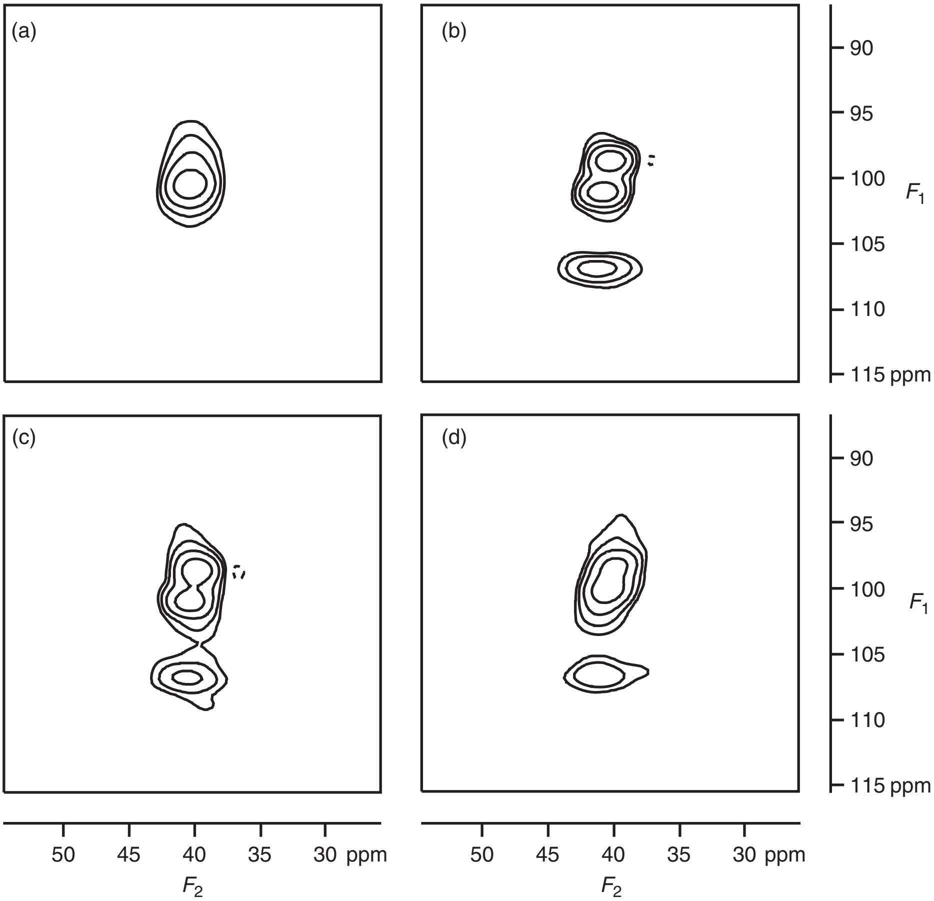

Figure 10.36 ^{27}Al (104.3 MHz) 5Q MAS spectra corresponding to the tetrahedral aluminum sites in the microporous aluminum methylphosphonates (a) AlMePO-α and (b) AlMePO-β, as well as (c) a physical mixture of the two forms, and (d) a sample in which the thermal transformation between the two forms was interrupted. 10.8
Summary

This chapter has given an overview of the wide range of solid-state NMR experiments available today. The central role of anisotropic interactions, for example, the CSA and the dipolar and quadrupolar couplings, has become evident. Through the orientation dependence imparted to the resonance frequency, access is made available to valuable structural and dynamic information. However, for a powder sample, the associated line broadening hinders the resolution of distinct sites. Achieving high-resolution NMR while retaining access to the information inherent to the anisotropic interactions particular to the solid state is a key aim of many of the described experimental methods.

A number of NMR methods applicable to small amounts (10–20 mg) of a powdered sample at natural abundance have been presented. In particular, recent advances in both NMR hardware and the development of new pulse sequences means that ^{1}H solid-state NMR is becoming routinely feasible. In this way, insight into the structure and dynamics of, in particular, hydrogen-bonded systems as well as aromatic π–π interactions can be provided. A further important new class of experiments are those which exploit the *J*-coupling to establish through-bond connectivities. As a general strategy, as much information as possible should be first gleaned for the sample at natural abundance (for large biological systems, global isotopic labeling is unavoidable). If pertinent questions remain unanswered, a strategy involving the synthesis of a sample incorporating selective isotopic labeling can be considered.

Solid-state NMR spectroscopy should certainly not be used in isolation. For example, the assignment of solid-state spectra is aided by the existence of solution-state NMR spectra, while if dynamic processes are to be investigated, it is very useful if differential scanning calorometry (DSC) curves can be first obtained, so that the temperatures at which phase transitions occur are known in advance. In addition, the advances in computing power as well as the development of methodology means that the use of quantum-chemical calculations of NMR parameters in the interpretation of experimental results will become ever more popular.

Solid-state NMR should not be considered as a replacement for the established diffraction methods. Instead, the two methods should be thought of as being complementary, as they have much to offer each other. For example, the existence of a single-crystal X-ray structure for a related system aids the interpretation of NMR spectra obtained for a system, where it is not possible to obtain a single crystal suitable for an X-ray analysis. In addition, solid-state NMR is of use when an X-ray single-crystal structure is available. For example, as structure determination by single-crystal X-ray diffraction methods, being based on the diffraction of X-rays by electrons, is not well suited to the localization of lighter atoms, the ability of solid-state NMR to provide distance constraints, which can be used in the optimization of a crystal structure, in particular the very relevant hydrogen-bonded part, is of much importance. Furthermore, solid-state NMR is extremely well suited to the investigation of dynamic processes. It can also detect polymorphic forms, which may be overlooked when selecting single crystals for X-ray diffraction analysis. Finally, by probing the CSA and quadrupolar interactions, solid-state NMR provides electronic information which is not accessible to X-ray studies.

Appendix

Anisotropic Interactions: The Orientation Dependence of the Resonance Frequency

For the CSA,

$$\omega_{\mathrm{CS}} = \omega_0(\sigma_{xx}^{\mathrm{PAS}}\cos^2\phi\,\sin^2\theta + \sigma_{yy}^{\mathrm{PAS}}\,\sin^2\phi\,\sin^2\theta + \sigma_{zz}^{\mathrm{PAS}}\cos^2\theta) \tag{A1}$$

where ω_0 is the Larmor frequency, $\sigma_{xx}^{\mathrm{PAS}}$, $\sigma_{yy}^{\mathrm{PAS}}$, and $\sigma_{zz}^{\mathrm{PAS}}$ are the principal values (eigenvalues) in the PAS, and φ and θ are polar angles defining the transformation of the PAS onto the laboratory frame defined by B_0 [4].

The CSA is more commonly expressed as a sum of an isotropic and an anisotropic part. The isotropic chemical shift is given by

$$\sigma_{\mathrm{iso}} = \frac{1}{3}(\sigma_{xx}^{\mathrm{PAS}} + \sigma_{yy}^{\mathrm{PAS}} + \sigma_{zz}^{\mathrm{PAS}}) \tag{A2}$$

while the anisotropic frequency is

$$\omega_{\mathrm{aniso}} = \frac{\delta}{2}(3\cos^2\theta - 1 - \eta\sin^2\theta\cos 2\phi) \tag{A3}$$

where δ and η describe the anisotropy and the asymmetry of the interaction, respectively.

An important feature of solid-state NMR is that the orientation dependence of the CSA, dipolar, and first-order quadrupolar interactions can all be represented by what are referred to as *second-rank tensors*. As a consequence, Eq. (A3) can be considered as a general expression which applies to all three interactions. It should be noted that the isotropic part is zero for both the dipolar coupling and the first-order quadrupolar interaction.

For the dipolar coupling between a pair of spins, the interaction is always axially symmetric and thus $\eta = 0$. It is necessary to distinguish between a heteronuclear and a homonuclear dipolar coupling. For the heteronuclear case,

$$\delta = D \tag{A4}$$

while for the homonuclear case,

$$\delta = \frac{3D}{2} \tag{A5}$$

where D is the dipolar coupling constant:

$$D = \frac{\mu_0 \eta \gamma_{\mathrm{I}} \gamma_{\mathrm{S}}}{4\pi r^3} \tag{A6}$$

r denotes the internuclear distance, while γ corresponds to the magnetogyric ratio.

For the first-order quadrupolar interaction,

$$\delta = \frac{3\pi C_{\mathrm{Q}}}{2I(2I-1)} \tag{A7}$$

where the quadrupolar coupling constant, C_Q (in units of Hz), is given by

$$C_Q = \frac{e^2qQ}{h} \tag{A8}$$

eq corresponds to the electric field gradient at the nucleus and Q to the nuclear quadrupole moment.

Section IV
Methods 3: Mass Spectrometry

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

11
Mass Spectrometry

Michael Przybylski

11.1
Introduction: Principles of Mass Spectrometry

Mass spectrometry (MS) is an analytical method in which gaseous ions are produced and subsequently subjected to magnetic and electric fields in a high vacuum for analysis of mass/charge ratios. Although initially developed predominantly for physicochemical investigations, MS now has broad application areas for more than three decades in the analysis of complex organic, bioorganic, and nearly all classes of biochemical molecules [1–3]. Initial applications of MS in the study of biological processes using stable isotope ratio measurements date back to the 1940s. Using gas phase ionization, complex mixtures of compounds that either were volatile or could be derivatized to enhance volatility could be analyzed by combined gas chromatography–mass spectrometry (GC-MS). However, the use of MS in applications in life sciences was possible only on solving one of the central problems, the generation and gas-phase transfer of intact, structurally relevant ions of biomacromolecules [4–6]. In recent years, dramatic analytical developments and advancements in instrumentation have rendered MS central to many problems in modern biopolymer chemistry and biochemistry. These advances have made it possible to determine the molecular masses of large biomacromolecules to isotopic accuracy (Section 11.2.4); this opened new possibilities and approaches in identifying, for example, small – yet functionally critical – posttranslational modifications of proteins, supramolecular interactions in biopolymers, and biomolecular recognition processes, using small sample amounts with low purity and even mixtures, unrivaled by classical methods of structure determination [6, 7].

Since the 1980s, a revolution in the utility of MS for biological analyses has occurred, and continues to date. A major reason for this development was the introduction of a first set of ‘‘soft’’ ionization techniques such as fast atom bombardment (FAB), 252Cf-plasma desorption Parkinson’s Disease (PD), and thermospray (TSP), which permitted the production of gas phase ions from charged and polar biopolymers [6–10]. It reached culmination with the award of the 2002 Nobel prize in chemistry to two scientists pioneering the development of electrospray ionization mass spectrometry (ESI-MS) and matrix-assisted laser

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

desorption/ionization mass spectrometry (MALDI-MS), John Fenn *et al.* [11] and Koichi Tanaka *et al.* [12]. Today, ESI-MS and MALDI-MS are the two central standard ionization methods in the analysis of biopolymers.

11.1.1
Application Areas of Mass Spectrometry to Biopolymer Analysis

The development of efficient ''soft'' ionization methods has led to a breakthrough in the direct molecular characterization of biopolymers, such as proteins and nucleic acids [5–7]. While FAB and 252Cf-plasma desorption (PD) have enabled accurate mass determinations of polypeptides and small proteins, biopolymers considerably beyond 100 kDa have become feasible by ESI-MS and MALDI-MS [11, 12]. In addition to molecular weight determinations, ''soft'' desorption–ionization MS methods are now used in *primary structure* analysis of proteins; characterization of *intracellular processing* pathways; and the identification of *posttranslational structure* modifications. Beyond these, recent approaches to the characterization of *higher order* (secondary and tertiary) structures, *structure–function* studies, *noncovalent interactions* of proteins, and even *specific biomolecular recognition* of structures have been emerging as exciting new areas of MS [13–15]. Moreover, the feasibility of the use of soft ionization MS methods in the analysis of multicomponent proteolytic mixtures (peptide mapping) has been applied successfully to the molecular characterization of chemical modification sites in proteins, providing useful structural information, for example, on surface topology, tertiary structure microenvironment, and specific antigenic binding sites (epitopes) to antibodies [15–19]. More recently, conformation- and topology-specific approaches of biopolymer analysis have become amenable through the development of new hybrid MS systems, notably ion mobility mass spectrometry (IM-MS) [20–22].

In this chapter, classical and modern ionization techniques and instrumental development of MS are described in the first part in order to provide an overview and understanding of its current feasibility and application in life sciences. In a subsequent part (Section 11.2.5), an overview of important sample preparation and handling techniques for bioanalytical applications is given. Today, amounts of samples down to the attomole (10^{-11} M) range and molecular masses of proteins and biopolymer complexes over the mega dalton range can be analyzed with accuracies many thousand times greater than those with classical gel electrophoresis; moreover, today's analyzers and electronics developments enable some of these powerful mass spectrometers to be relatively small and easy to use. This performance has recently experienced further unrivaled breakthroughs with the development of Fourier transform ion cyclotron resonance mass spectrometry (FTICR-MS), and orbitrap-MS (Section 11.2.4). In the final part (Section 11.3), selected application examples are then described to illustrate the feasibility and perspectives of the application of mass spectrometric methods in biopolymer analysis; the most recent offsprings, *proteome analysis* and application to protein *''misfolding''-aggregation* pathways, have been included as two final parts to illustrate new exciting areas emerging from advances in instrumentation and technology developments [22, 23]. This part is by no means intended to provide a comprehensive review of the field of bioanalytical MS application; rather, it should provide perspectives on today's MS instrumentation and the applications of a highly dynamic area for biomolecular analysis.

11.2
Techniques and Instrumentation of Mass Spectrometry

11.2.1
Sample Introduction and Ionization Methods

11.2.1.1 Preconditions

In MS, ions are subjected to magnetic and electric fields in vacuum. For this purpose, a compound has to be in a charged state or must be ionized prior to mass spectrometric analysis. Moreover, the ions have to be transferred to the gas phase in the vacuum system of a mass spectrometer. MS, in general, is used to analyze free ions in high vacuum. The main challenge in its biochemical application during the past decades has been the nondestructive transfer of polar and thermally labile molecules into the gas phase, especially in the presence of suitable matrices. Gaseous or heat-volatile samples can be easily handled but many compounds cannot be heated without decomposition.

Therefore, specific ionization methods capable of providing desolvation and/or desorption of the analyte out of different matrices and simultaneous ionization had to be developed. The choice of an ionization method depends on the characteristics of the analyte and the required type of analytical information. Classically, ''hard ionization'' methods such as *electron ionization* (EI) or *chemical ionization* (CI) make use of their fragmentation capabilities to gain structural information, typically of small organic molecules. In contrast, ''soft ionization'' techniques such as ESI or laser desorption are used to obtain mass spectra of intact molecules with little or no fragmentation, being capable of analyzing complex multicomponent mixtures.

11.2.1.2 Gas Phase (''Hard'') Ionization Methods

11.2.1.2.1 Electron Impact Ionization (EI) This classical ''hard'' ionization method employs an electron beam passing through the sample in the gas phase [24]. When colliding with neutral analyte molecules, another electron can be knocked off either resulting in a positively charged molecular ion of the intact analyte molecule or more often producing fragment ions corresponding to a certain molecular substructure. Typically, electron beams of 70 eV are used for EI (Figure 11.1). Decreasing this energy may result in reduced fragmentation, but it also causes reduced sensitivity.

The samples are usually introduced through a heated direct insertion probe or, for extremely volatile samples, through a gas chromatograph. EI is the oldest and best characterized ionization method and can be applied to all volatile and thermally stable compounds. EI mass spectra show a high reproducibility (''fingerprinting''),

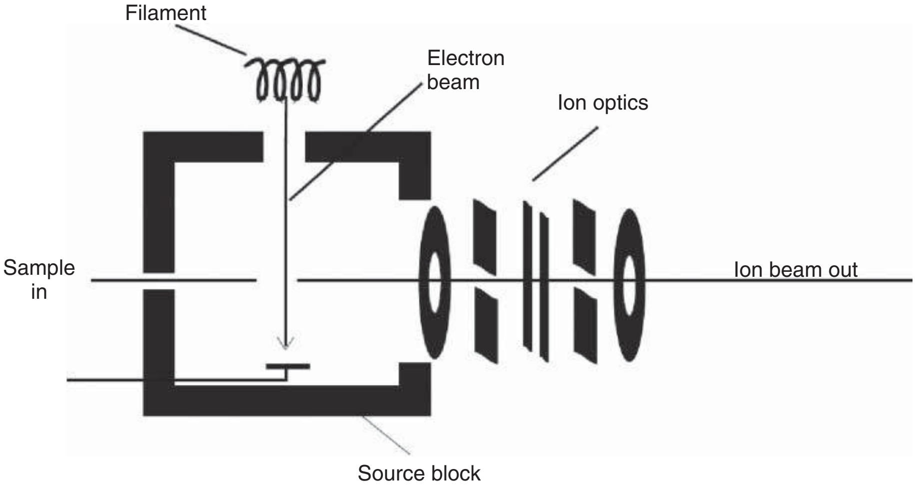

Figure 11.1 Scheme of an ion source for electron ionisation (EI). The analyte sample has to be available in gaseous state within the ion source. Sample admission may be performed by gaseous and liquid inlet systems or with a heatable solid insertion probe.

often used in combination with mass spectral libraries [25]. Additionally, structural information can be obtained from the fragmentation pattern produced.

11.2.1.2.2 **Chemical Ionization (CI)** In CI, a reagent gas such as ammonia or methane is ionized by electron impact [26]. Ion–molecule reactions between ions and neutral molecules of the reagent gas occur because of a high reagent gas pressure within the source. Some of these ions can react with analyte molecules to form analyte ions. The reagent gas is an energy mediator reducing the energy transfer to the sample molecules. Therefore, compared to EI, fragmentation is reduced and molecular ions such as $[M + H]^+$ are obtained.

Samples can be introduced into the ion source through a heated direct insertion probe or by a gas chromatograph. As a variation on CI, the analyte can be placed on a filament and rapidly heated in the CI plasma in the presence of a reagent gas. This so-called desorption CI reduces fragmentation and is applicable to samples that cannot be thermally desorbed without decomposition.

11.2.1.3 “Soft” Ionization Techniques

Targeting the detection and analysis of intact molecular ions of biopolymers, “soft” ionization techniques had to be developed. Field desorption (FD) was the first ionization technique established to produce mass spectra with little or no fragment ion content. FD is based on electron tunneling from an emitter biased at a high electrical potential [27]. The filament of the emitter is heated and the sample is evaporated into the gas phase. Typically, intact molecular ions are detected. This method is limited to relatively low-molecular-weight compounds, which additionally have to be thermally stable to some extent.

A further soft ionization method 252Cf-plasma desorption (PD) has been developed and has been successfully applied to a range of polypeptides [28]. The nuclear decay of ^{252}Cf results in two 100 MeV products that desorb the analyte molecules from a nitrocellulose-coated film and give the start signal for the pulsed time-of-flight (TOF) detection as well.

11.2.1.3.1 **Fast Atom Bombardment (FAB)**

FAB is particularly capable of analyzing polar molecules, and has been applied to biomolecules, typically with molecular weights up to about 10–15 kDa [29]. The sample is dissolved in a liquid matrix with low volatility such as glycerol or *m*-nitrobenzyl alcohol and deposited on a target. The target is then bombarded with a continuous beam of fast atoms (e.g., Xe) or ions (e.g., $^{131}Cs^+$). In the latter case, this ionization method is also referred to as secondary ion mass spectrometry (SIMS). Molecular ions and fragments of the analyte are desorbed together with cluster ions from the liquid matrix. The latter are responsible for some chemical background in the mass spectra.

Besides the direct insertion probe, liquid chromatography (LC) has been interfaced to FAB-MS [30]. This rapid and simple ionization method is relatively tolerant of variations in sampling and is suitable for a large variety of compounds. It is limited by a high chemical background and the consequent difficulty in distinguishing low molecular weight components from the background.

11.2.1.3.2 **Electrospray Ionization (ESI)**

Electrospray ionization (ESI) is a method in which the analyte is sprayed at atmospheric pressure into an interface to the vacuum of the mass spectrometer ion source [31]. The sample solution is sprayed across a high potential difference (1–4 kV) from a needle tip into an orifice of the mass spectrometer. Heat and gas flows (e.g., a countercurrent gas) may assist in the desolvation of the charged droplets containing the analyte molecular ions. Finally, ion emission (Taylor cone model) leads to the formation of multiply protonated or deprotonated ions (Figure 11.2).

The extremely soft desolvation and ionization in ESI allow the detection of tertiary structure-related biopolymer ions, and even intact noncovalent complexes comprising specific interactions (Section 11.3.3). Typically, multiply charged molecular ions are produced. The number of charges increases with increasing molecular weight and surface structure (or extended topology) [6, 13, 17, 23]. Furthermore, ion compositions correlate well with, for example, the presence of a basic or acidic analyte structure. Results of several model studies and applications have provided evidence for a correlation of the *charge structures* of ions, and the solution structures of biopolymers [13, 31]. This feasibility for characterization of higher order biopolymer structures is one of the outstanding features of ESI-MS, among other ‘‘soft’’ ionization methods [6, 15–17].

Solution flow rates can range from nano/microliters to several milliliters, making this ionization method well suited for interfacing it to chromatographic and other microseparation methods. During the past few years, several microflow devices have been developed to meet the needs in protein analysis caused by low amounts of available sample [32, 33]. Especially, nanoelectrospray has been shown to be

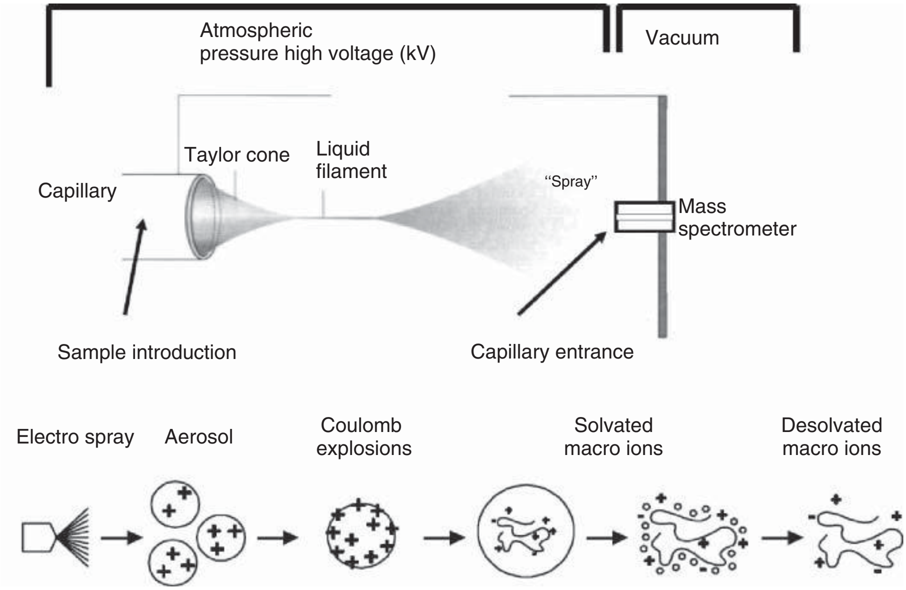

Figure 11.2 Principle of ionisation source and mechanism of gaseous ion formation in ESI MS. The sample solution is admitted through a small capillary from which the spray is formed at atmospheric pressure condition. The charged aerosol is evaporated due to Coulomb explosions to smaller droplets which finally result in desolvated macro-ions.

feasible for protein analysis and also for the characterization of noncovalent complexes [6, 13]. The small nanospray droplets enable a higher ionization efficacy at significantly reduced spray potentials. The low flow rates provide enhanced experimental variation, which is especially useful for MS/MS experiments and for multiple reaction monitoring (MRM) [34, 35].

In atmospheric pressure chemical ionization (APCI), a corona discharge is used to ionize the analyte in the source of the mass spectrometer [32]. Complementary to ESI, which is especially suitable for charged basic or polar analytes, APCI can be used for analysis of uncharged or low-polarity compounds (e.g., steroids).

11.2.1.3.3 **Matrix-Assisted Laser Desorption/Ionization (MALDI)** For laser desorption–ionization methods, a pulsed laser is typically used to desorb species from a target surface. Therefore, a mass analyzer compatible with pulsed ionization methods has to be used. Typically, TOF analyzers are employed, but several hybrid systems [quadrupole time-of-flight (Q-TOF)] and, recently, high-resolution FTICR analyzers have been successfully adapted (Section 11.2.4). Direct laser desorption relies on the very rapid heating of the sample or sample substrate to vaporize molecules without decomposition. The more recent development of MALDI relies on the absorption of laser energy by a solid, microcrystalline matrix compound such as α-cyano-4-hydroxy cinnamic acid or sinapinic acid [8, 36]. MALDI has become the most widely used method for the rapid and sensitive analysis of high-molecular-weight biomolecules [4].

The analyte is typically dissolved in a solution containing an excess of the matrix that contains a chromophore absorbing at the laser wavelength. Mainly, UV lasers are used for protein analysis, but for certain biopolymer classes such as polynucleotides IR lasers are also employed [8, 36]. Several sample preparation techniques have been developed to place a small amount of solution on the target. The MALDI process is schematically depicted in Figure 11.3. Although details of the mechanism are still unknown at present, it is generally accepted that the matrix absorbs energy from the laser pulse and produces a plasma, resulting in the desorption of matrix–analyte clusters and also in the ionization of analyte molecules [37]. Notably, low charges are generally produced even for large biopolymers (e.g., singly and doubly protonated ions) in contrast to the multiply charged ion structure series in ESI-MS [31].

11.2.2
Mass Spectrometric Analyzers

In a mass spectrometer, ion formation, mass analysis, and ion detection are combined. Various mass analyzers have been developed to separate ions according to their mass-to-charge ratio. Each analyzer has its own special characteristics and field of application, and no single mass analyzer can meet all possible requirements. The choice of the analyzer generally should be based on the application, the desired performance, and the cost.

All commonly used mass analyzers employ electric and/or magnetic fields to apply a force on charged molecules. The acceleration force is dependent on the mass as well as on the ionic charge. With the general understanding that mass spectrometers separate ions according to their mass-to-charge ratio (m/z), all principles of m/z analyzers depend on ion energies, with the exception of FTICR. Since kinetic energy differences are crucial for biopolymer ions and are limiting

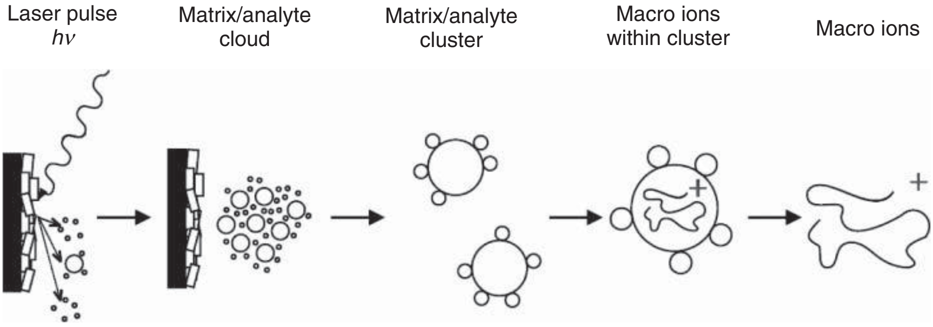

Figure 11.3 Principle of ionisation/desorption in MALDI MS. A matrix/analyte-cloud is desorbed from the microcrystalline matrix/sample preparation by a laser-pulse. Proton-transfer from matrix ions is thought to be primarily responsible to subsequently generate analyte ions.

analyzer performance, this renders FTICR-MS a prominent tool for high-resolution analysis of biopolymers (Section 11.2.4).

11.2.2.1 **Magnetic Sector Mass Analyzers**

In a magnetic deflection mass spectrometer, ions leave the ion source and are accelerated to high velocity. The ions subsequently pass through a magnetic sector in which the magnetic field is applied in a direction perpendicular to the direction of ion motion. Applying an acceleration perpendicular to the direction of motion of an object, the object's velocity remains constant, but the object travels in a circular path. Therefore, the magnetic sector follows an arc, the radius and angle of which vary with different ion optical designs.

A magnetic sector alone will separate ions according to their mass-to-charge ratio, but the resolution is limited by the fact that ions leaving the ion source do not all have exactly the same energy and therefore do not have identical velocity. To focus ions according to their kinetic energy, an additional electric sector is necessary to achieve higher resolution. Similar to the magnetic sector, the electric sector applies a force perpendicular to the direction of ion motion, and therefore has the form of an arc.

A schematic representation of a double-focusing mass spectrometer is shown in Figure 11.4. For historical reasons, this setup is referred to as a *reverse-geometry magnetic sector mass spectrometer*, which means that the magnetic sector precedes the electric sector [1]. The simplest mode of operation of a magnetic sector mass spectrometer keeps the accelerating potential and the electric sector potential constant and varies the magnetic field. Ions that have a constant kinetic energy, but different mass-to-charge ratio are brought into focus at the detector slit at different magnetic field strengths. The working equation of a magnetic sector mass

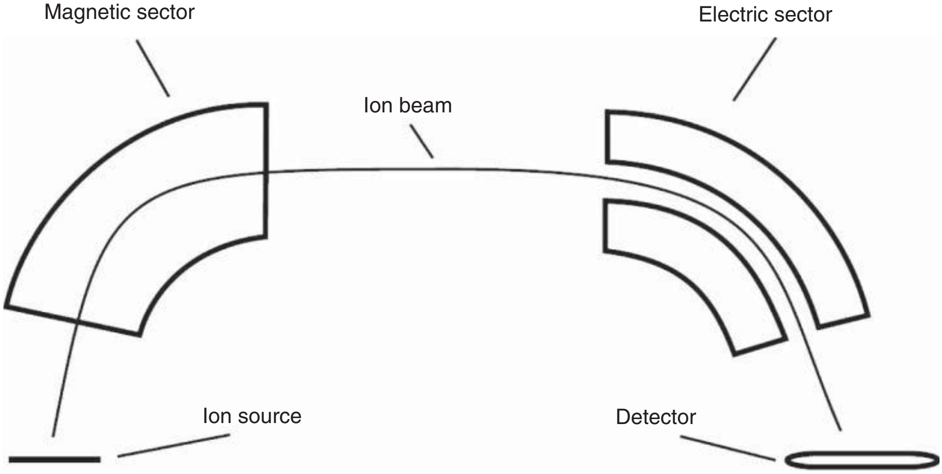

Figure 11.4 Scheme of a double-focusing magnetic sector instrument with BE configuration. Dependant on the mass-to-charge ratio the ions are distracted by the magnetic field to a circular arch with different radii.

spectrometer shows the dependency of m/z from the magnetic field B and the kinetic energy of the ions resulting from a certain acceleration voltage V:

$$\frac{m}{z} = \frac{B^2r^2}{2V}$$

Typically, the electric sector is held constant at a value that passes only ions having a specific kinetic energy. Therefore, the parameter that is most commonly varied is the magnetic field strength B. A magnetic field scan can be used to cover a wide range of mass-to-charge ratios with a sensitivity that is essentially independent of the mass-to-charge ratio. The maximum ion transmission and sensitivity occur at the maximum working accelerating voltage for a given magnetic sector mass spectrometer, whereas the effective mass range of the mass spectrometer can be increased by decreasing the accelerating voltage. The resolving power of a magnetic sector mass spectrometer is determined by the slit widths. Higher resolution is obtained by decreasing the slit widths, thereby decreasing the number of ions that reach the detector.

Linked scans, in which the magnetic and electric fields are scanned together, can be used to perform MS/MS experiments (product, precursor, and neutral loss) with a double focusing mass spectrometer.

Focal plane (array) detectors can detect a range of masses simultaneously. This provides a multichannel advantage that can improve the sensitivity for magnetic sectors, and detection limits can be improved if the analysis is limited by the analyte ion current instead of the chemical background level. This is the case for experiments such as MS/MS, ESI, and FD. Array detectors can be used with pulsed ionization methods, but the array detectors for commercial magnetic sector mass spectrometers can only detect a portion of the entire mass range at any given instant.

Double focusing magnetic sector mass analyzers provide very high reproducibility, high resolution, and a high dynamic range. However, their use is limited by their size and higher cost compared to other mass analyzers.

11.2.2.2 **Quadrupole Mass Analyzers**

The quadrupole mass analyzer is a ‘‘mass filter.’’ Combined DC and RF potentials on the quadrupole rods can be set to pass only ions of a selected mass-to-charge ratio [38]. All other ions do not have a stable trajectory through the quadrupole mass analyzer and will collide with the quadrupole rods, never reaching the detector. The operation of a quadrupole mass analyzer is usually treated in terms of a stability diagram that relates the applied DC potential and the applied RF potential, and the RF frequency to a stable versus unstable ion trajectory through the quadrupole rods. A schematic diagram of a quadrupole mass filter is shown in Figure 11.5.

Increasing the resolution decreases the number of ions that reach the detector. Good resolution also depends on the quality of the machining for the quadrupole rods. Quadrupole rods can have other functions besides their use as a mass filter. An RF-only quadrupole will act as an ion guide for ions within a broad mass range. For example, the collision region of a triple quadrupole mass spectrometer uses an RF ion guide. A DC-only quadrupole is used as a lens element in some ion optical systems.

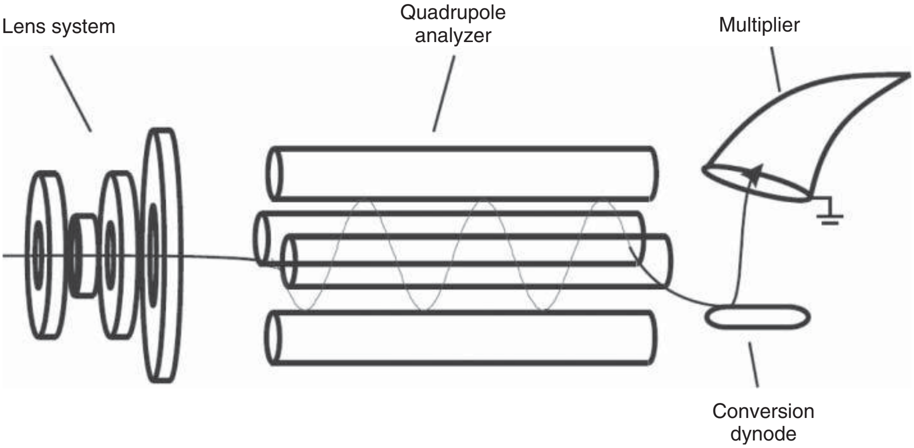

Figure 11.5 Scheme of a quadrupole mass analyser. Only ions with selected mass-to-charge ratio pass the combined DC and RF potentials on the quadrupole rods to reach the detector.

Quadrupole mass analyzers provide good reproducibility and represent a relatively small and low-cost system. Low-energy collision-induced dissociation collision-induced dissociation (CID) MS/MS experiments are feasible with triple quadrupole and hybrid mass spectrometers and have efficient conversion of precursors to products. These spectra strongly depend on energy, collision gas, pressure, and other factors. The use of quadrupole mass analyzers alone has limitations because of their comparatively low resolution. In addition, they are not well suited for pulsed ionization methods. Quadrupole mass analyzers are employed in the majority of benchtop GC/MS and LC/MS systems because of their low cost and stable operation. Moreover, they are gaining increasing importance as components in new hybrid-type mass spectrometers, as illustrated in Section 11.2.6.4.

11.2.2.3 **Time-of-Flight Mass Analyzers**

A TOF mass spectrometer measures the mass-dependent time it takes ions of different masses to move from the ion source to the detector. This requires that the start time (the time at which the ions leave the ion source) be well defined. Therefore, ions are formed by a pulsed ionization method (typically MALDI-MS), or various kinds of rapid electric field switching are used as a ‘‘gate’’ to release the ions from the ion source in a very short time.

The working equation for the TOF mass spectrometer is

$$\frac{m}{z} = \frac{2 \times V \times t^2}{L^2}$$

The ions leaving the ion source of a TOF mass spectrometer do not have exactly the same starting times or exactly the same kinetic energies. Various types of TOF mass spectrometers have been developed to compensate for these differences. A linear-field reflectron allows ions with greater kinetic energies to penetrate deeper into the reflectron than ions with smaller kinetic energies. The ions that penetrate deeper will take longer to return to the detector. If a packet of ions of a given mass-to-charge ratio contains ions with varying kinetic energies, then the reflectron will decrease the spread in the ion flight times, and therefore improve the resolution of the TOF mass spectrometer. A curved-field reflectron ensures that the ideal detector position for the TOF mass spectrometer does not vary with mass-to-charge ratio. This also results in improved resolution for TOF mass spectrometers.

TOF analyzers are the fastest MS analyzers making them especially suitable for application in high-performance LC/MS. They are well suited for pulsed ionization methods (method of choice for the majority of MALDI-MS systems). MS/MS information can be obtained from post-source decay. TOF analyzers also provide the highest practical mass range of all MS analyzers, but require pulsed ionization or ion beam switching. Furthermore, for most MS/MS experiments, ion selectivity is limited.

11.2.2.4 **Trapped-Ion Mass Analyzers**

There are two principal trapped-ion mass analyzers: three-dimensional quadrupole ion traps (“dynamic” traps) and ion cyclotron resonance mass spectrometers (“static” traps, see Section 11.2.3.1). Both operate by storing ions in the trap and manipulating the ions by using DC and RF electric fields in a series of carefully timed events. This provides several unique capabilities, such as extended MS/MS experiments, very high resolution, and high sensitivity. The trade-off is that trapping the ions for long periods (milliseconds to hours) provides sufficient time for the ions to degrade spontaneously (unimolecular decomposition), to experience unwanted interactions with other ions (space charge effects), neutral molecules (ion–molecule reactions), or perturbations in the ion motion due to imperfect electric fields [38]. This can lead to artifacts and unexpected changes in the mass spectrum (the so called “nonclassical mass spectra”).

In quadrupole ion traps, ions are dynamically stored in a three-dimensional quadrupole ion storage device (Figure 11.6) [39]. The RF and DC potentials can be scanned to eject successive mass-to-charge ratios from the trap into the detector (mass-selective ejection). Ions are formed within the ion trap or injected into an ion trap from an external source. The ions are dynamically trapped by the applied RF potentials (a common trap design also makes use of a “bath gas” to help contain the ions in the trap). The trapped ions can be manipulated by RF events to perform ion ejection, ion excitation, and mass-selective ejection. This provides MS/MS and MS^n experiments, which are eminently suited for structure determination of biopolymers [40] (Section 11.2.4).

Space-charge effects (ion–ion repulsion) limit the inherent dynamic range of the ion trap. This is usually handled by autoranging: a pre-scan is performed to determine the ion current and the ionizing electron current is then adjusted to reduce the number of ions formed to within the working range. This can be done wherever the ion formation event can be manipulated to control the number of ions formed.

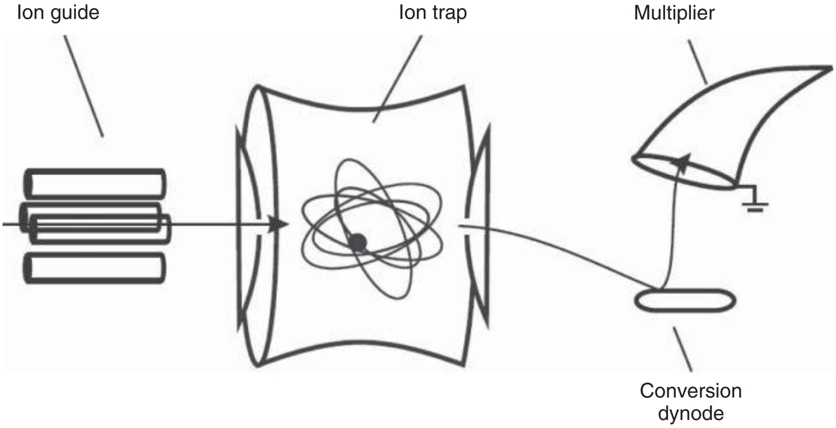

Figure 11.6 Scheme of an ion trap mass spectrometer. A defined ion beam is admitted into the trap through a focusing ion guide, e.g. a quadrupole.

11.2.2.5 Hybrid Analyzers

Hybrid TOF mass spectrometers make use of a TOF analyzer placed orthogonal to a beam of ions. Ions are deflected at right angles into the TOF analyzer by a pulsed electrical potential from an electrode placed alongside the beam.

By having a quadrupole analyzer as a gate in conjunction with an orthogonal TOF analyzer (Q-TOF analyzer) [41], a full mass spectrum may be obtained of all ions from an ion source if the ‘‘gate’’ is open. Alternatively, precursor ions can be selected for MS/MS so as to give the fragment ion spectrum characteristics of the precursor ions chosen, which gives structural information [42].

Combining an ion trap instrument with an orthogonal TOF instrument leads to a hybrid with high sensitivity in both MS and MS/MS modes and rapid switching between both modes [43]. The combination is particularly useful for biochemical analyses because of its high sensitivity and the ease of obtaining MS/MS structural information from small amounts of material. In either case, the TOF analyzer is used to obtain the mass spectrum. Furthermore, this hybrid provides high sensitivity and a linear mass scale to 10 000 at full sensitivity. The digitized accumulation of spectra provides a better signal-to-noise ratio than can be obtained from one spectrum alone.

11.2.3
High-Resolution Mass Spectrometers

11.2.3.1 Fourier Transform Ion Cyclotron Resonance Mass Spectrometry

Ions move in a circular path in a magnetic field. The cyclotron frequency of the ion’s circular motion is mass dependent. By measuring the cyclotron frequency, one can determine an ion’s mass [44].

The working equation for ion cyclotron resonance (ICR) can be quickly derived by equating the centripetal force and the Lorentz force experienced by an ion in a magnetic field:

$$\frac{m}{z} = \frac{B}{\omega_z}$$

A group of ions of the same mass-to-charge ratio will have the same cyclotron frequency f_c, but they will be moving independently and out of phase at roughly thermal energy ranges. If an excitation pulse is applied at the cyclotron frequency, the ''resonant'' ions will absorb energy and be brought into phase with the excitation pulse. As ions absorb energy, the size of their orbit also increases.

The packet of ions passes close to the receiver plates in the ICR cell and induces image currents that can be amplified and digitized. The signal induced in the receiver plates depends on the number of ions and their distance from the receiver plates.

If several different masses are present, one must apply an excitation pulse that contains components at all cyclotron frequencies. This is carried out by using a rapid frequency sweep (''chirp''), an ''impulse'' excitation, or a tailored waveform. The image currents induced in the receiver plates will contain frequency components from all mass-to-charge ratios. The various frequencies and their relative abundances can be extracted mathematically by using a Fourier transformation that converts a time-domain signal (the image currents) to a frequency-domain spectrum (the mass spectrum).

A cubic ICR cell consists of three pairs of parallel plates (Figure 11.7). The functions of the excitation and receiver plates are apparent from the preceding discussion. A small potential is applied to the trapping plates to keep the ions contained within the ICR cell because the magnetic field does not constrain the ion motion along the direction of the applied magnetic field. Besides the cubic cell, many other ICR cell designs have been evaluated and used in FTICR instruments, each having its own special characteristics. A new cylindrical FTICR cell with dynamic harmonization that provides ultrahigh resolution has been recently developed by Nikolaev *et al.* [45].

Excitation events can be used to increase the kinetic energy of ions or to eject ions of a given mass-to-charge ratio from the cell by increasing the orbital radius until ions are lost by collisions with the cell plates. The background pressure of an FTICR should be very low to minimize ion–molecule reactions and ion–neutral collisions that damp the coherent ion motion. A variety of external ion source designs have been developed to deal with this problem, and each design has its own performance characteristics [46].

Most FTICR mass spectrometers use superconducting magnets that provide a stable calibration over a long period. Although some mass accuracy can be obtained without internal calibrant, mass accuracy and resolution are inversely proportional to m/z, and the best accurate mass measurements require an internal calibrant. Unlike the quadrupole ion trap, the FTICR mass spectrometer is not operated as a scanning device.

The above working equation of FTICR shows that the m/z measurement is only dependant on the external magnetic field, and – in contrast to all other mass spectrometric analyzer systems – independent of the ion's kinetic energy [44]. This feature provides the basis for the intrinsic high-resolution capability of the FTICR method for the analysis of biopolymers.

FTICR-MS has recently enabled a breakthrough in the ultra-high-resolution mass spectrometric analysis of biopolymers using both ESI and MALDI ionization. A unique attribute of FTICR-MS in comparison to other MS methods is its ability to simultaneously provide high mass resolution ($>10^7$), mass determination accuracy (<0.1 ppm), and sensitivity. A schematic diagram of a commercial FTICR mass spectrometer (Bruker Apex II/III with ESI and MALDI ionization sources) is shown in Figure 11.7. Of particular interest is the versatility of FTICR-MS^n techniques for structure determination using fragmentation by CID or IR laser irradiation [infrared multiphoton dissociation (IRMPD)] [47], and the coupling with micro/nano-ESI. As an example of the ESI-FTICR performance, the spectrum of the protein ubiquitin (Figure 11.8) provides a mass determination accuracy of about 1 ppm at a mass resolution of about 80 000 [48]. The charge states of the multiply protonated ions are readily defined from the mass difference of two adjacent isotopes, without the necessity of deconvolution techniques. This is of importance, for example, for the ESI-MS analysis of noncovalent complexes where a low charge distribution may yield only few peaks that are difficult to deconvolute [6, 13].

11.2.3.2 **Orbitrap Mass Spectrometry**

Orbitrap-MS has been recently emerging as a second high-resolution, high-performance mass analyzer, and has been established with an astounding pace in the last few years [49, 50]. The key features of the orbitrap analyzer are accurate

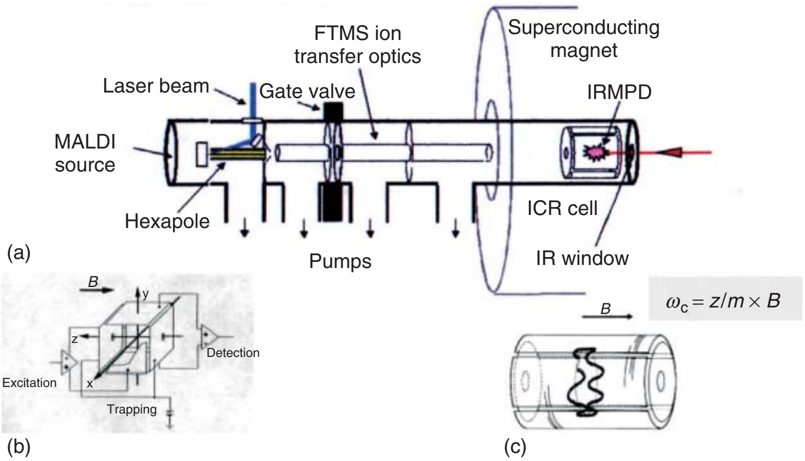

Figure 11.7 Scheme of the Bruker Apex-II/III FT-ICR mass spectrometer (a) with MALDI ionisation source and subsequent hexapole ion retardation, ion transfer optics/high vacuum system, and ICR cell with IRMPD system through a rear exit IR window. (b), (c) schematic illustration of cubic and cylindrical ICR cell configurations with excitation, trapping and detection plates.

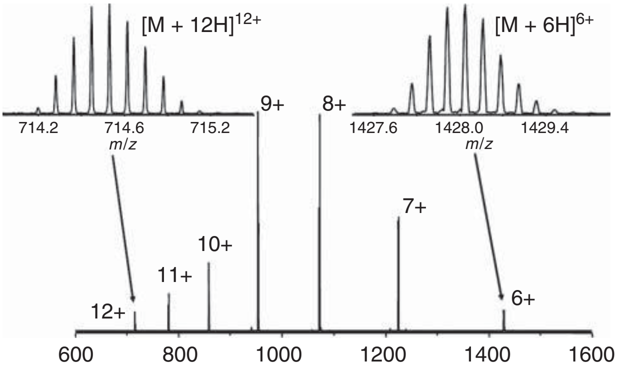

Figure 11.8 ESI-FT-ICR ESI-FTICR mass spectrum of bovine ubiquitin. A sample solution of c. 0.01 mg/ml in 3% aqueous acetic acid:methanol (4:1) was employed. The inserts show isotopic separations of the 6- and 12-fold protonated ions (monoisotopic molecular weight, determined: 8559,5912; calculated: 8559, 6162; Δm: 3 ppm).

mass determination and high resolution, similar to that achievable with FTICR instrumentation. The orbitrap can be applied to the identification, structural characterization, and quantification of a large variety of biomolecules and components in biological systems [50]. With its ability to deliver low-parts-per-million mass accuracy and extremely high resolution within a timescale compatible with nano-LC separations, the orbitrap has become a powerful instrument for many bioanalytical and proteomics applications.

The orbitrap mass analyzer consists of an inner (central) and an outer electrode that are suitable to trap ions in a quadrologarithmic electrostatic potential (Figure 11.9). Ions revolve about the central electrode and oscillate harmonically along its axis (the z-direction) with a frequency characteristic of their m/z values. Image current signal of these oscillations is converted to a frequency using Fourier transformation in a manner similar to that employed in FTICR. The orbitrap mass analyzer has demonstrated high resolving power, mass accuracy, and high space charge capacity with pulsed ion sources [51].

Although it may be possible to fragment ions in the orbitrap, it is more practical and faster to manipulate them in another mass analyzer to which the orbitrap can be linked as a detector. Recently, a linear ion trap was interfaced to the orbitrap to combine the tandem MS capability of the ion trap mass spectrometer with the high resolution and mass accuracy capability of the orbitrap. It was shown that a linear ion trap is an ideal partner for the orbitrap – it is exquisitely sensitive, fast, and capable of multiple levels of fragmentation. Ions accumulated in the linear ion trap can be transferred into an RF-only quadrupole called a *C-trap*, which accumulates and stores the ions. This additional storage improves the analytical capabilities of the instrument. The last part of the system is the orbitrap itself, which is filled by a pulse of ions accumulated in the C-trap. Therefore, this hybrid system contains two complete mass analyzers capable of detecting ions and recording spectra: the

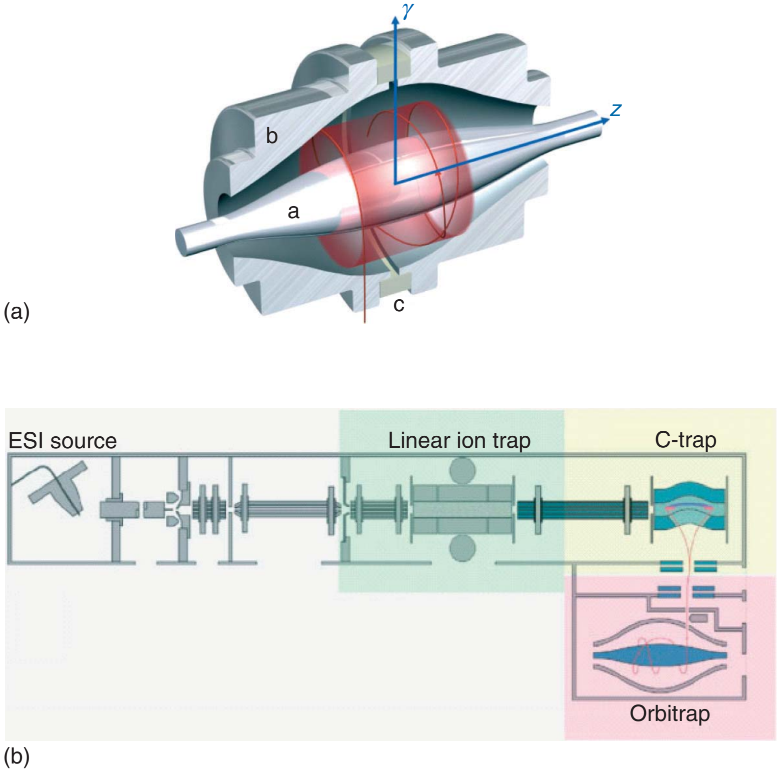

Figure 11.9 Schematic representation of the orbitrap mass analyzer (A) and of the LTQ Orbitrap (B). Ions are moving in spirals around a central electrode (a). An outer electrode (b) is split in half by an insulating ceramic ring (c). An image current induced by moving ions is detected via a differential amplifier between the two halves of the outer orbitrap electrode. The m/z if different ions in the orbitrap can be determined from respective frequencies of oscillation after a Fourier transformation.

linear ion trap and the orbitrap. Depending on the requirements for analysis, the two analyzers can be used independently or in concert [51].

11.2.4
Ion Detection and Spectra Acquisition

After the mass analyzer has dispersed the ions in space or in time according to their m/z values, they may be collected by a detector. In modern MS, a detector consists of a planar assembly of small electron multipliers, called an *array* in one case (spatial separation) and a *microchannel plate* in the other (temporal separation). Collectors can either detect the arrival of all ions sequentially at a point (point ion collector) or detect the arrival of all ions simultaneously (array or multipoint collector).

Quadrupole mass spectrometers (mass filters) allow ions at each m/z value to pass through the analyzer sequentially. Therefore, the ion collector at the end of the quadrupole unit needs only to cover one point or focus in space and thus can be placed immediately behind the analyzer. A complete mass spectrum is recorded over a period of time, which is set by the voltages on the quadrupole analyzer. The resolution of m/z values is entirely dependent on the analyzer and not on the detector.

A multipoint ion collector (also called *detector*) consists of a large number of miniature electron multiplier elements assembled side by side over a plane. A multipoint collector may be an array detecting a dispersed beam of ions simultaneously over a range of m/z values, and is frequently used with a sector type mass spectrometer. Alternatively, a microchannel plate collector detects all ions of one m/z value. When combined with a TOF analyzer, the microchannel plate affords an almost instantaneous mass spectrum. Because of their construction and operation, microchannel plate detectors are cheaper to fit and maintain.

Other types of mass spectrometer may use point or array detectors, or both types of ion detection. Ion trap mass spectrometers may detect ions sequentially or simultaneously and, in some cases, may not use a formal electron multiplier type of ion collector at all; the ions can be detected by their different electric field frequencies in flight, according to their m/z values.

11.2.5
Sample Preparation and Handling in Bioanalytical Applications

Most biological samples analyzed by GC/MS or LC/MS need sample preparation, depending on the matrix content and concentration of the analyte. In clinical chemistry and forensic toxicology, for example, body fluids such as blood/serum and urine have to be analyzed as well as tissue samples (organs, muscle), stomach contents, and hair [52]. In environmental toxicology, sewage sludge, sediments, wastewater, or plant material may contain only traces of the analytes of interest; thus, concentration and clean-up steps are necessary prior to analysis.

For the determination of drugs in plasma, extraction and concentration are also necessary in most cases. Matrix effects can influence the chromatographic separation in GC/MS or LC/MS and also the ionization process in ESI-MS [52, 53].

11.2.5.1 Liquid–Liquid Extraction (LLE)

Liquid–liquid extraction (LLE) of organic, nonpolar analytes for subsequent mass spectrometric analysis is still a common method in clinical, pharmaceutical, and environmental analysis, especially for the analysis of aqueous phases such as plasma and urine, but also for tissue samples. Major goals of methodology development in the past few years have been miniaturization, automation [54], and the removal of solvents with high toxicity (e.g., benzene and halogenated solvents). LLE is usually a robust method because only two natural constants are relevant for the extraction efficiency, the distribution constant between organic and aqueous phase, and the dissociation constant of the acidic or basic analyte; moreover, pH and temperature can be easily optimized and controlled. LLE can provide high selectivity for the analytes of interest. Considerable efforts in automation have been made for high-throughput pharmacokinetic analysis of human plasma samples, by using deep-well 96-well plates for extraction (e.g., in the determination of the anticancer drug methotrexate [55]), or an automated liquid handling system customized with integrated mechanical shaker and valve systems [54].

For systematic clinical toxicological analysis – also known as ''*general unknown screening*'' – Pfleger *et al.* [56] have developed extraction and derivatization methods for GC/MS analysis with subsequent electron impact mass spectral library searching. In this procedure, urine (plasma or gastric content) is extracted either directly or after acidic hydrolysis (for cleavage of phase II metabolites) with solvent mixtures containing ethyl acetate, diethylether, and dichloromethane. The hydrolyzed fraction is acetylated prior to GC/MS to convert amines and hydroxides into volatile derivatives. Other derivatization methods employed include alkylation with phase-transfer catalysis and silylation, for example, for the detection of carboxylic acids. In LLE procedures for drugs from plasma or urine, 1-chlorobutane has been used for subsequent GC/MS or high-performance liquid chromatography (HPLC) analysis [57, 58].

11.2.5.2 **Solid-Phase Extraction (SPE)**

In contrast to LLE, solid-phase extraction (SPE) is considerably more complex and is based on a sorbent with specific affinity for the analyte. Several sorbents have been developed, most being silica-based with different modifications (reversed phase, ion exchange, diol and amino phases) or polymer based (e.g., polystyrene–divinylbenzene copolymer). SPE methods for toxicological screening have been reviewed by Franke and De Zeeuw [59] with the conclusion that although silica-bonded phases (especially mixed-bonded phases with reversed-phase C8 or ion-exchange functions) were favorably used for screening analysis, no single extraction procedure provides optimum results for different sample types and detection techniques. Sample pretreatment is highly dependent on the sample type: For example, whole blood or tissue homogenate cannot be applied directly on SPE columns, whereas plasma or urine can be applied directly or after simple dilution.

Using SPE disks or small bead-volume cartridges for miniaturization of sample volumes, and robotics with 96-well plates, automation is facilitated for large numbers of plasma and urine samples – especially in combination with LC/MS/MS detection [60, 61]. Online sample concentration by trapping columns for automated LC/MS analysis will be discussed in Chapter 11.2.6.1.

11.2.5.3 **Immunoaffinity Extraction (IAE)**

Immunoaffinity extraction (IAE) is probably the most effective way for the extraction of trace amounts of analytes from biological samples, especially if coupled directly to LC/MS/MS. Henion *et al.* [62, 63] reported a method for automated IAE-LC/LC-MS/MS-analysis for detection of lysergic acid diethylamide (LSD) metabolites and β-agonists in urine and benzodiazepines from chemical libraries, whereas Maurer *et al.* [64] used IAE for the determination of amanitines in urine. Approximately

20-fold higher sensitivity was obtained in these studies by IAE compared to a standard SPE method. However, a disadvantage of IAE is the narrow linear range because antibodies may be easily overloaded.

11.2.5.4 Solid-Phase Microextraction

Solid-phase microextraction (SPME) is currently under investigation in many laboratories for its usefulness for a large variety of bioanalytical applications. SPME involves extraction and preconcentration with a fused silica fiber or tubing coated with a polymeric stationary phase. SPME can be performed in two-phase (sample–fiber coating) and three-phase (sample–headspace–fiber coating) systems [65].

Desorption for GC analysis is performed directly in the GC injector by elevated temperature. For HPLC analysis, an interface has been constructed for solvent extraction of the analyte from the fiber, followed by introduction of the solvent into the LC injector [66, 67]. Besides applications to volatiles from solid samples, liquids, and gaseous samples, polar and less volatile compounds are increasingly under study as analytical targets, and difficulties with small partition coefficients and long equilibration times have been identified. Headspace methods minimize interactions between sample and fiber and have proved useful for semivolatile analytes such as amphetamines from urine, and free volatile fatty acids in wastewater [68]. Several experimental concepts have been pursued for optimization of the method, including matrix modification by heating, addition of salt, and pH buffering.

Automated ‘‘in-tube’’ SPME has recently been coupled with LC/ESI-MS, for example, for the determination of drugs in urine [69]. In-tube SPME is an extraction technique in which analytes are extracted from the sample directly into an open tubular capillary by repeated draw/eject cycles of sample solution. The analyte is then desorbed with methanol and transferred to an analytical HPLC column.

The SPME device has been also employed as a time-weighted average (TWA) sampler for gas phase analytes [70]. This was performed by retracting the coated fiber for a known distance into its needle housing during the sampling period. Unlike in conventional spot sampling with SPME, the TWA sampling approach does not allow the analytes to reach equilibrium with the fiber coating, but rather they diffuse through the opening in the needle to the location of the sorbent. The amount of analytes accumulated over time gives the average concentration to which the device was exposed. Depending on the sorbent used, TWA sampling is possible for durations from 15 min to 12 h.

11.2.5.5 Supercritical Fluid Extraction (SFE)

Supercritical fluid extraction (SFE) has been automated for serial extraction of samples. Fields of application of SFE with supercritical carbon dioxide and additional modifiers have been environmental (sewage sludge [71]) and forensic toxicology (drugs [72, 73]), as well as food and plant analysis [74]. Online coupling to different analytical methods (IR, NMR, fluorescence detection, MS) has recently been reviewed [75], but most bioanalytical applications are based on the off-line extraction with subsequent analysis by GC/MS or LC/MS.

11.2.6
Combination of Mass Spectrometry with Microseparation Methods and New Mass Spectrometric Hybrid Systems

A detailed review on interfacing microseparation methods with MS has been published by Tomer [76], which covers the development of interfaces for micro- and nano-LC, capillary electrophoresis (CE), capillary electrochromatography (CEC), micellar electrokinetic chromatography (MEKC), and capillary isotachophoresis (ITP) MS. Furthermore, multidimensional chromatography-MS, microfabricated microfluidic devices (microchip)/MS, LC/MALDI-MS, affinity chromatography/MS, and supercritical fluid chromatography/MS have been discussed in this chapter. Although GC-MS is often considered a mature field, new developments in GC-MS have been covered including fast GC-MS using TOF-MS and supersonic molecular beam GC-MS. In the following, overviews are given about new developments in the combination of (i) electrophoresis with MS and (ii) the miniaturization of LC-MS, since both combinations are key tools in proteomics and have become routine techniques in many bioanalytical laboratories, as well as for the structural identification of biopolymers. In addition, perspectives for bioanalytical applications are briefly discussed for two new hybrid MS, online bioaffinity/biosensor-MS [77] and IM-MS [20–22], both of which are presently emerging with promising future application potential as microseparation-MS tools from complex biological mixtures.

11.2.6.1 *Liquid Chromatography-Mass Spectrometry Coupling (LC-MS)*

GC/MS with capillary columns has been the gold standard for more than 20 years, but LC/MS has become a complementary method because of the remarkable success in interface development with atmospheric pressure ionization (API) for low-molecular-weight compounds, as well as the application to biopolymers. For many areas of analytical chemistry and biochemistry, LC/MS has become indispensible because of its advantages over GC/MS for polar and thermolabile analytes. A limiting factor for LC/MS has been the incompatibility between the liquid eluting from the LC and the mass spectrometer vacuum. However, this has been overcome in ESI with the use of a nebulizer gas (“ion spray”) or additional heated drying gas (“turbo ion spray”) [78, 79]. Because of its high sensitivity and selectivity, API-MS has become a standard tool for the structure elucidation of analytes from many complex mixtures.

Standard electrospray is limited to flow rates below 10 µl min^{-1}, while nebulizer-assisted ESI can handle up to 100 µl (ion spray); turbo ion spray, orthogonal, or Z-spray (from different instrument manufacturers) can handle flow rates up to 2 ml min^{-1} without split. APCI is normally used with flow rates of 0.2–1 ml min^{-1} and can be used with normal- and narrow-bore columns without splitting the eluent, while ESI can also be used with microseparation methods. Microseparation methods such as nanocapillary-HPLC, CE, and CEC have the advantage that higher separation efficiencies are achieved, yielding narrow analytes peaks and high peak concentrations. Drawbacks of the microseparation approaches are that only low sample amounts are applicable [80] and only a short path length can be used for detection. The advantage of low flow rates is that the complete effluent can be transferred to the mass spectrometer thus yielding high detection sensitivity. Several ESI parameters such as the diameter of the spray tip and position relative to the sampling orifice can be optimized to improve ionization efficiency and ion sampling. As noted in Section 11.2.1.3, the use of microsprays systems enhances sampling efficiency. Another way to increase the number of ions fed to the mass spectrometer is the use of larger entrance skimmers or capillaries; however, this requires a higher gas flow entering the mass spectrometer. The relationship between flow rate and sensitivity has been investigated by Hopfgartner *et al.* [81] and Oosterkamp *et al.* [82], showing that optimum flow rates for conventional ESI range from 1 to 10 $\mu l\,min^{-1}$, while rates for ion sprays range from 50 to 1000 $\mu l\,min^{-1}$ using a heated drying gas. Micro-LC/ESI-MS can be performed with conventional ESI sources with ESI emitters of small internal diameter [83], whereas for nano-LC (flow rates $<2\,\mu l\,min^{-1}$), micro-ESI interfaces with custom-made ESI emitters have been used [84]. Low diameter ESI emitters have been produced by different techniques, for example, by electropolishing of metal needles, treatment of silica capillaries with HF, or drawing with a laser puller with subsequent surface coating (gold sputtering) [85]. However, most promising is the coupling of nanoscale capillary-LC with nanospray-MS using a coaxial sheath flow interface. Flow rates below 200 $nl\,min^{-1}$ [33] can be achieved, yielding high sensitivity, for example, for peptide mixture analysis. With the downscaling of LC-separation and ESI interfaces, detection limits down to the low femtomole range have been obtained; however, online separations with flow rates $>100\,nl\,min^{-1}$ are still less sensitive compared to continuous sample flow from nanoelectrospray tips [86, 87], which have typical flow rates of 1–20 $nl\,min^{-1}$. Furthermore, online preconcentration by column-switching prior to micro- or nano-LC/MS has been shown to improve detection limits [88] and can be used to overcome limited sample volumes. During the last few years, ESI emitters for nano-flow LC or CE separations have become commercially available. A major drawback of nano-LC/MS is still its lack of robustness due to capillary plugging; however, miniaturized LC/MS systems will likely be further optimized in the near future.

11.2.6.2 **Combination of Mass Spectrometry with Electrophoresis**

The combination of desorption–ionization methods of MS (ESI-; MALDI-MS) with gel electrophoresis has developed in the last few years to one of the most successful microseparation-MS combinations, and has been widely employed in the analysis of biopolymers from biological samples, particularly in proteomics [89, 90]. For microseparation using both polyacrylamide sodium dodecyl sulfate gel electrophoresis sodium dodecyl sulfate- polyacrylamide gel electrophoresis (SDS-PAGE) under denaturation conditions, or native electrophoresis, a variety of detection and visualization techniques for protein bands or spots from one- and two-dimensional electrophoretic separations have been employed in mass spectrometric proteomics (Section 11.3.5). Well-established staining procedures for visualization of proteins have used dyes such as Coomassie Brilliant Blue, silver salts, and fluorescent dyes (Flamingo, Sypro® Ruby) [91]. Although several of these approaches provide high detection sensitivities for proteins, major problems are frequently encountered with the compatibility of staining procedures with mass spectrometric analysis because of the high background arising from polar staining materials and the need for applying destaining procedures for isolated proteins [91].

Recently, alternative procedures are being explored to overcome these problems, using unstained gels in electrophoretic separations [92–95]. In fluorescence labeling studies of glycoproteins, Zhao *et al*. observed a fluorescent signal for non-glycosylated proteins such as hen lysozyme, which was attributed to intrinsic (native) protein fluorescence [92]. Fluorescence detection of proteins has been evaluated with pre- or post-electrophoretic incorporation of halogenated compounds such as trichloromethane, trichloroethanol, and trichloroacetic acid, which react with tryptophane residues upon UV light exposure, yielding products with emission in the visible light range, suitable for visualization of protein bands [93]. A direct UV fluorescence detection method for unstained proteins, first reported by Roegener *et al*. [93] showed the visualization of proteins in both 1D- and 2D-gel separations with low detection limits (1–5 ng).

A commercial gel bioanalyzer based on native fluorescence has been recently developed (LaVision-BioTec; Bielefeld, Germany) [94], and applied in a recent study for the development of native fluorescence detection in one- and two-dimensional gel electrophoretic separations in mass spectrometric proteome analysis. The sensitivity of the stain-free native fluorescence detection with the gel–bioanalyzer was evaluated in comparison with standard staining procedures by Coomassie and silver visualization, showing comparable sensitivities for the fluorescence detection and silver staining (detection limits 1–5 ng), while Coomassie-stained gel bands were not detectable at this concentration range [94]. Moreover, it was shown that in stain-free visualization, no fixation step is needed following gel electrophoretic separation, and protein spots can be directly analyzed after scanning, providing proteomics data with high sensitivity and nearly complete lack of background, for example, in bacterial proteomics [94, 95]. These results, providing unequivocal protein identifications at low detection limits, indicate broad applicability of the stain-free gel separation and visualization approach as an efficient and sensitive tool in mass spectrometric proteomics, as illustrated in a study of bacterial proteins from *Desulfotignum phosphitoxidans* by the identification of a new NAD(P)-dependent epimerase/dehydratase, and its different phosphorylated forms (Figure 11.10) [95].

11.2.6.2.1 **Capillary Electrophoresis (CE)-Mass Spectrometry** In contrast to HPLC, flow rates of capillary zone electrophoresis (CE) are in the low nanoliter-per-minute range. Migration of analytes between the buffer reservoirs at both ends of a fused-silica capillary is effected by electromigration and electroosmosis [96]. Electrophoretic migration occurs with positively charged species from the anode (high positive potential) to the cathode (low or ground potential) or vice versa. Electroosmotic flow (EOF) occurs with an electrical potential applied across a liquid-filled porous medium; it acts to sweep all solutes through the capillary and does not promote separation. Surface deactivation can lead to suppression of the EOF so that the flow of solvent from the capillary is minimized.

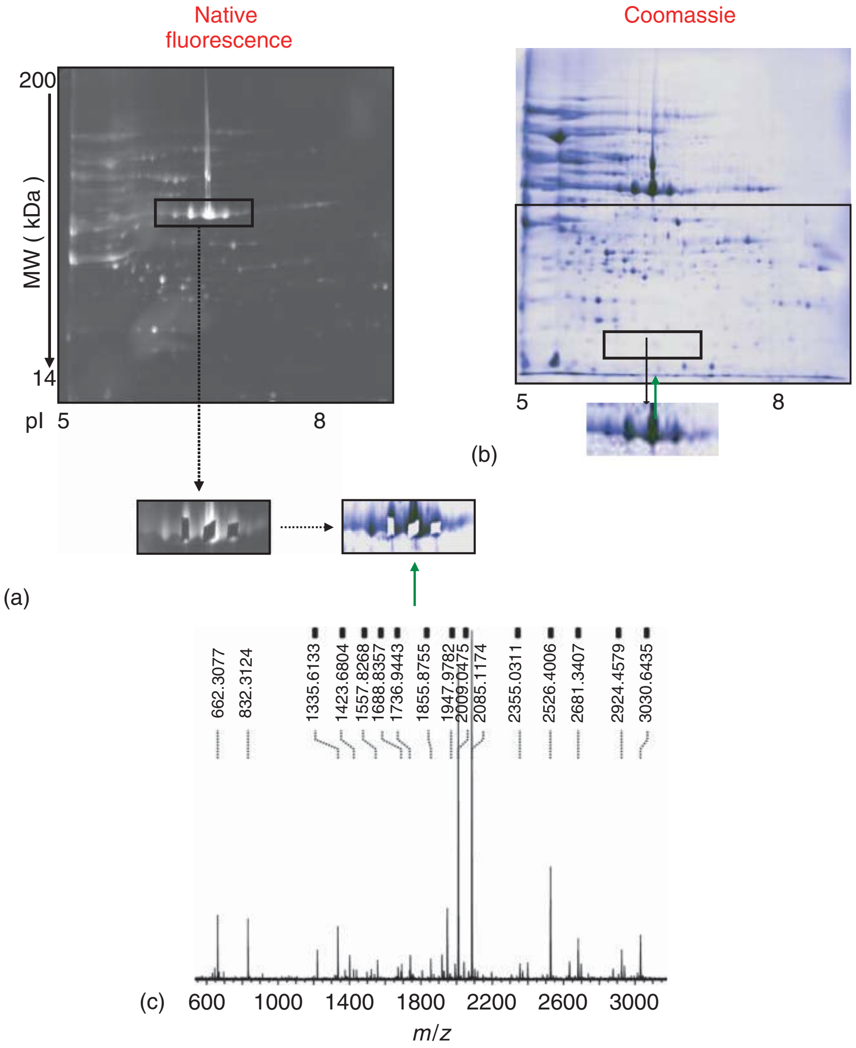

Figure 11.10 Detection and localisation of protein spots in 2D-gels by native fluorescence using precise spot localization and picking tools. Separation gels were prepared with protein extracts from Desulfotignum phosphitoxidans (grown with phosphite/fumarate/sulfate; approximately 0.4 mg total protein were applied onto 17 cm IPG strips 5–8). Spot picking tools were used to cut spots from unstained gels. (a), Unstained gel with native fluorescence detection. (b), 2D gel stained with Coomassie, prepared in identical manner with the Bio-Analyzer gel. (c), MALDI-TOF mass spectrometric identification of NAD(P)-dependent epimerase/dehydratase from Desulfotignum phosphitoxidans. Spot 3 was excised from the native fluorescence gel, digested with trypsin and analysed by MS. Masses of peptide ions for protein spot 3 were compared with the calculated masses for fragment ions of the open reading frame obtained from genomic DNA amplification.

For CE-MS coupling, different sheath-flow interfaces have been designed [97–99] in addition to a liquid-junction interface (using a liquid reservoir for electrical contact without a make-up flow of liquid). Furthermore, off-line coupling devices have been developed for the coupling of MALDI to CE, basically by means of sheath-flow interfaces for sample collection and subsequent target preparation [100, 101]. To overcome the low amounts of analyte in CE, capillary transient isotachophoresis (tITP) has been used for analyte concentration [102, 103]. The high separation efficiency of CE makes it attractive for the analysis of complex mixtures after sample clean-up and concentration; a main drawback still is the limited amount of sample load onto the CE capillary.

In CEC, a liquid flow through a packed capillary is created by application of an electric field. Several interfaces have been designed for coupling to ESI-MS, and current applications have been reviewed [104, 105]. CEC is a good alternative for neutral analytes in combination with mass spectrometric detection, since no interferences with micellular matrix can occur [106]. The combination with LC, resulting in an electrically and pneumatically driven flow of solvent, has been called *pressurized CEC*. This combination offers new opportunities for the separation of complex mixtures.

11.2.6.3 **Online Bioaffinity–Mass Spectrometry**

Although a number of affinity techniques have become established approaches over the last decades for the analysis of biomolecular interactions, their combination with MS is only recently developing as a new hybrid methodology for structure identification and quantification of bioaffinity ligands and in the molecular characterization of biopolymer interactions [77]. Methods widely used for characterization of protein–ligand interactions include immunoaffinity analysis such as ELISA and Western blot, isothermal titration calorimetry (ITC), and biosensor technologies, such as surface plasmon resonance (SPR), surface-acoustic wave (SAW), and quartz-crystal microbalance (QCM) [77]. For example, SPR has already developed into a highly efficient, standard tool for the analysis of biomolecular recognition processes at a biosensor surface, and has been successfully applied as a quantitative probe to a variety of biopolymer interactions, such as protein–peptide, protein–nucleotide, and –antibody complexes [6, 7, 13, 77]. However, while providing sensitive and accurate determinations of binding/dissociation constants (K_i or K_D), a major limitation of all bioaffinity methods is the lack of chemical structure information of affinity-bound ligands. In contrast, the direct, online combination of biosensor detection and MS provides access to both structural identification and quantification of bioaffinity interactions and the involved biomolecular ligands.

One of the newest methods of affinity-MS is the recently developed online coupling of biosensor to ESI-MS, which allows simultaneous detection and quantification of affinity interactions and chemical structure identification of the ligand [77]. The SAW technology, which employs a piezoelectric detection of mass differences according to the ‘‘love-wave’’ principle [107], was first employed for online bioaffinity-MS; however, most recently alternative biosensors such as the QCM have also been successfully employed. The use of ESI to this combination provides two important advantages; (i) the possibility to implement the online analysis within a continuous microfluidic system that provides direct structural characterization of the ligand molecules involved in the affinity interaction and (ii) the generation of multiply charged ions whose m/z values are easy to determine. In order to effectively obtain the coupling of biosensor and MS, several preconditions must be met, particularly to remove or reduce the high salt content from the biosensor sample, and to adjust the different flow rates used for the biosensor and into the ESI-MS ion source. Both preconditions have been effectively solved by the development of a biosensor–MS interface [77] consisting of two electrical multiport valves that connect the biosensor and the mass spectrometer (Figure 11.11). The interface is capable of (i) transferring the sample from the biosensor outlet to the ESI ion source; (ii) desalting the sample by trapping the ligand on a guard column, and removing the salts for subsequent transfer of the ligand into the ESI source; and (iii) providing a flow rate equilibration, typically between 15 and 40 μl min^{-1} (optimal flow rate of the ESI ion source). A suitable software has also been developed (Biosensor2MS; [77]) for the automation of the transfer procedure.

First bioanalytical applications of the online bioaffinity–MS combination include the identification of calmodulin–polypeptide complexes, and the structural characterization and differentiation of β-amyloid (Aβ) peptide epitopes upon binding to Aβ-specific antibodies, and the identification of bioaffinity-specific posttranslational protein modifications [77, 108, 109]. An example of the latter application

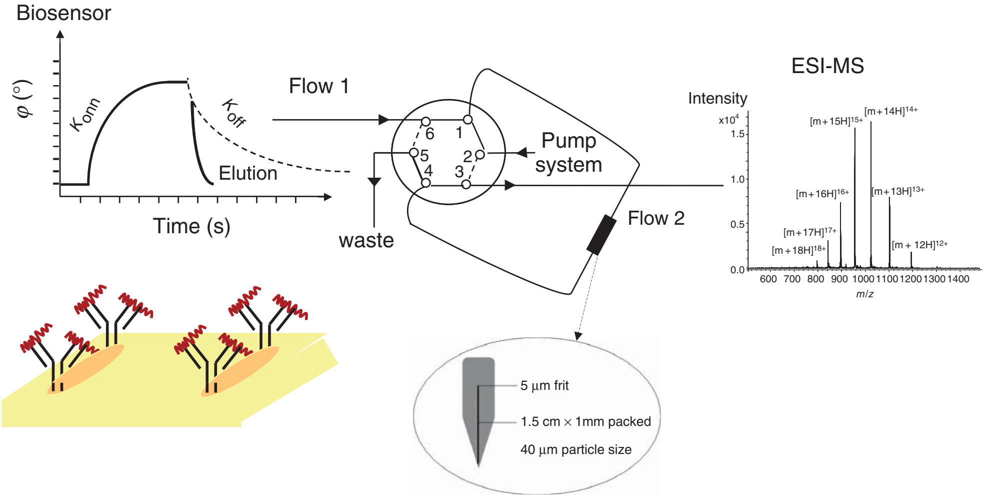

Figure 11.11 Schematic of the on-line SAW-ESI-MS combination using an SSens/K5-SAW biosensor and a six-port-valve micro-column interface. (a) The biosensor exit capillary is connected to the interface in position 6, with the ESI-MS inlet capillary in position 3. Dissociation of the ligand from the SAM-Chip is performed by eluting with acidic glycine buffer or hydrochloric acid into the micro-column interface (flow 1). (b), Removal of buffer salt solution and transfer of the eluate into the ESI source by switching the interface valve to position inject, and elution with aqueous acetonitrile/HCOOH as described in the Experimental section (flow 2).

is the direct identification of a tyrosine nitration in physiological proteins in eosinophils by the bioaffinity-isolated 3-nitrotyrosine-modified peptide bound to a nitrotyrosine-specific antibody [110]. In all cases, accurate determinations of dissociation constants of the protein– and antibody–peptide complexes in the micro- to nanomolar concentration range were obtained from the biosensor signal. These initial results indicate broad bioanalytical application potential of the online biosensor–MS combination for the simultaneous label-free structure determination and quantification of biopolymer–ligand interactions, as diverse as antigen–antibody and lectin–carbohydrate complexes.

11.2.6.4 **Ion Mobility Mass Spectrometry**

Among the range of hybrid systems of MS suitable for combining microseparation and molecular characterization by MS, IM-MS has recently emerged as the most successful new MS system [21]. Ion mobility spectrometry (IMS) was introduced in the 1970s as a portable, economical alternative to MS for the detection of airborne volatiles, for example, environmental and industrial process contaminants, explosives, chemical warfare agents, and drugs [20, 21, 111]. Over the past decade, two major technical developments decisively broadened the analytical range of IMS: (i) the effective coupling of IMS to MS, especially the advent of IMS-TOF instrumentation that enables a parallel dispersion of ion mixtures in mobility and mass/charge (m/z) dimensions [23] and (ii) interfacing of ESI and MALDI ionization sources to IMS and IMS/MS [112], which enabled access to many bioanalytical applications.

IMS and MS share a similar theoretical background, the historical development of which was presented by Uetrecht *et al.* [22]. Mass spectrometric methods are limited to the separation of ions measured by mass-to-charge (m/z) ratios and ion intensities, while IM separates ions based on their mobility and measures the time it takes an ion to migrate through a buffer gas in the presence of a low electric field (drift time) (Figure 11.12). The ion velocity, v (drift velocity) is directly proportional to E with the proportionality constant K called *ion mobility* and is determined by measuring the time (t_D) required to traverse a drift cell of known dimensions, d:

$$v = KE = \frac{d}{t_D}$$

The development of ‘‘soft-ionization’’ methods of MS in the last years, such as ESI-MS, has enabled substantial progress in the characterization of chemical structures and their modifications, for example, in proteome analysis; however, applications of HPLC-MS methods are unsuitable to direct ‘‘in situ’’ analysis of conformational states and reaction intermediates in protein assemblies. Most recently, IM-MS is emerging as a new tool to probe protein complex structures from solution phase structures, owing to the potential of IM-MS for the separation of mixtures of protein complexes by conformation state and spatial shape and topology. A first commercial quadrupole-TOF IM-MS instrument has been developed, which is suitable for the analysis of large biopolymers (Waters-Synapt IM-Q-TOF-MS). In this IM-MS system, ions produced by ESI and preselected by a quadrupole are

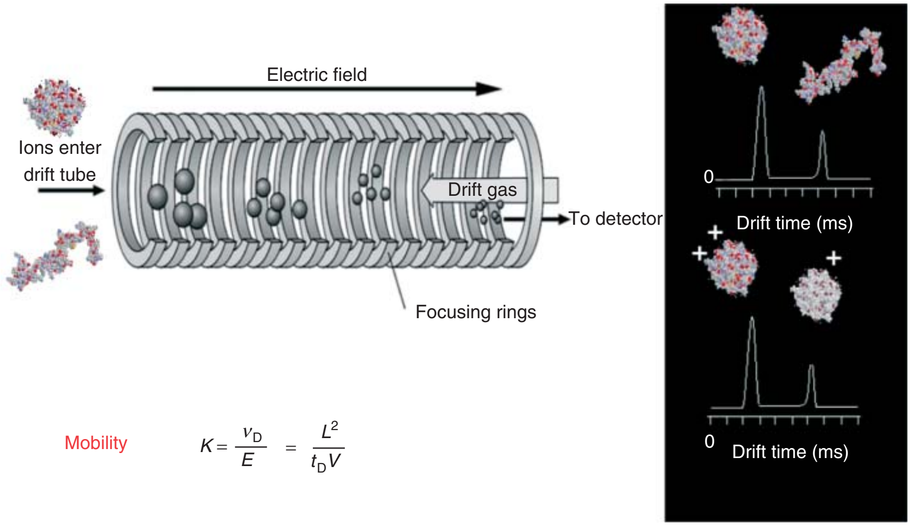

Figure 11.12 Principle of ion mobility-MS. Ion mobility separates ions based on their mobility and the drift time to migrate through a buffer gas in the presence of a low electric field. The ion velocity is proportional to E and is determined by measuring the time required to traverse a drift cell of known dimensions. IMS-MS separates species according to their collisional cross section (CCS) which represents the orientationally averaged area of the ion capable to interact with a buffer gas. For macromolecular ions Ω is approximated computationally. IMS-MS enables the differentiation of protein conformational states, protein folding and unfolding, as schematically shown.

separated according to their conformation/topography-dependent cross sections upon passing an electric drift field, and MS-MS-generated product ions are identified by a TOF-MS. First successful applications include the characterization of large protein complexes, structural differentiation of isomers, and conformational studies [113–115], clearly indicating the broad application potential of IM-MS. Applications of IM-MS to the structure identification of reaction intermediates in the oligomerization–aggregation of target proteins of neurodegenerative diseases are described in Section 11.3.7.

11.3
Applications of Mass Spectrometry to Biopolymer Analysis

11.3.1
Introduction

As pointed out in the introductory chapter (cf. 11.1.1), the development of "soft"-ionization MS has caused a revolution both in the range of bioanalytical application areas and, particularly, in the possibilities for molecular structure–function analysis of biopolymers. The two currently dominant techniques, ESI-MS and MALDI-MS have driven the refinement and perfection of several high-resolution separation techniques, particularly 2D-gel electrophoresis and HPLC, for mass spectrometric applications. Combinations of these MS approaches with suitable protein-chemical and biochemical procedures have become feasible for molecular studies of even complex mixtures and heterogeneous forms of biopolymers [6, 13]. Thus, mass spectrometric approaches are now suitable for the identification of low levels of specific sequence mutations, posttranslational modifications, and other subtle covalent structural changes, frequently hitherto undetectable [5–7]. Moreover, MS approaches have been recently developed for new applications with great demand, owing to a lack of conventional molecular-biochemical techniques, for example, in the characterization of tertiary structures and conformational states, specific *non-covalent* biopolymer complexes, and *molecular recognition* structures (epitopes) [31].

In the following paragraphs, illustrations of *some* of these applications are presented, including an outline of mass spectrometric *proteome* analysis as an area that has recently been exerting a dramatic impact on biotechnology and biomedical research. Furthermore, the particular role of high-resolution MS as a molecular tool in biopolymer analysis will be illustrated. Within these bioanalytical applications, studies employing a combination of specific protein-chemical modification reactions and mass spectrometric peptide mapping have been included [15, 16] to illustrate the wide variety of useful structural information amenable to biopolymer MS, such as on surface topology and tertiary structure microenvironment.

11.3.2
Analysis of Peptide and Protein Primary Structures and Posttranslational Structure Modifications

Mass spectrometric methods have been effectively developed in the last years for the sequence determination (partial or complete) of polypeptides and even *de-novo* sequencing of proteins [7, 116, 117]. The two general strategies for peptide sequencing, (i) mass spectrometric fragmentation of a peptide backbone using tandem-MS methodologies and (ii) specific enzymatic or chemical cleavage and subsequent mass spectrometric analysis of truncated peptide mixtures, are complementary to each other. Different types of MS/MS instrumentation with triple quadrupole and tandem magnetic sector spectrometers have been successfully employed and have been summarized in reviews [117, 118]. Fragmentations at the peptide backbone produce major types of sequence-specific ions from both the N- and C-terminal ends (e.g., ‘‘b’’- and ‘‘y’’-ions, Figure 11.13), which have been termed according to a nomenclature first proposed by Roepstorff and Fohlman [119]. Such fragmentations can occur as a result of the ionization method directly, such as capillary-skimmer voltage-induced dissociation of molecular ions in ESI-MS (ΔCS), or by collision-induced decomposition (CID) with a neutral gas; they are, in principle, suitable both for sequence determinations and the identification of posttranslational modifications.

Sequence determinations have been performed by FAB-MS/MS fragmentations of $[M + H]^+$ ions both with magnetic sector and triple-quadrupole instruments.

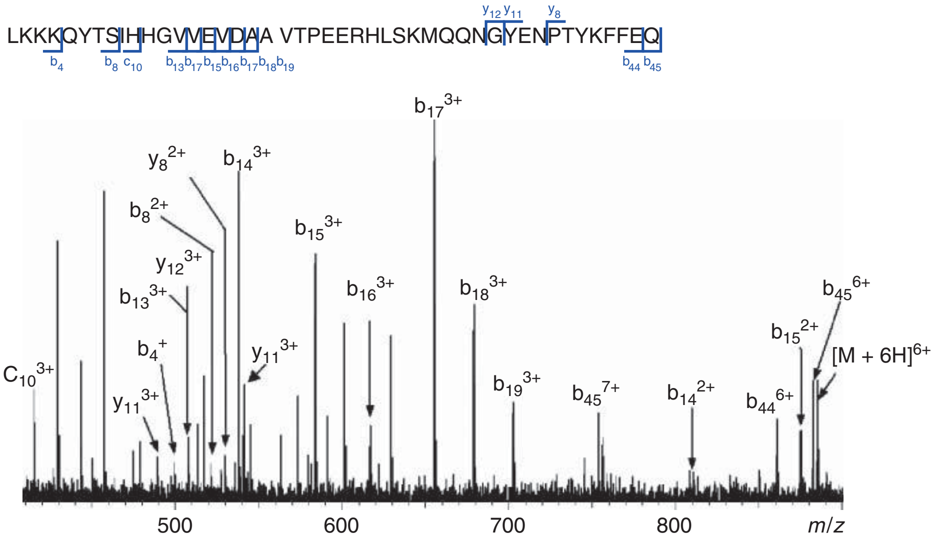

Figure 11.13 ESI-FTICR spectrum showing capillary-skimmer fragmentation of the cytosolic polypeptide domain of Alzheimer-amyloid-precursor protein, APP(723–767). Sequence-specific b- and y-ions are indicated with sequence positions and charge states in the spectrum, and partially in the sequence. Capillary exit voltage, 130 V; sample concentration ca. 0.01 µg/µl.

A major disadvantage of the tandem magnetic sector is the relatively large and expensive instrumentation, while triple-quadrupole MS/MS as smaller, low-resolution instruments have been shown to be effective for rapid sequencing of peptides [7, 32, 117]. ESI has been also used effectively for peptide sequencing, both with triple-quadrupole MS/MS and ion trap systems [116, 119]. More recently, FTICR- and orbitrap-MS have been shown to provide substantial advances by the high mass determination accuracy and high sensitivity over a wide mass range; the possibility of simultaneous excitation and detection of *in-source* fragment ions of all mass-to-charge ratios and of collision-induced dissociation (CID) in the ICR ion cell enables the acquisition of detailed primary structure data [44, 47, 48, 120–122]. This is illustrated in Figure 11.13 by the capillary-skimmer fragmentation in the ESI-FTICR spectrum of a cytoplasmic polypeptide of Alzheimer-amyloid precursor protein, APP(723–767). It has been shown that the cleavage of APP to amyloidogenic products involves a complex pathway that is mediated by intracellular targeting sequences located in the cytoplasmic tail; hence, knowledge of the cytoplasmic APP structure is important for understanding the amyloid formation at the molecular level [123, 124]. The accuracy of fragment ion mass determinations (Figure 11.13) yields detailed structural information by b- and y-sequence ions [125]. In addition, fragmentation by ESI-FTICR using collision-induced dissociation [sustained off-resonance irradiation collision-induced dissociation (SORI-CID)] in the ICR cell provides fragment ions covering the complete sequence.

A second general approach consists of the successive chemical and/or enzymatic exopeptidolytic cleavage, in combination with mass spectrometric analysis of the truncated peptide mixture [7]. This approach has been quite successful in obtaining *partial* sequence determinations with a variety of carboxypeptidases and aminopeptidases of broad specificity (such as carboxypeptidase Y) by using ESI-MS and MALDI-MS, and is suitable for identifying modified amino acids in peptides [126–128]. The limitations of this approach are that (i) isobaric residues cannot be determined (Leu/Ile), (ii) Gln/Lys require high-resolution MS with isotopic mass accuracy [129], and (iii) it is difficult to produce a homogeneous truncated peptide series. For the last reason, techniques employing N-terminal Edman degradation and mass spectrometric analysis of the stepwise shortened peptide have been successfully employed [130, 131]; for example, the addition of a small amount of reaction-terminating phenyl isocyanate in Edman degradation to produce a homogeneous truncation series (''ladder sequencing'') has been successful in determining shorter peptide sequences [132].

Mass spectrometric sequencing and specific fragmentation methods have been developed with considerable success (in some cases as key techniques) for the identification of covalent posttranslational modifications in proteins, such as glycosylation, acylation, intramolecular disulfide linkages, and phosphorylations [133–138]. Using suitable chemical procedures for (i) selective cleavage of the modification group from the peptide backbone and (ii) partial sequencing, in conjunction with MS, the modification position within the polypeptide chain can be often identified even in cases where a complete structure determination is not feasible [137, 138]. Such approaches include the mass spectrometric analysis of the intact protein before and after removal of a modification group, and/or Edman degradation and MS analysis of the modified sequence. While these methods have been successful in the identification of single-site modifications such as alkylated or fatty acylated residues [139, 140], more complex modification structures such as glycosylations [141–143] require a specific setup of chemical reactions in combination with MS. For the analysis of glycosylations, the identification of carbohydrate attachment sites (N- and O-linked) is a tedious task, aided by the consensus Asn-tripeptide motif for possible N- (but not O-) glycosylation. However, the considerable heterogeneity and structural complexity (e.g., branched, multiantennary) of glycosylations make it frequently necessary to use separate analytical strategies for the carbohydrate analysis. Mass spectrometric determination of carbohydrate structures in glycosylated proteins have been summarized in reviews [144].

The characterization of phosphorylated protein structures is discussed in the following to illustrate the use of specific mass spectrometric strategies for posttranslational modifications. Phosphorylation is a key modification not only for replication control but also for regulation of gene expression and protein synthesis controlling cell growth, division, and differentiation; hence, the identification of the specific phosphorylation site is essential in order to understand the molecular basis of these regulatory mechanisms. Owing to the low level and complexity (multiplicity) of many phosphorylations, the use of immobilized metal ion affinity (IMAC) enrichment of phosphopeptides from proteolytic mixtures has been shown to be essential for their identification by MALDI-MS and ESI-MS [145, 146]. The adsorption in IMAC is based on a reversible complex between the phosphate and Ga-III under acidic conditions, which dissociates at slightly alkaline pH. Enzymatic cleavage by alkaline phosphatase, in combination with Ga-III-IMAC and MALDI-MS, provides the identification of phosphopeptides based on 80 amu mass shifts, and by analysis of metastable fragmentations (loss of HPO_3 and H_3PO_4) [147].

The selectivity of Ga-III-IMAC for phosphopeptides, combined with the specificity of mass determination by MALDI-MS, often enables the identification of phosphopeptide candidates by comparing the predicted proteolytic peptide masses with experimental mass values. However, the high mass determination accuracy of FTICR-MS or orbitrap-MS may enable the *direct* (without enrichment) characterization of phosphorylation structures, as shown in a study of the multi-phosphorylated Tau protein [48, 148]. Tau is a microtubule-associated protein involved in promoting microtubule assembly that has recently gained widespread interest as a target protein for neurofibrillary tangle formation in Alzheimer's disease [149]; the pathophysiological aggregation of tau in brain tissue has been shown to be associated to hyperphosphorylation. In the ESI-FTICR spectrum of a tryptic peptide mixture of human neurofibrillary tau, the complete primary structure including a total of 18 serine and threonine phosphorylations could be identified, illustrating the high efficiency of high-resolution MS; for the tryptic peptides 7 and 5, phosphorylation sites could be directly identified as multiphosphorylation domains (512–538) and (382–398), respectively (Figure 11.14).

11.3.3
Tertiary Structure Characterization by Chemical Modification and Mass Spectrometry

Chemical modification reactions have long been employed in structure–function studies of proteins, for example, for modifying enzymatic properties and immunological reactivity [15, 150]. Although a number of specific reactions for amino acid residues have been evaluated ([13, 15] for reviews), their full development has long been impeded by the lack of specific methods for characterizing multiple reaction products [150]. In contrast to conventional methods based on electrophoretic or chromatographic procedures, mass spectrometric peptide mapping of proteolytic digest mixtures has been found highly suitable for the rapid and sensitive identification of multiple chemical modification sites [151, 152]. A general analytical scheme has been developed for the characterization of ''native-like'' chemically modified proteins [15], which involves the determination of the extent of modification (i.e., number and distribution of modified residues) by direct mass spectrometric molecular weight determination, as a first step. Here, an additional level of information is provided by ESI-MS by the distribution of multiply charged ions (''charge structures'' [13, 31]) due to their correlation with conformation states in solution [13]. In a second step, proteolytic digestion is performed, and the sites of modifications are identified by mass spectrometric peptide mapping [129]. Moreover, assignments of relative reactivities at specific residues can be obtained from a series of partially modified proteins [128].

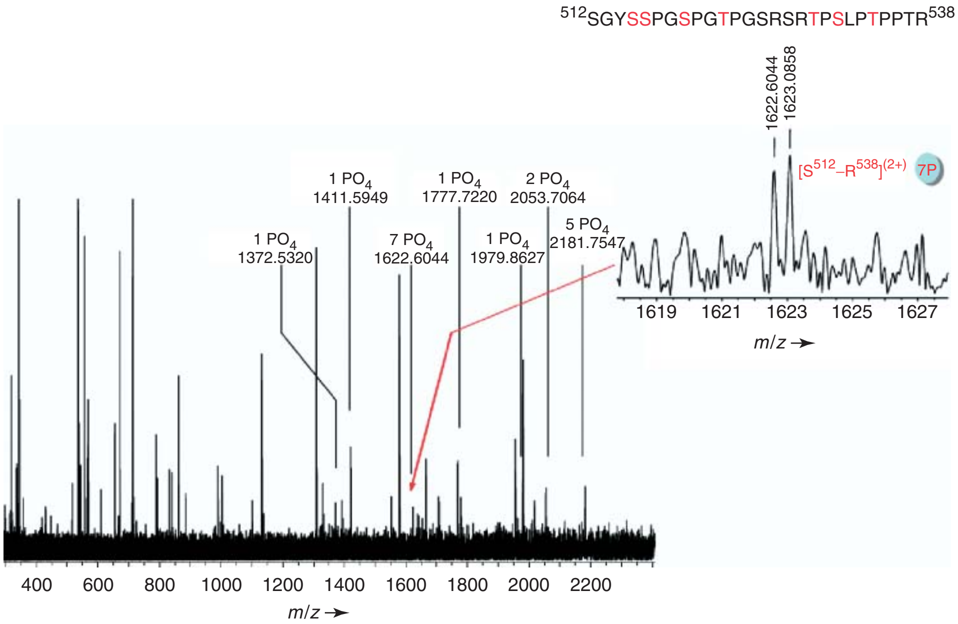

Figure 11.14 ESI-FTICR mass spectrum of tryptic digest mixture of multi- phosphorylated human neurofibrillary tau protein. Peak assignments within the m/z detection range, 200–2500, are shown for phosphorylated peptides. The insert shows the peptide fragment of the phosphorylation domain (512–538); the seven phosphorylation sites, identified using information of NiceProt View of Swiss Prot database (primary accession number P10636), are indicated in red (C_{113}, H_{191}, N_{36}, P_7, doubly protonated; calc. 1622.55513, found 1622.60435, $\Delta = 30$ ppm).

Using this approach, mass spectrometric determinations of reactive sites in intact protein structures by chemical modifications in proteins have been found highly useful in structure–function studies of proteins [15], for example, for ion-channel proteins (porins; Figure 11.15). The structures of several bacterial porins have been determined by X-ray crystallography; for example, the porin from *Rhodobacter capsulatus* (R.c.-porin) [153] forms a trimeric complex of 16- or 18-stranded β-barrels. A characteristic structure element of R.c.-porin is a central constriction loop inside the β-barrel, which has been suggested as the central site determining cation/anion permeability and transport selectivity [15]. The R.c.-porin was succinylated at conditions that provide native-like acylation of amino groups [154]. The structure of the succinylated porin was identified by X-ray crystallography at 2.4 Å resolution (*i 15*); however, the electron density maps did not permit an assignment of the succinylated groups, although ion transport experiments revealed substantial single channel conductance. The precise extent and sites of succinylations were determined by MALDI-MS, which revealed the formation of a specifically tetra-succinylated protein (Mw 31 941 Da; Figure 11.15) [154]. The identification of the succinylation sites by MALDI-MS peptide mapping showed

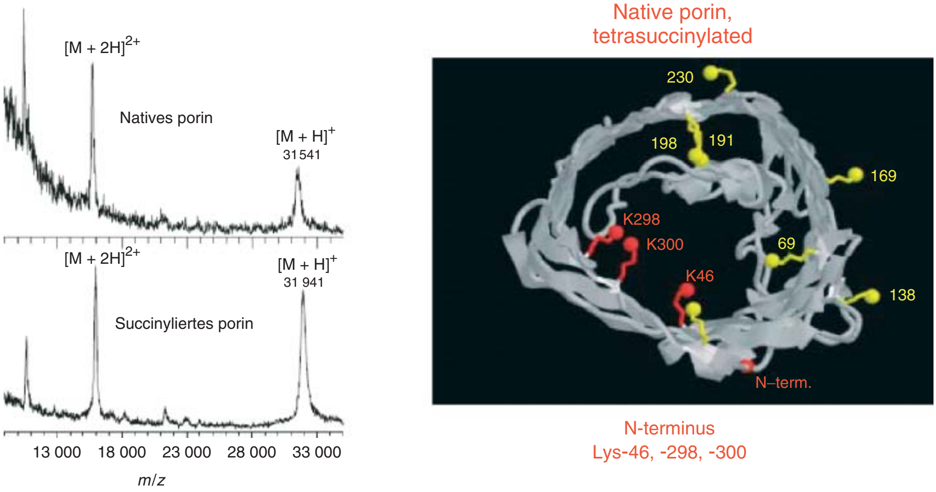

Figure 11.15 MALDI mass spectra (left) of native and tetra-succininylated Rhodobacter capsulatus porin, and x-ray structure (right) of the succinylated porin. The modified residues Lys-46, −298 and −300 and the N-termin are indicated in red; unmodified Lys residues are shown in yellow.

selective modification of three Lys-amino groups at the inner channel surface (K-46, K-298, K-300), and of Lys-46 at the channel constriction loop. This pattern was in agreement with a point charge model explaining the concomitant increase of single-channel conductance *and* cation selectivity.

11.3.4
Characterization of Noncovalent Supramolecular Complexes

Beyond the characterization of primary structures, the direct analysis of tertiary structure states and even noncovalent supramolecular complexes by MS has not been considered feasible in initial biopolymer-MS work. In a few cases, structure correlations were found, for example, specific fragmentations in FAB mass spectra of α-helical polypeptides and some MALDI and PD mass spectra of proteins, suggesting the formation of "native-like" macromolecular ions [126, 127]. This situation has changed substantially in the past few years with the analytical development of ESI-MS. A large number of ESI-MS studies have demonstrated the identification of supramolecular complexes of biopolymers, as well as specific noncovalent complexes with low-molecular-weight constituents [15–18, 31]. In contrast to other ionization methods in which predominantly *singly charged* ions are produced (FAB, MALDI), the continuous series of *multiply charged* macroions in ESI-MS reflects charge states and distributions characteristic of the solution structure (charge structure; cf. 11.2.1.3.2) [31]. Moreover, ESI-MS can be readily carried out with aqueous solutions at physiological conditions, enabling comparative studies with other structure determination methods such as NMR [155]. This feasibility of the direct mass spectrometric characterization of noncovalent complexes has clearly opened new analytical perspectives for supramolecular chemistry and biochemistry (“native mass spectrometry”) [6, 156–158].

Although the mechanism of ion formation in ESI-MS has not yet been elucidated in detail, a large variety of noncovalent interactions (e.g., ionic, hydrophobic) have been successfully characterized. Experimental parameters and criteria employed for the identification of noncovalent complexes based on chemical conditions of complex formation, and their effects on the ion formation in ESI-MS have been summarized [31]. These include the identification of the specific stoichiometry of complexes by modification of the stoichiometry of solution components and modification of the ESI-MS conditions (interface temperature; declustering potential). Further evidence is provided by competition experiments between complex components and analysis of the specificity of pH or concentration changes. An illustrative example demonstrating the close correlation between solution structures and charge structures of molecular ions are the pH-dependent ESI spectra of myoglobin [13]. The high-resolution ESI-FTICR spectrum in aqueous solution at pH 6 reveals a most abundant $[M+9H]^{9+}$ ion of the intact hem-protein complex, while under acidic conditions (pH 2) complete dissociation is observed showing the apoprotein molecular ions of high charge states (up to 20+) and the ion of the free heme group (Figure 11.16). A particularly attractive feature of high-resolution MS analysis is the complete isotopic resolution and direct characterization of charge states [48, 159].

Thus, although the quantitative characterization of equilibria of complex formation has not yet been established, the large number of already successful

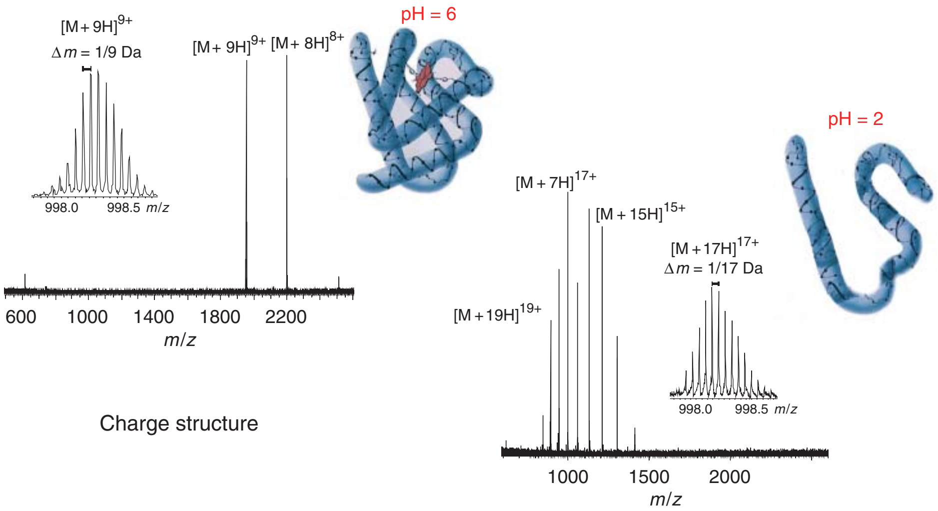

Figure 11.16 ESI-FT-ICR mass spectra of (a) the native intact hem-protein complex of horse heart myoglobin; (b) spectrum of the denatured apoprotein upon dissociation of hem in trifluoroacetic acid, pH 3. The inserts show isotopic resolutions for the 9- and 17-fold protonated molecular ions.

applications indicates broad potential for the analysis of noncovalent complexes by ESI-MS.

11.3.5
Mass Spectrometric Proteome Analysis

During the past decade, large amounts of protein sequence data have been deposited in a number of databases as a result of different genome projects [160]. Only a minor part of these sequence data has been from expressed proteins, whereas a major portion has been deduced from the corresponding gene sequences. Sequence determination of several genomes in the past few years has reached a first culmination point in the completion of the human genome in 2001 [161]. It has become clear that functions from such protein sequences are frequently only predicted and remain undefined for a substantial part of structural genes, for example, due to processes such as alternative splicing, RNA editing, and posttranslational protein modifications [160, 162]. With this consideration, *proteomics*, using the term *proteome* to define the PROTE in complement of the genOME [160], has created an explosion of interest with the use of MS as a key technology for the large-scale identification of proteins from cellular expression material [163]; the reader is referred to recent reviews in this area [162–164]).

Within the past few years, several combinations of high-performance separation techniques with mass spectrometric peptide mapping have been developed and employed for the identification of proteins from complex biological systems, such as cell lysates [164]. At present, one of the most efficient techniques is the proteolytic degradation of proteins, separated by 2D-gel electrophoresis, within the gel matrix and subsequent mass spectrometric analysis of eluted peptide fragments. Both MALDI-MS and ESI-MS have been extensively employed for these studies [164]. The unequivocal identification of proteins from sequence databases using peptide mass fingerprint data without any additional sequence information such as sequence tags and MS/MS data [164, 165] requires typically a set of 10–20 peptide masses with high mass determination accuracy (<200 ppm mass error) [166]. Furthermore, a high sequence coverage by the observed peptide molecular ions is an important criteria for the certainty of protein identification.

In recent proteome studies, the combination of 2D-gel electrophoresis with high-resolution MS has been widely employed as a powerful tool [167, 168]; the high (low parts per million) mass determination accuracy and isotopic fine structure obtained by high-resolution MS provide particular advantages for the identification of cellular proteins expressed with minor or very low abundance. Accurate masses obtained by high-resolution MS allow the use of low tolerance thresholds in database searches and greatly improve the selectivity of protein identification, compared to standard techniques, for example, using MALDI-TOF-MS [164]. The identification of a protein component, TNFα-IgG, in a serum cryoprecipitate from a patient with cryogobulinemia by MALDI-FTICR-MS is illustrated in Figure 11.17, requiring only a minimum number of peptides [144]. Cryoglobulins are cold-precipitated serum immunoglobulins associated with a number of infectious,

7, 8, 9 - Anti TNF- α antibody light chain fab fragment

Figure 11.17 2D-PAGE Separation of a cryoglobulin isolated from serum of a patient with glomerulonephritis (left) and MALDI-FT-ICR-MS of tryptic in-gel digest mixture of spot 7 (right). The MS-fit search using SwissProt data base yielded identification of anti-TNF-alpha-light chain fragment.

autoimmune, and neoplastic disorders such as hepatitis C [169, 170]; therefore, their characterization using high-performance proteomics tools has become of considerable interest. The main protein components in a serum cryoprecipitate from a patient with type II cryogobulinemia were identified by MALDI-FTICR-MS as IgG and IgM μ- and γ-heavy chains, κ- and λ-light chains, and j-chains [171].

One major shortcoming in applications of the combination of 2D-gel electrophoresis with MS is the loss of information about specific protein–protein interactions and molecular recognition processes due to the denaturing electrophoretic conditions. At present, only a few – yet promising – attempts have been made to directly analyze interactions in proteome studies [19, 164, 172]. More recently, a new approach for the identification of affinity-bound proteins by proteolytic generation and mass spectrometric analysis of its antibody-bound epitope peptides has been described [173]. The selectivity of identification of antibody-bound proteins using the combination of antigen–antibody specificity, and the redundancy of epitope peptide sequences render this ''affinity-proteomics'' approach a powerful tool for the mass spectrometric identification of proteins from complex biological material [173].

11.3.6
Application of Affinity-Mass Spectrometry to the Analysis of Biomolecular Recognition Structures

Although the application of affinity techniques in the analysis of biopolymers by MS has become an established approach over the last decade, it is re-emerging as new methodology combinations and tools for the structure identification and quantification of biopolymer interactions become available. Affinity MS techniques can be productively used for the identification of proteins and protein complexes from biological material and for the enrichment and analysis of protein structure modifications. These approaches may be viewed as examples of ''affinity MS''; they are presently emerging as valuable tools for a variety of important research areas, from identification of the epitopes involved in biomolecular interactions and quantitative determination of their interactions to utilizing them in personalized medicine.

A recent focus issue of the *Journal of the American Society for Mass Spectrometry* gives an assessment of the current state of affinity MS by presenting a number of studies that illustrate both methods and applications [174]. Applications include approaches for studying antibody–peptide epitopes and quantifying their affinities; identifying posttranslational modifications; mapping epitopes using chemical modification reactions; utilizing and improving the specificity of proteomics; and applications to problems in personalized medicine [108, 175–178]. Thus, the ''marriage'' of affinity techniques with the structure determination capability of MS has opened new applications in biochemistry, immunology, and biomedicine. These developments also show that the combination provides information that cannot be provided by other methods, and not by any single methodology.

A new approach for the analysis of protein–carbohydrate interactions is described in the following as an example for methodology and application of affinity MS. The interaction of carbohydrates with proteins is one of the most important types of biological interactions in cell differentiation, fertilization, pathogen infection, signal transduction, inflammation processes, and cancer cell metastasis. The characterization of such interactions is of crucial importance in understanding the mechanisms by which lectins, anticarbohydrate antibodies, and carbohydrate-processing enzymes exert their functions. Although X-ray and NMR are capable of revealing details of carbohydrate recognition structures and binding, their application is limited by the large amounts of high purity material needed [179]. Recently, a new molecular method for identifying carbohydrate recognition structures with high sensitivity, specificity, and low requirements in sample purity has been described, based on the combination of MS and proteolytic excision of

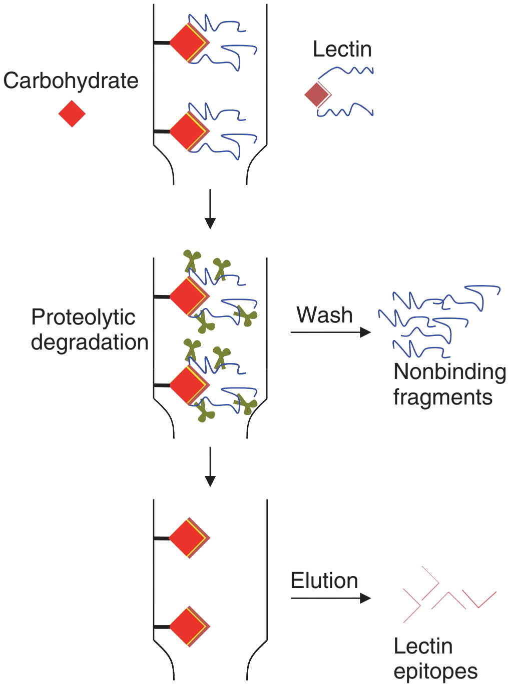

Figure 11.18 Analytical concept of proteolytic-excision mass spectrometric identification of CRD sequences. The carbohydrate binding protein (lectin, antibody, etc) is bound on a column with immobilised carbohydrate and the complex digested with proteases. The protein fragments not binding to the carbohydrate are washed from the column and analysed by mass spectrometry. The remaining bound fragments are eluted and analyzed by mass spectrometry. Competitive elution of remaining bound CRD peptides is performed with the carbohydrate, or with a substitute mixture of organic solvents (acetonitrile, acetic acid, etc.). The native conformation of the bound protein is kept by physiological conditions maintained during the binding experiment.

protein–carbohydrate complexes: carbohydrate recognition domain excision-mass spectrometry (CREDEX-MS) [180, 181]. This new method has been initially demonstrated by the carbohydrate recognition structure determination of galectin-1 and galectin-3 (Gal-3), which were selected owing to the known crystal structures of their carbohydrate complexes. The CREDEX-MS approach consists of immobilizing the carbohydrate on an affinity column, adding the binding protein and allowing formation of the complex, which is then digested with proteases, followed by washing away nonbinding protein fragments (Figure 11.18). The remaining affinity-bound epitope peptides are then isolated for mass spectrometric analysis, employing competitive elution with the carbohydrate or, alternatively, by a supplementing aqueous organic solvent mixture [180]. Galectin-1 and Gal-3 are intimately involved in tumor growth and progression, as well as in inflammatory diseases such as rheumatic arthritis. The Gal-3 complexes with lactose and *N*-acetyl lactosamine have been determined by X-ray crystallography at 2.1 Å resolution [179] (Figure 11.19), showing that the C-4 hydroxyl group of galactose is central for binding by interacting with the highly conserved Gal-3 residues His-158, Asn-160, and Arg-162, while the galactose C-6 hydroxyl group interacts with Glu-184 and Asn-174, and the planar C-3 to C-6 carbon atoms of galactose are in van der Waals contact with the side chain of Trp-181 [179].

Human Gal-3 was bound to lactosyl-Sepharose (prepared by covalent binding of lactose to epoxy-activated Sepharose 6B) and digested using trypsin. When the last washing fraction did not show any ion signals, elution was performed with 0.3 M lactose. MALDI-MS of the elution fractions identified two Gal-3 peptides, (152–162) and (177–183) (Figure 11.19b); in contrast, MALDI-MS of a control digestion mixture showed all expected peptides. When galectin 3 was digested in solution and the digest mixture added to the lactosyl-Sepharose column, identical peptides, (152–162) and (177–183) were identified in the elution fraction, providing evidence for these sequences as the lactose-binding site. The peptide (152–162) contains H-158, N-160, R-162, all of which are essential residues for the carbohydrate binding in the crystal structure. The peptide (177–183) comprises a single residue, W-181 interacting with the carbohydrate. These results were in complete accordance with the X-ray crystallographic data (Fig. 11.19a, c).

The same approach was applied to identify the Gal-3 CRD peptides for blood group A-trisaccharide (Tri-A). Peptides remaining affinity-bound upon trypsin digestion were isolated by competitive elution using a high lactose concentration, as supplement to the more expensive Tri-A. MALDI-MS of the elution fraction identified two specific peptides, (152–162) and (130–144). Despite the lack of X-ray crystal structure data for the orientation of the trisaccharide, the presence of the Gal-3 (130–144) peptide is well explained by the binding of *N*-acetylgalactosamine or fucose ring in an extended binding site comprising the Arg-144 residue. The specificity of all CRD peptides was ascertained by functional binding assays of two carcinoma cell lines, showing specific inhibition of intact Gal-3 [180].

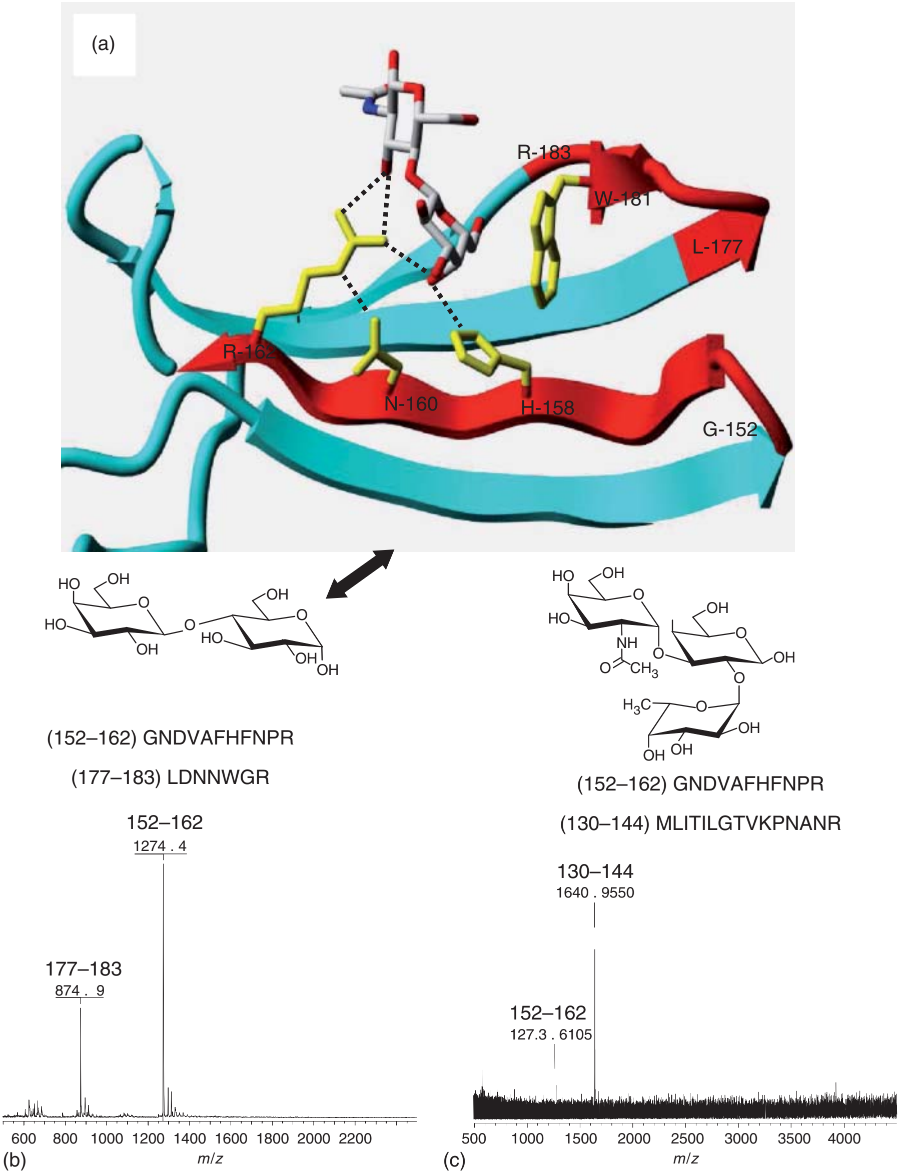

Figure 11.19 Topology of galectin-3 CRD peptides identified by CREDEX-MS (152–162) and (177–183) (in red) in the crystal structure of galectin-3. Representation of the crystal structure is described by PDB file 1A3K (Brookhaven Laboratory). Amino acid side chains involved in direct interaction with the carbohydrate are shown in yellow (H158, N160, R162, W181). The structures of lactose and Tri-A are given in the lower part of the Figure. (B), MALDI-FTICR-MS of the elution fraction for the galectin-3/lactose complex reveals two CRD peptides (152–162) and (177–183) with the sequences given. (C), MALDI-FTICR-MS of the elution fraction for the galectin-3/blood group Tri-A complex reveals two CRD peptides (152–162) and (130–144).

11.3.7

Identification of Oligomerization – Aggregation Structures and Pathways of Neurodegenerative Proteins by Ion Mobility Mass Spectrometry

A large variety of cellular processes are based on the formation and dynamics of multi- and supramolecular protein assemblies, and several diseases, previously thought to be unrelated, such as cancer and neurodegenerative diseases, are characterized by "misfolded" protein aggregates. Several neurodegenerative diseases are associated with the formation and accumulation of different types of "misfolding-aggregation" products [182–184]. The formation of neurotoxic oligomers is generally thought to precede aggregation, as shown for Aβ polypeptide, Tau protein, and the key protein in Parkinson's disease (PD), α-Synuclein (αSyn) [185]. Chemical structures and reaction pathways of pathophysiological aggregates are only poorly characterized and understood at present. "Soft-ionization" MS, such as HPLC-ESI-MS, is frequently unsuitable for the direct analysis of reaction pathways involved in aggregation, particularly because of the low concentrations of intermediates. IM-MS has been recently emerging as a new, powerful tool for the analysis of protein oligomerization–aggregation reactions, owing to the concentration-independent gas phase separation capability of IM-MS.

Direct, *in situ* applications of IM-MS are illustrated in the following for the *in vitro* oligomerization of αSyn, a key protein of Parkinson's disease (PD) [113, 186]. αSyn, a 140-aa protein occurring in the presynaptic terminals of neurons, is strongly correlated with PD. αSyn is natively unfolded but adopts an α-helical structure when it binds to lipid vesicles, and forms a β-sheet that facilitates the formation of aggregated morphologies [186]. Intracellular accumulation of αSyn aggregates has been recognized at conditions inducing PD. Although oligomeric intermediates may represent major neurotoxic species [185], chemical structures of αSyn oligomers and possible intermediates have not been previously identified. The slow rates of formation and low concentrations of aggregating intermediates may be major reasons for the failure of conventional MS methods to detect and identify oligomers. IM-MS studies of the time-dependent *in vitro* oligomerization–aggregation of αSyn provided the first identification of specific autoproteolytic fragments, which were previously observed by gel electrophoresis but not identified [113], particularly a highly reactive C-terminal fragment, αSyn(72–140), formed by cleavage within the central aggregation-prone domain of the protein (Figure 11.20). The αSyn(72–140) polypeptide, synthesized both by chemical solid-phase peptide synthesis (SPPS) and by recombinant expression, showed rapid formation of oligomers and substantially faster aggregation and increased neurotoxicity, compared to the intact protein. Most recently, further IM-MS studies of drift time profiles ascertained the formation of conformationally different forms of αSyn upon incubation *in vitro* [186]. Moreover, first studies of αSyn *in vivo* by online affinity MS using an αSyn-antibody with C-terminal epitope specificity enabled the direct structure identification of αSyn polypeptides from mouse brain material [187]. These results suggest IM-MS as a powerful tool for the molecular elucidation of structures involved in oligomerization–aggregation of neurodegenerative proteins, providing a

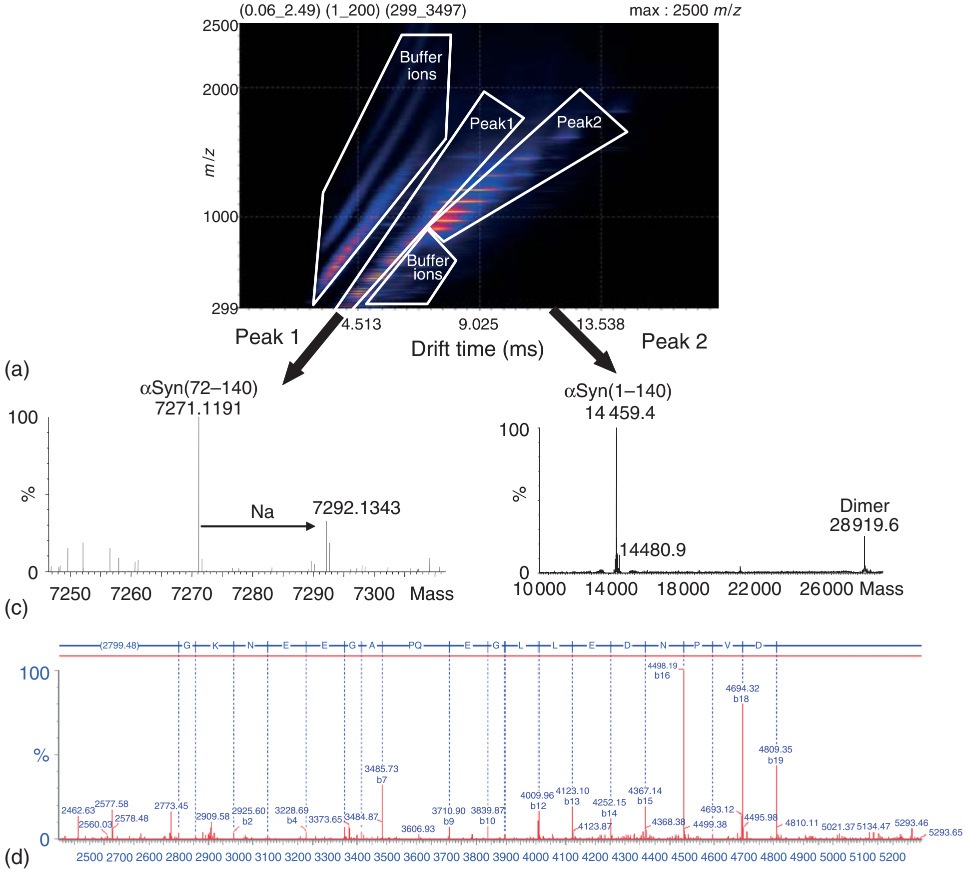

Figure 11.20 Identification of autoproteolytic truncation products of αSyn by ion-mobility mass spectrometry: (a), HDMS analysis (driftscope data view) of oligomerization-aggregation products of αSyn incubated in PBS for 7 d at 37 °C. Signals corresponding to monomers, dimers and truncated peptide sequences are observed. Each pixel represents one ion with color representing intensity from low (blue) to high (yellow); (b), Extracted deconvoluted spectrum of peak 1 is the truncated peptide sequence αSyn(72–140); (c), Extracted deconvoluted spectrum of peak 2 showing monomer plus dimer of αSyn; (d) MS/MS fragmentation of 1455.6 (+5) m/z precursor ion using elevated collision energy in the transfer region provides identification of the proteolytic product, αSyn(72–140).

basis for the detailed study of reaction pathways and intermediates, and the design of peptides capable of inhibiting or modifying aggregation.

Multiparametric Analysis of Mass Spectrometry-Based Proteome Profiling in Gestation-Related Diseases

Michael O. Glocker, Claudia Röwer, Manja Wölter, Cornelia Koy, Toralf Reimer, and Ulrich Pecks

12.1

Introduction on Gestational Diseases

Physiological pregnancy leads to distinct alterations in maternal organ functionalities. The cardiovascular, hematologic, metabolic, renal, and respiratory systems, all are affected in order to assist fetal survival as well as in preparation for labor [1]. Failures in any of the involved systems to respond adequately to pregnancy-associated physiological changes consequently result in pregnancy-related disorders, such as gestational diabetes or pregnancy-induced hypertension, and ultimately lead to poor maternal and/or fetal outcome. Moreover, women suffering from gestation-related disorders are at an increased risk of developing diabetes mellitus or cardiovascular diseases later in their lives. As such, pregnancy itself might be regarded as a ‘‘stress test’’ for maternal metabolic and vascular functions [2, 3].

In this chapter, we focus on mass spectrometric profiling of severe forms of hypertension that complicate pregnancy. Clinically manifested gestation-related diseases, such as preeclampsia (PE) and associated conditions, such as HELLP syndrome (hemolysis, elevated liver enzymes, and low platelets), as well as intrauterine growth restriction (IUGR), are of major concern, as it is of utmost importance to learn about their molecular pathogenesis processes. Such knowledge may hopefully lead to novel therapy and clinical care options.

12.1.1

Preeclampsia

Preeclampsia is defined as new onset of hypertension $\geq$140/90 mm Hg and proteinuria of more than 300 mg day^{-1} that, according to definition, manifests after the twentieth week of gestation. From a more clinical point of view PE is also defined as a combination of new onset hypertension and further complications that affect at least one more organ system. Hence, PE may be diagnosed even in the absence of proteinuria. Regardless of its definition, PE is recognized as a multisystemic disorder that may lead to renal insufficiency, liver disease (potentially leading to HELLP),

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

hematological disturbances, placental insufficiency (likely causing IUGR), and/or neurological problems including convulsions (which is then called *eclampsia*) [4].

Despite more than 100 years of excessive research, the pathogenesis of PE still remains unclear. Two main reasons might be responsible for this phenomenon. First, PE is a specific disease in humans and does not exist in animal mammals. Therefore, no adequate animal model can be developed with which one might be able to study the disease in a laboratory setting. Second, it is likely that the disease initiates early in pregnancy, weeks to months before the onset of symptoms. For obvious practical and ethical reasons, most of the biological samples obtained for studying the disease are taken earliest at appearance of disease symptoms or even later, for example, at delivery–very likely a long time after the condition had been initiated. Hence, early events of cellular or molecular changes that lead to the disease are not accessible.

However, it is generally accepted that rather than the fetus' or the mother's physiology, the placenta triggers the disease. This is evidenced by several known associations. (i) PE is a pregnancy-specific disease. No similar pathology exists outside of pregnancy. (ii) The risk increases with placental size. For example, women with twin pregnancies have a fourfold increased risk for developing PE. (iii) PE occurs even without a fetus, that is, in hydatidiform moles. (iv) The symptoms disappear after removal of the placenta (delivery) [5].

Current hypothesis states a two-stage pathophysiological model. The first stage is characterized by a disturbed placentation, whereas an overactive inflammatory maternal response reflects the second stage [6]. In normal early human pregnancy, roughly by week 5, specific placental cells, the cytotrophoblasts, invade the maternal endometrium. Cytotrophoblasts enter uterine spiral arteries and permanently dilate the vessels' walls in order to guarantee sufficient materno-placental blood flow. Insufficient trophoblast invasion and, as a consequence, impaired spiral artery remodeling have been suggested to play a central part in the pathogenesis of PE [7]. These pathophysiological incidences result in placental ischemia-reperfusion and hypoxia followed by an increased formation of reactive oxygen species and inflammatory factors [8]. In consequence, placental particles are extruded and released into the maternal circulation [9, 10], and, depending on maternal susceptibility, this leads to a systemic inflammatory response and endothelial activation [11]. Hypertension in PE is primarily due to marked vasoconstriction. Both, vasoconstriction and the development of glomerular lesions in the kidney, cause a decrement of renal plasma flow and glomerular filtration rate, leading to the second essential symptom of PE: proteinuria [12].

However, it is likely that PE is a heterogeneous disorder. The terms *placental* and *maternal* PE have been introduced to describe the two pathophysiological stages that seem to be most affected [13]. Placental PE comprises about 20% of all PE cases worldwide and usually occurs before the thirty-fourth week of gestation (early onset). It is usually a more severe form and pregnancy has to be terminated preterm in order to assure maternal and/or fetal survival. Most patients, however, suffer from the so-called ''late-onset'' form that typically affects patients after the thirty-fourth week of gestation. This form is often present in patients with predisposing factors, such as a history of renal or cardiac diseases, diabetes, and/or obesity. Moreover, it has been suggested to differentiate PE that has been further complicated by IUGR or by the HELLP syndrome from those that are not additionally affected [7, 14, 15]. Thus, PE can be subclassified according to clinical and molecular biological and/or laboratory chemical findings. It is likely that the development of PE involves several different pathophysiological mechanisms, as evidenced by the diversity of proteins that have been studied to date.

Several biomarkers have been considered for early detection of PE. Among them, serum concentrations of pro- and antiangiogenic factors, such as placental growth factor (PlGF), soluble vascular endothelial growth factor receptor-1 (sVEGFR-1 or sFlt-1), and soluble endoglin were found to be altered in maternal blood, even weeks before the onset of symptoms [16–18]. Moreover, extracorporal removal of sFlt-1 seems to be a promising approach to treat severe PE in order to prolong pregnancy and therefore improve outcome [19]. Other molecules that have been studied include activin A, inhibin A, pentraxin 3 (PTX3), pregnancy-associated plasma protein-A (PAPP-A), and placental protein 13 (PP13) [20–25]. However, neither a prediction model nor a prevention strategy exists by now that is sufficiently reliable for the prediciton of all forms of preeclampsia.

12.1.2
HELLP Syndrome

In 1954, Pritchard *et al.* [26] described three cases of PE/eclampsia, associated with intravascular hemolysis, thrombocytopenia, clotting defects, and evidence of hepatic dysfunction; two of their patients died. Several reports on case series followed until the acronym ''HELLP syndrome'' was introduced for the hematological changes seen in this disorder in 1982. HELLP stands for hemolysis, elevated liver enzymes, and low platelets [27]. The incidence of the HELLP syndrome is $<1\%$ of all pregnancies. Although a rare condition, it is a leading cause of maternal mortality in the western world. About 80% of women presenting with HELLP syndrome have pregnancy-related hypertension and/or proteinuria [28]. Hence, the HELLP syndrome was also regarded as a severe variant of PE. Whether the HELLP syndrome may represent a unique disease entity is still under debate. The pathophysiology is unknown. Hemolysis in HELLP syndrome presents as microangiopathic hemolytic anemia that is confirmed by schistocytes, burr cells, or by low serum haptoglobin concentration. Hepatic histopathology presents as focal parenchymal necrosis and periportal hemorrhage [29]. Inflammatory processes lead to swelling of the liver with distension of the Glisson's capsule. In consequence, epigastric or right upper abdominal pain can frequently be observed in the HELLP syndrome. A decrease in circulating platelets is secondary to an increased rate of platelet aggregation and consumption by the disturbed vascular endothelium. Common complications of the HELLP syndrome are placental abruption, disseminated intravascular coagulation (DIC), and acute renal failure. Less frequently, eclampsia, pulmonary edema, and subcapsular liver hematoma can be observed in association with HELLP [28]. The presenting symptoms and clinical and laboratory findings in women with HELLP syndrome overlap with a variety of other medical conditions. Hence, the HELLP syndrome might sometimes be misdiagnosed as ‘‘acute fatty liver,’’ ‘‘thrombotic thrombocytopenic purpura,’’ ‘‘hemolytic uremic syndrome,’’ or other hepatic diseases and vice versa [30]. Clinical management strategies between these conditions differ substantially, and hence, misdiagnosis leads to a delayed accurate treatment. As is the case for pure PE, delivery is the only definitive cure for HELLP to date. Even more, once a HELLP syndrome is diagnosed expedient delivery is often needed owing to its rapid progression. However, about 30% of HELLP syndromes occur in the post partum period, that is, after delivery. Hitherto, neither reliable preclinical recognition nor effective prevention strategies for the HELLP syndrome are available. As the course of HELLP is incalculable, rapidly determinable, reliable diagnostic markers, or marker profiles, are urgently needed.

12.1.3

Intrauterine Growth Restriction (IUGR)

IUGR affects about 3–8% of pregnancies. It is defined as a condition in that the fetus does not reach its genetically given growth potential, resulting in low birth weight. IUGR is an important cause of perinatal morbidity and mortality, thus contributing substantially to medically indicated preterm birth in order to prevent fetal death [15, 31].

Neonates with birth weight below the 10th (5th, 3rd) percentile are considered to be ‘‘small for gestational age’’ (SGA) [32]. Unfortunately, both terms, *SGA* and *IUGR*, are often used synonymously in the literature, which sometimes leads to confusion. It should be noted that the term *SGA* simply is a description for an underweight newborn baby. SGA, hence, neither refers to fetal growth nor does it take into account the underlying conditions that lead to the low birth weight. It needs to be stated firmly that a child that is born SGA has not necessarily suffered from IUGR [32]. Instead, considerable numbers of SGA infants are small at the time of birth simply because of factors determined by maternal ethnicity, parity, weight, or height. Therefore, some authors have used the term *constitutional small* to underline the physiologic condition in a subset of SGA children [33, 34].

By contrast, IUGR is diagnosed by a deceleration of fetal growth velocity in serial antenatal sonographic measurements of fetal biometry (crossing percentiles). Fetal growth is viewed as having three consecutive dynamic cell growth phases [35, 36]. Until week 16 of pregnancy, the early phase, fetal growth is primarily due to rapid cell division and an increase in cell numbers (hyperplasia). Between 16 and 32 weeks of gestation, concomitant increase of both, cell size and cell number, can be observed. The last phase, after 32 weeks, is mainly determined by cellular hypertrophy (increasing cell size) in which most fetal fat and glycogen deposits are built up. The clinical pattern of IUGR varies depending on the nature of the causative factors, stage of gestation, and duration of the intrauterine insult [37]. An IUGR-influencing factor that occurs within the first 16 weeks of gestation is more likely to lead to an overall diminished cell division, and the resulting growth-restricted fetus appears symmetric with proportional head to abdominal circumferences. Approximately 30% of growth-restricted infants exhibit a symmetric phenotype, and a variety of underlying causes have been described, including chromosomal anomalies, fetal infections, and multifactorial congenital malformations, or maternal diseases. On the contrary, asymmetric growth restriction occurs in 70% of IUGR cases and refers to a greater decrease in the size of the abdomen than that of the head, called *head-sparing phenomenon*. Asymmetric fetuses are therefore more likely to arise in the middle or last phase of fetal growth and it has been proposed that this phenomenon occurs secondary to placental insufficiency. In other words, the increasing fetal nutritional and oxygen demand with ongoing pregnancy exceeds placental nutritional capacity more and more. The diminished nutritional supply causes the fetus to redistribute its cardiac output in favor of vital organs. This phenomenon is reflected by changes in fetal blood flow resistance indices, which are measurable by fetal Doppler sonography. In clinical practice, IUGR is defined as low estimated fetal weight in addition to signs of compromised fetal well-being (pathological fetal cardiogram or resistance indices in Doppler sonographic measurements, asymmetry, and/or reduced amniotic fluid index in ultrasonographic examinations [31]).

The leading cause of placental insufficiency in the pathogenesis of asymmetric IUGR still remains unclear. Diminished cytotrophoblast invasion and uterine spiral artery remodeling has been hypothesized to play a crucial role. Hence, the pathomechanisms in IUGR are similar to those in PE, which might explain why both conditions occur simultaneously in 5–18% of the cases [6, 7].

Over the last decades it has become evident that abnormal intrauterine conditions also increase the infant's risk for cardiovascular and metabolic diseases later in life. The association of being born SGA and of developing atherosclerotic cardiovascular diseases later in life has been shown by several epidemiologic studies [38–40]. Such observations have led to the ''fetal origins of disease hypothesis'' or ''Barker's hypothesis'' in that abnormal conditions in the intrauterine environment may cause long-lasting structural and functional systemic alterations, predisposing an individual to the development of associated disorders. The mechanisms of ''fetal programming'' till now are unclear, but once noticeable disturbances in fetal blood composition toward an atherogenic phenotype in IUGR fetuses are found, biomarker and/or molecular-profile-guided research avenues are opened [41].

12.2
Mass Spectrometric Data Acquisition from Plasma Samples

Analyzing complex gestation-related pathophysiological conditions, such as PE, HELLP syndrome, and IUGR, requires methods that can cope with the complexity of the samples. One of the approaches to study such polygenic diseases that generated considerable interest due to its clinical potential is mass spectrometry (MS)-based proteomic pattern diagnostics. Protein MS with soft-ionizing properties, particularly matrix-assisted laser desorption/ionization-time of flight mass spectrometry (MALDI-TOF MS), proved in our studies to be the best choice for the required data sampling prerequisites. Owing to unsurpassed properties, such as low detection limits, multiplexing capability, rapidity, and facile sample preparation, and because of unbiased protein detection likelihood, which is independent from protein composition and structure, MALDI-MS combines many necessary features for blood profiling. MALDI-MS is an automated technique that can detect hundreds of peptide and/or protein ion signals from clinically obtained body fluids in one measurement with good reproducibility and robustness.

Simultaneously, in order to reduce the complexity of biological samples that typically contain numerous constituents, and particularly for detecting quantitative differences, mostly fractionation steps are applied before the above-mentioned MS-based screening analyses, in an attempt to facilitate detection of suitable markers but not to introduce unknown variables that may change the composition of the investigated samples in an unpredictable manner.

Here, we describe the steps of sample preparation, multiplexed data collection, and advanced multiparametric bioinformational data analysis, emphasizing on implementation and, equally important, the purpose for which a particular method is applied. The aim of our studies is to provide an easy to use reliable assay procedure that includes automated data analysis.

12.2.1

Mass Spectrometric Data Collection Without Sample Fractionation

MS-based screening approaches for describing peptide profiles in combination with fractionation of the proteins/peptides, such as peptidomics [42], surface-enhanced laser desorption/ionization (SELDI) [43], or the use of functionalized bead surfaces [44] have been reported. They have the advantage in common that no previous knowledge about the molecule of interest is needed for performing the assay. This stands in contrast to immunoassay-based techniques, such as ELISA (enzyme-linked immunosorbent assay), where the antigen needs to be known prior to carrying out the analysis.

We have developed a protein profiling method without fractionation [45] that relies on the use of a cryodetector mass spectrometer with principally unlimited mass range and ultra high detection sensitivity throughout the entire mass range [46]. This approach was successfully applied to the analysis of plasma samples from HELLP patients and from controls. The mass spectrometric profiling analysis included high molecular mass proteins that also displayed characteristic differences in the protein abundance profiles in plasma samples from HELLP patients and from healthy women prior to and after delivery.

The mass spectra that were obtained from all plasma samples using the cryodetector mass spectrometer were found to show only minor differences in the overall appearance in our case up to a mass range of m/z 200 000 (Figure 12.1). Mass accuracy of the cryodetector mass spectrometer is 100 ppm at 12.6 kDa and 1000 ppm at 1.5 MDa. In addition to ion signals with high abundance, the spectra showed numerous ion signals of lesser intensity due to the complexity of the protein mixture in plasma.

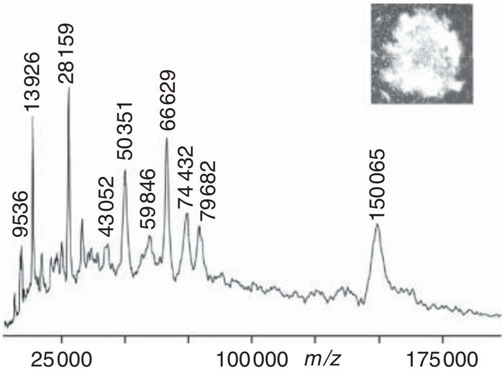

Figure 12.1 MALDI linear TOF cryodetector mass spectrum from plasma proteins of a HELLP patient after delivery; *m/z* range 5000–200 000. Ten selected ion signals are labeled. Ferulic acid was used as matrix. The inset shows a homogeneous sample/matrix distribution on the mass spectrometry target.

Reproducibility of experimental data was sufficient in the investigated cases. Differences in ion signal abundances between measurements of one and the same sample were by far smaller (typically by a factor of 10) than those resulting from the biological differences between samples. Some of the most intense ion signals were tentatively assigned to likely protein candidates, assuming that the corresponding protein ion signals represent the more abundant proteins in plasma [47, 48]. The 66.6 kDa ion signal, for example, is assigned to serum albumin.

The most striking difference in the spectra between most of the HELLP cases and those from the same persons after delivery (post-HELLP) was the presence or absence, respectively, of the so-called 11.8 kDa ion signal (absent in Figure 12.1). On the basis of results from previous studies with plasma samples [49, 50] and in accordance with UniProt data, this ion signal was assigned as serum amyloid A (SAA), although SAA is not an abundant plasma protein.

As indicated, monitoring of this one factor alone seemed not enough to come to a clinically relevant conclusion in all HELLP cases. Instead, statistical analysis of peak intensities of 10 selected ion signals clearly demonstrated that HELLP spectra were distinguishable from those of the post-HELLP samples. The mass spectrometric profiles were in fact different enough in their appearances to enable differentiation between the groups by statistical comparison of the peak intensities. Multifactorial analysis of these ion signal intensities proved reliable in all studied cases. At the same time, we noticed high homogeneity of the spectra within the groups and concluded that the observed intragroup differences were mirroring interindividual variations.

Our results showed that significant differences in ion intensities between post-HELLP (control) control samples and HELLP patients could be recorded without sample fractionation using the cryodetector MS equipment. The method described here is fast, very robust, and suitable to cope with large sample numbers. The assay is easily adaptable to current clinical sample collection procedures and shows high reliability when standard operating procedures are adopted, and, in principle, the method is easily adaptable to procedures that encompass pre-fractionation steps.

12.2.2
Mass Spectrometric Data Collection upon Sample Fractionation

In our next study we applied MALDI-TOF MS-based serum protein analysis as a means to detect PE patients by analyzing samples from pregnant women. We investigated the possibility of the method to reliably differentiate patient samples from those of control individuals, a prerequisite for potential clinical use. Again, from all individuals blood samples were taken and serum proteins were isolated with standardized procedures. However, in this study fractionation of serum proteins was conducted by applying a commercially available reversed-phase coated bead system (ClinProt® Profiling Kit MB-HIC 8).

This procedure proved to be well applicable for fractionation of serum proteins yielding samples suitable for MALDI-MS profiling without further work-up. An overview mass spectrum, using a commercially available time-of-flight (TOF) mass spectrometer equipped with a multichannel plate detector, showed abundant and well resolved protein ion signals between *m/z* 4500 and *m/z* 25 000 (Figure 12.2).

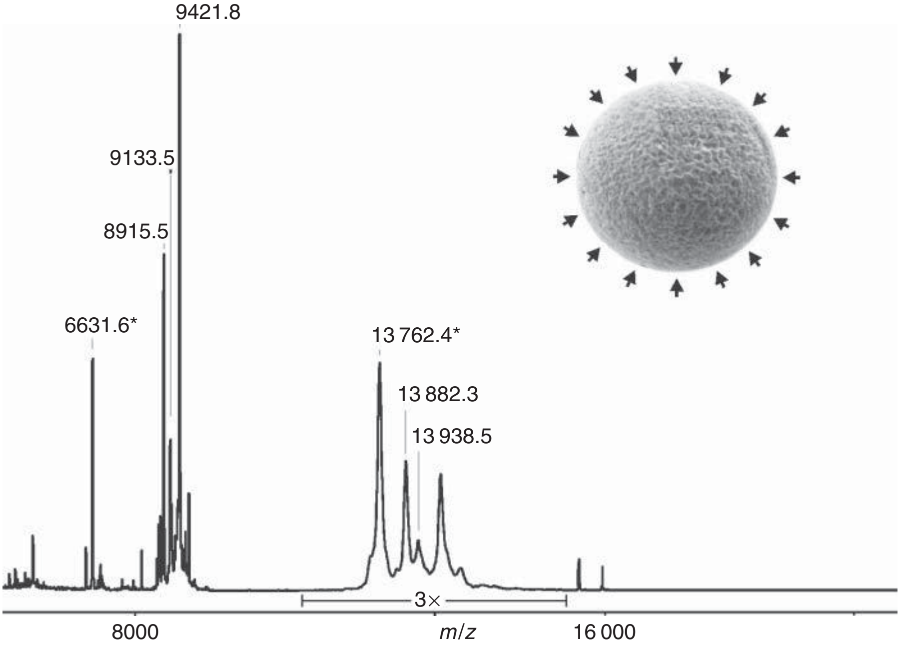

Figure 12.2 MALDI linear TOF mass spectrum of a serum sample after ClinProt® work-up from a preeclampsia patient; *m/z* range 4500–25 000. Selected ion signals are labeled. Signals marked with asterisks were used for calibration. Ferulic acid was used as matrix. The inset shows a magnified bead image to which plasma proteins bind selectively according to their physicochemical properties (indicated by arrows).

In order to better distinguish between the two groups under study and to more accurately assign a given spectrum to either the PE or the control group, a multiparametric analysis was performed in which the normalized ion signal areas within each spectrum were brought into context with each other [14].

In contrast to using the full mass spectrum as sample profile, we searched for a handful of distinctive signature signals by which a sample could be characterized. It turned out that the three most intense singly charged ion signals and the three best group-differentiating singly charged ion signals carried enough information to form rules that enabled accurate sorting of individual spectra, that is, of individual samples, when considering the relations of ion signal intensities in one spectrum (details are given in 12.3).

As a result, we obtained a group of protein ion signals that can be regarded as a "signature for PE" with the most prominent group of ion signals around m/z 13 715. Sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS PAGE) analysis and peptide mass fingerprinting suggested that these ion signals belonged to a protein called *transthyretin*. Consistent with this, nephelometric analyses showed lower transthyretin concentrations in samples from PE patients with respect to the control group. It should be noted that the transthyretin concentrations of all samples were below the reference value for serum, which is expected to be the case during pregnancy due to plasma volume expansion [51].

To the best of our knowledge, this is the first report of a decrease in transthyretin concentration in serum of the "subgroup of severe early-onset PE" before 34 gestational weeks with respect to transthyretin levels of individuals with uneventful pregnancies. In our experiments, it again turned out that just one marker protein ion signal was not sufficient to differentiate an individual PE sample from a control sample. By contrast, the so-called "multifactorial signatures" are believed to be more adequate for distinguishing two polygenic phenotypes [52–56].

12.3
Multiparametric Analysis of Mass Spectrometry Data

12.3.1
Recalibration and Standardization Strategies

Owing to their quite satisfactory performance, ClinProt® beads were applied to prefractionate serum samples also in other proteome profiling studies by us, as they enabled rapid work-up and yielded in high spectral quality (see preceding paragraph). Subsequent to mass spectrometric data collection, accurate ion signal assignments, that is, determination of correct m/z values for a given ion signal, had to be achieved in order to enable comparison of multiple spectra. The ClinProTools® 2.2 software (Bruker Daltonik, Bremen, Germany) was used to analyze the spectra from patients and controls. Settings had been specified and retained unchanged for all measurement analyses for (i) peak picking, which happened on the total average spectrum of the particular class, (ii) for signal to noise threshold (baseline), the value of which was set to 5.00, and (iii) the relative threshold base peak, the value of which was set to 0.00 (details on baseline effects are given in the next paragraph).

Particularly in order to enabling interassay comparisons with samples from different clinical centers, all mass spectra needed to be internally recalibrated using average masses of defined ion signals. As a calibration example, the ion signal for singly charged and unmodified transthyretin (UniProt accession number P02766) was set to m/z 13 762.4, and the ion signal for the singly charged and unmodified apolipoprotein C-I (UniProt accession number P02654) was set to m/z 6631.6. Transferring these settings to all spectra enabled to correct for calibration errors that needed to be eliminated prior to assigning matching ion signals in each spectrum (Figure 12.3). Precise assignment of ion signals was particularly

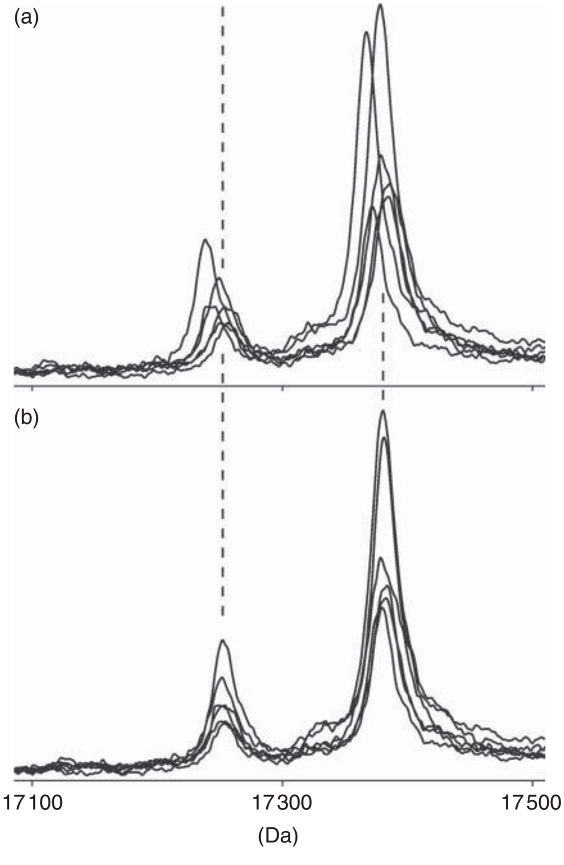

Figure 12.3 MALDI linear TOF mass spectrum of serum samples after ClinProt® work-up from cord blood samples; m/z range 17 100–17 500. (a) Ion signals are overlayed from six sample measurements prior to recalibration. (b) Overlay of the same ion signals after recalibration. The hatched vertical lines show the value of the determined m/z values 17 253.3 and 17 381.5, respectively.

important in regions with multiple ion signals in close proximity in order to exclude false assignments which otherwise would lead to poor overall assay results.

Spectra were recalibrated such that only those masses were taken into account which occurred in at least 30% of the spectra. The maximal mass tolerance between reference mass and peak mass was set to 1500 ppm. Hence, those spectra were excluded from analysis which either could not be recalibrated owing to larger mass differences or which contained too few ion signals for calibration. Smoothing of spectra was performed by applying the Savitsky–Golay algorithm, width 2.0 *m/z* for three cycles.

With successful assignment of correct *m/z* values to each ion signal in the spectrum, the decision of whether a given signal was regarded as belonging to the set of "signature ion signals" was enabled, fulfilling the first prerequisite of the clinically important assessment of whether a selected sample could be grouped into the patients cohort.

12.3.2
Statistical Procedures for Baseline Subtraction and Correction for Intercenter Offsets

Clearly, the next crucial issue to be addressed when analyzing ion signal intensities is the kind of baseline present around the ion signals, as the baseline shape is crucial for determining the area under the peak. As exemplified here, a linear baseline model (Figure 12.4) leads to different peak area values in comparison to a curved baseline approximation. The linear baseline approximation is generating correct peak area results when a flat baseline is present anywhere in the spectrum. By contrast, the curved baseline approximation regards the vicinity of the ion signals, and hence corrects for local baseline anomalies.

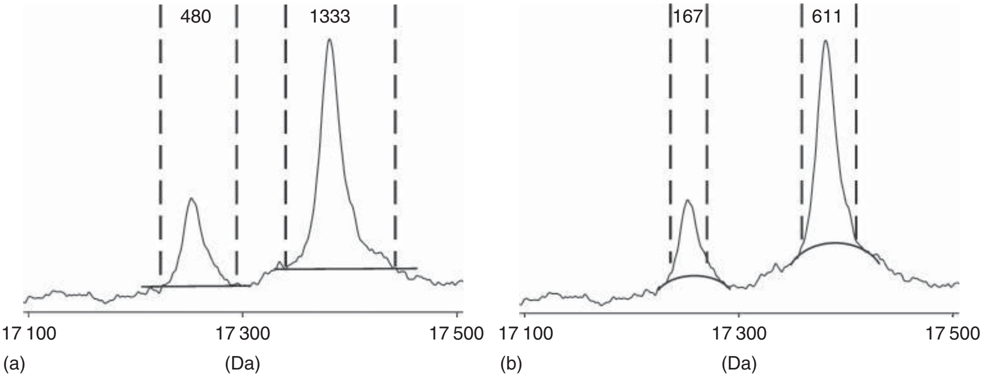

Figure 12.4 MALDI linear TOF mass spectrum of serum samples after ClinProt® work-up from cord blood samples; *m/z* range 17 100–17 500. (a) Areas under the curves of ion signals are determined assuming flat baselines. (b) Areas under the curves of ion signals determined with curved baseline approximation. Approximated baselines are shown as solid lines. The hatched vertical lines show the left and right margins of the ion signals that were set for integration. Calculated peak areas are given in arbitrary units.

In our experiments, baseline subtraction was performed in the ‘‘Top Hat Baseline mode’’ of the software. Further, all ion intensities in the spectra, measured as the integrated area of respective ion signals, were normalized to their own total ion count (TIC), which was determined as the sum of all intensities of all ion signals in the spectrum. Subsequently, single intensities of ion signals in this spectrum were divided by the summed-up TIC value obtained.

Even with precise matching of m/z values of ion signals and appropriate baseline subtraction in each spectrum, additional intercenter offsets in ion signal areas needed to be corrected when multicenter studies were performed. This was achieved using a standardization procedure for calculating the so-called z-scores for each peak area with Eq. (12.1), in which x describes an individual ion signal area, μ is the mean of the ion signal areas from all patients for the corresponding center, and σ is the standard deviation of μ.

$$z = \frac{x - \mu}{\sigma} \tag{12.1}$$

In our cases ‘‘+10’’ was added to all z-score values in order to avoid negative numbers for z [57]. This procedure cures unavoidable sample handling differences that come along when multicenter studies are performed. Multicenter studies are common in clinical research as they increase the available numbers of patient samples per cohort. Obviously, the analysis method of choice needs to be robust with respect to intercenter deviations that otherwise would add to the interindividual variability of sample values.

12.3.3
Determination of Cut-Off Values for Ion Signal Areas

As mentioned above, ion signals that were determined as being suitable for characterizing a spectrum, that is, sample, as either belonging to the group of patients or to the group of control individuals, were selected by statistical evaluation. Statistical significance was tested with a Wilcoxon rank-sum test [58] combined with a Kruskal–Wallis test [59], an Anderson–Darling test [60], and an ANOVA (analysis of variance) test combined with a Student’s t-test for two populations [61, 62]. All tests were performed on significance levels of 0.05. Using this approach, we generally obtained two kinds of ion signals when comparing spectra from both groups. The first category of ion signals encompassed those that displayed invariable areas regardless of their group origin. The second set of ion signals contained those that displayed on average quite distinct area values, and hence were considered suitable for differentiation of the groups. In our understanding, both kinds of ion signals carried valuable information about their sample. In order to make use of all available information, we calculated several quotients of the standardized and normalized areas of selected ion signals in pairs (Figure 12.5).

Graphical representations of the obtained values of the quotients were depicted as box-and-whisker plots [63], for example, using the Origin software (Version 6.1G, OriginLab Corporation, Northampton, MA, USA). With our MS data it turned out that the cutoff values for the scoring system were determined such that they had to

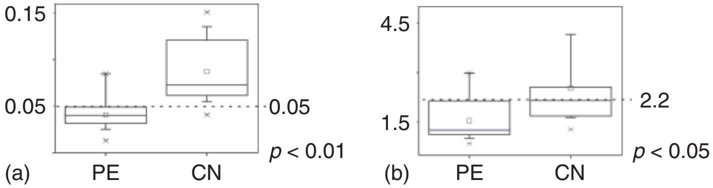

Figure 12.5 Distributions of peak area quotients from selected ion signal pairs derived from MS measurements of plasma samples after ClinProt® work-up (box and whiskers plots). Samples were from patients with preeclampsia (PE) and from healthy pregnant controls (CN). (a) Example with sufficient separation of the values, that is, little overlapping value ranges (P-value < 0.01). (b) Example with poor separation, that is, highly overlapping value ranges (P-value < 0.05). Boxes represent the upper (75% value) and lower quartile (25% value). The separation line in the box marks the 50% value (mean). Vertical bars indicate the standard deviation. Average values are depicted as little boxes. Upper and lower extreme values are indicated with a "minus sign." × symbols show the 99 and 1% range of the individual values, respectively. The horizontal hatched lines mark the cutoff values that were chosen for separation of the two groups.

be at least higher than the upper quartile (75% value) of the group that consistently showed lower values, and, ideally, lower than the lower quartile (25% value) of the group that consistently possessed higher values. There is no need to mention that the lesser the overlap between the values of the two groups, the better the separation by the cutoff line. In cases where the above-introduced criteria could not be reached, it was decided to still place the cutoff value higher than the upper quartile (75% value) of the group with consistently lower values. When the values of the quotients for the samples of patients were lower, as was the case in a few of our control assays [14], the number of true positives remained as high as desired; just the number of false positives increased. This effect turned out to be more tolerable in the overall assay outcome than the opposite.

Using the information of abundant but not differentiating ion signals of a given spectrum together with differentiating ones allowed the inclusion of internal check marks for each spectrum together with determining the individual sample profiles, which simultaneously corrected for mass spectrometric interassay variabilities, such as detector performance, ionization yields, and so on, and, most importantly, improved the overall data quality.

12.3.4
Biostatistical Assay Evaluation and Data Visualization

Testing whether in a given sample spectrum a defined area quotient reached the respective cutoff value provided a "yes" or "no" allocation for each test. When, for example, the value of one quotient was higher than the respective cutoff, a score of "1" was given to this respective sample. In the contrary case, the score for this sample was set to "0." This check was independently carried out n times for each of the defined ion signal ratios with each individual spectrum. Hence, each spectrum, that is, each sample, could ultimately reach a cumulative score between "0" and "n."

Subsequently, it was determined that a cumulative score above "$n - x$" was sorting the respective spectrum (sample) into the group of patients. Otherwise, it fell to the group of controls. Applying these dichotomic grouping rules enabled a clear-cut separation of PE samples into the PE group and control samples into the control group [57].

In the end, the results of this scoring system were compared to group assignments according to clinical criteria (the standard of truth). This enabled assessing biostatistical significance by calculating sensitivity, specificity, false positive rate, false negative rate, positive predictive value, and negative predictive value, and so on. In order to display clinically relevant quantities, for example, sensitivity, specificity, and likelihood ratios receiver operator characteristic (ROC) plots (Figure 12.6) have become increasingly popular.

Applying such ROC analyses is useful in general in evaluating a test system for its diagnostic performance or its accuracy [64, 65]. Areas under curves (AUC), for example, ROC, can be classified into groups that allow quality estimations. An AUC of 0.5 indicates "random" assignments, which is equal to an unacceptable test performance. An AUC of 1.0, on the other hand, is reached with a "perfect" assay that categorizes all samples into the correct groups–patients versus control individuals in our samples. Owing to cryptic sample inconsistencies that are lying outside of the control of the experimentator (a clinical cohort of patients is always an assembly of heterogeneous individuals), a "perfect" assay result is almost never observed in practice. An assay performance scaling in between "perfect" and "random" with decreasing AUC values uses the terms "excellent" ($\text{AUC} \geq 0.9$), "good" ($0.8 \leq \text{AUC} \geq 0.9$), "fair" ($0.7 \leq \text{AUC} \geq 0.8$), and "poor" ($\text{AUC} < 0.7$) [64, 66]. In our experience, an AUC category of at least "good" is required for clinically meaningful assays with the chosen group size [67]. Lesser AUC values may be of interest with very large sample sizes or in preclinical research for improving assays such that they gain in quality, ultimately reaching a level that makes them

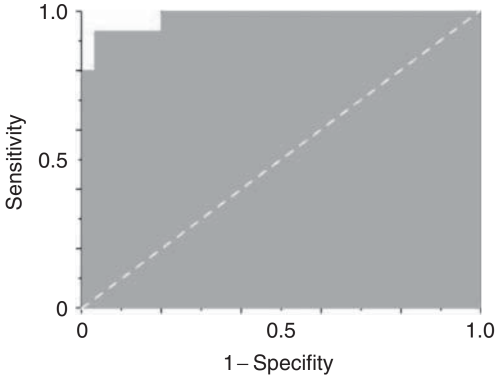

Figure 12.6 Receiver operator characteristic (ROC) curve for a cumulative score consisting of five additive criteria by which cord blood samples from IUGR infants were separated from those of controls. Calculated area under curve (AUC): 0.99. The hatched diagonal marks the 0.5 value.

interesting for clinical application. While testing, the biostatistical meaning of a given procedure is very helpful to describe the overall assay quality; in the end, the clinician is interested in getting access to a diagnostic (or even prognostic) procedure that is capable of identifying whether an individual sample is from a patient that carries the disease.

In order to display a complex data space with multiple entries but at the same time with individual sample resolution, the so-called ''heat maps'' derived from hierarchical clustering aligned in dendrograms is regarded as the ideal choice. In our examples, normalized values of selected ion signal area quotients are graphically represented in independent lines for each of the rules (quotients of normalized ion signal areas) that were selected for the assay (Figure 12.7). Individual patients and control samples are listed in columns from left to right.

Hierarchical clustering was performed on the basis of the complete linkage method and Spearman's correlation coefficient as a measure of similarity. Signal intensities were centered and scaled row-wise for visualization purposes [68] and enabled clear separation of the patients from the control samples with five independent classifier rules. Note that all PE patient samples were clustered correctly into the patient group. Only two control individuals were erroneously sorted into the patient group. All other control individuals were clustering in the control group. With this information, the clinician is instantly able to check clinical data of the patient/person of interest that may help interpret the overall assay result.

Interestingly, while in our example all patients are forking from one major branch of the tree (branch 3 at the left), the control group seemed to consist of two subgroups (separated by branches 1 and 2 at the right). The fact that the control

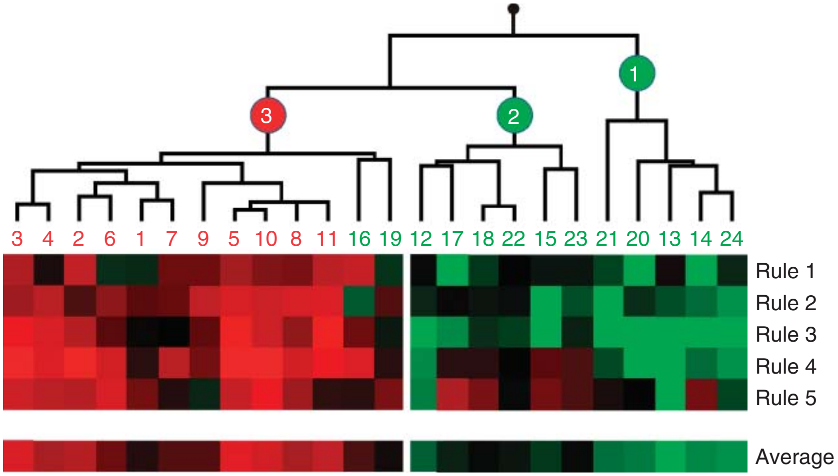

Figure 12.7 Hierarchical clustering of preeclampsia and control samples (PE; patient numbers in red) and control (CN; patient numbers in green). The vertical white line separates the main branches of the tree; branch 3 is on the left and branches 2 and 1 are on the right.

group displayed a broader heterogeneity than the patient group was observed quite frequently in clinical studies. Larger inhomogeneity of the control group seems system immanent because the clinical definition normally precisely describes the disease characteristics (Section 12.1), but gives no clear definition about the control group, except for defining the absence of the disease symptoms. Given these circumstances, such high accuracy of separation, as shown here, is considered satisfactory with respect to accurately identifying patient samples. In conclusion, the high reliability of the proteome signature that was defined with the above outlined approach was proven again.

12.4

Conclusion and Clinical Relevance

Proteomic pattern analysis of polygenic diseases generates considerable clinical interest owing to its diagnostic potential. With increasing power of computerized data analysis, it has become feasible to tackle the challenge to analyze data from complex clinical samples, such as blood serum. MALDI-TOF MS is an advanced technique that can detect hundreds of peptide and/or protein ion signals from clinically obtained body fluids in just one measurement with high fidelity and robustness. Hence, MALDI-TOF MS has enabled the multiparametric analysis of the reservoir of proteins derived from high-abundance endogenous circulating proteins. As a consequence, mass spectrometric measurements of the entire set of protein abundances in biological fluids allow the representation of proteome signatures for a particular pathology. An advantage of MS-based proteomics is that this approach does not require prior knowledge of the pathophysiological mechanisms underlying the condition of interest or even the existence of any single specific protein, as long as the signature of recorded signals remains differential. As a consequence, mass spectrometric measurements of the entire set of protein abundances in biological fluids (proteome signatures) allow the representation of a particular pathology, and the resulting signature is, in the best case, unique to the disease.

In all three gestation-related diseases mentioned, the placenta and/or the liver plays important roles. The placenta assumes dominating functions for life support of the fetus and contributes to the fetus' plasma/serum protein constitution. Owing to remarkable interconnections between the circulations of mothers and fetuses through the placenta, the likelihood of finding gestational disease-related alterations in the composition of the mothers' blood proteins is rather high, particularly, when the mothers' liver functions are also affected. Hence, comprehensive blood protein analysis during pregnancy provides sophisticated molecular diagnostics of such polygenic diseases, which is the key for forwarding our knowledge on gestational disease pathology. In our studies, we aimed at seeking disease-related plasma/serum protein constitution alterations that may become useful for diagnostics and perhaps even prognostics of gestational diseases. This endeavor has become feasible as with increasing power of computerized data analysis it has become possible to analyze complex data sets from clinical samples. Once the robustness of all involved steps is shown, clinics worldwide should be ready to adopt such analysis procedures on a routine basis. Hence, MALDI-TOF MS, either in combination with fractionation of the sample or without (as shown with the cryodetector system) enabled the multiparametric analysis of the reservoir of proteins derived from high-abundance endogenous circulating molecules from pregnant women, paving the way for fast decision-making for the best therapy and clinical care for each individual patient in the future.

13.1
Introduction

Mass spectrometry (MS), defined as the analytical science related to the study of charged particles in the gas phase by measuring their mass-to-charge (m/z) ratio, has always profited from a large variety of different methods for vaporizing and ionizing the samples. The formation of gas-phase ions from solid, liquid, or gaseous neutrals is in fact the first key step of any mass spectrometric analysis. Classically, electron impact (EI) ionization, where the sample interacts with an electron beam, and chemical ionization (CI), a soft ionization method where an auxiliary ionized gas is utilized, have been used. Both EI and CI are, however, restricted to volatile or gaseous samples. Early on, energetic beams were used for direct ion production from nonvolatile solids. For example, in secondary ion mass spectrometry (SIMS), an energetic ion beam bombards a solid sample surface and liberates secondary ions that are indicative of the composition of the surface. In ^{252}Cf plasma desorption, the products of a nuclear fission event interact with a nonvolatile sample, again liberating ions that can be used to determine the sample composition. Incidentally, many of these desorption/ionization methods turned out to be quite soft, that is, little fragmentation occurred, even from complex organic molecules. It was only natural that laser beams were also employed for ion generation from nonvolatile solids. This method was called ‘‘laser desorption mass spectrometry’’ (LDMS).

In the 1970s, lasers become commercially available and more affordable, leading to their extensive use in physics. For example, experiments by Hillenkamp and coworkers in Germany [1] were conducted to locally deposit energy on surfaces by laser irradiation. Desorption/ionization of organic and inorganic nonvolatile compounds that showed optical absorption at the wavelength of the laser was demonstrated, opening a new field of investigation for MS. A decade later, the matrix-assisted laser desorption/ionization (MALDI) technique was discovered by Hillenkamp and Karas in Germany [2], and almost simultaneously by Tanaka in Japan [3]. Very large and fragile biological molecules can now be easily ionized by MALDI, a method which is widely used in bioanalysis, and especially proteomics.

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

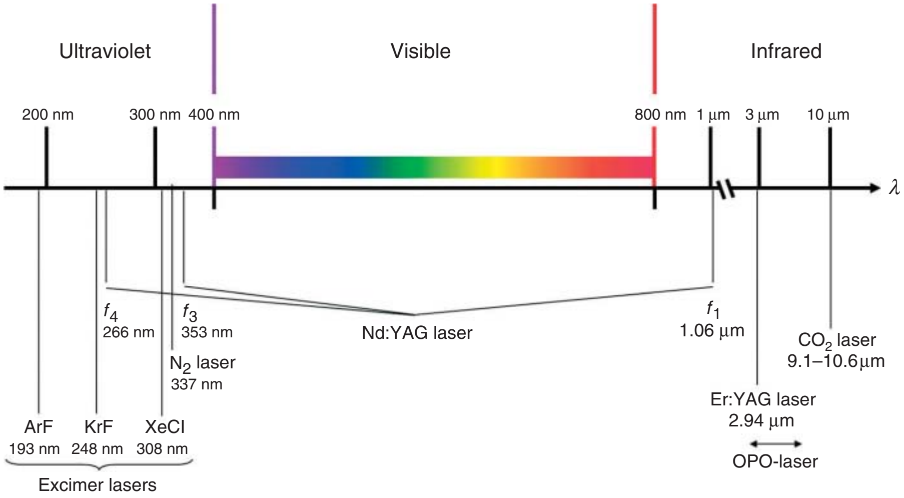

Figure 13.1 Wavelengths of lasers that are frequently used in mass spectrometry.

Lasers (Figure 13.1) also offer the possibility to deposit energy in gaseous ions at a variety of wavelengths, leading to the exploration of new fragmentation pathways that are often distinct from those usually observed by collision-induced dissociation (CID). This chapter thus covers not only ion generation by laser desorption/ionization (LDI) [4, 5] – arguably the most important use of lasers in MS – but also laser ablation and laser desorption for generating volatile species from solid samples that are then ionized by an alternative method, laser-induced dissociation, laser post-ionization, and laser spectroscopy of ions. We will explore the benefits of using lasers in MS by discussing some fundamentals aspects. At the end of the chapter, several typical applications of the use of lasers will be presented.

13.2
Laser Desorption/Ionization

13.2.1
Laser Microprobe Mass Spectrometry

In 1975, the group of Hillenkamp was the first to describe the use of lasers for the analysis of the chemical composition of surfaces [1]. A laser beam was focused on a spot a few micrometers in diameter on the target surface. With a pulse energy of some tenths of microjoules that is normally used, the resulting power density (irradiance) is $>10^8$ W cm^{-2}. An irradiance close to the threshold of ion formation favors the desorption/ionization of molecular ions from the sample surface, from an area with a diameter of 3–5 μm and a depth of some tenths of a micrometer. The great advantage of using lasers is the possibility to easily tune the irradiance in order to cover a wide range of ionization conditions. In fact, when the irradiance is 100–1000 times above threshold, evaporation of the total target volume occurs, along with extensive molecular rearrangement and fragmentation. This latter phenomenon is called *laser pyrolysis*. A commercial instrument, the so-called laser microprobe mass analyzer (LAMMA) became available for these analyses. The LAMMA was originally equipped with a frequency-doubled ruby laser ($\lambda = 347$ nm), and later with a frequency-quadrupled Nd:YAG (neodymium-doped yttrium aluminum garnet) laser ($\lambda = 266$ nm) (Figure 13.2).

The LAMMA instrument was capable of detecting light inorganic ions (Li^+, Na^+, K^+, Mg^{2+}, Ca^{2+}, and Co^{2+}) in the positive ion mode (Figure 13.3) and oxide ions $XO_n{}^-$ in the negative ion mode. The m/z values were measured with a time-of-flight (ToF) instrument [7]. For pulsed ion production by a laser, the ToF analyzer is the perfect choice and is in fact frequently used in all forms of LDMS. We will thus give some details here. A ToF analyzer works by accelerating the ions formed in the source region with a high voltage (2–20 kV) and by then measuring their

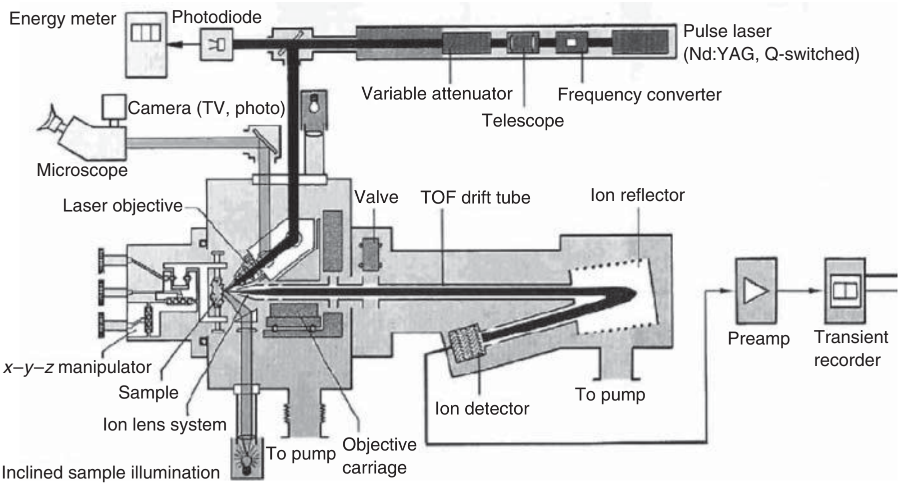

Figure 13.2 General scheme of a LAMMA or MALDI-TOF instrument [6]. (From [6]. Copyright Elsevier.)

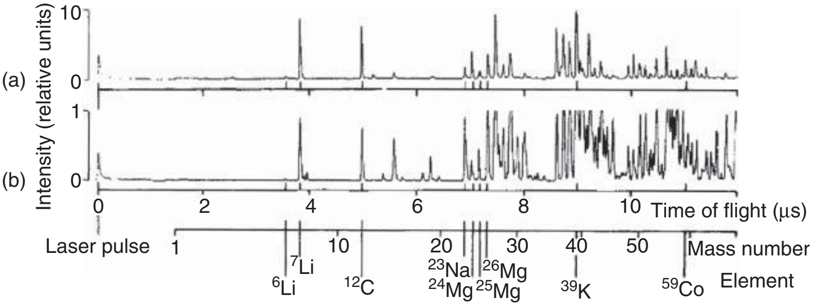

Figure 13.3 LAMMA-TOF mass spectra obtained from epoxy resin doped with lithium, manganese, and cobalt at (a) 40 and (b) 5 ppm [1]. (From [1]. Copyright Nature Publishing Group.)

ToF through a free-field drift region. The ToF is directly proportional to the square root of the mass-to-charge ratio (m/z) of the different ions. A small fraction of the laser beam is usually split onto a photodiode in order to provide a start pulse for the ion current measurement by a digital oscilloscope. The main advantages of the linear ToF analyzer are its simplicity, the possibility to simultaneously transmit a large number of ions to the detector without losses, few problems due to signal suppression, and reasonably good mass accuracy ($\sim$100 ppm). The mass resolution, however, is poor – only a few hundreds. However, mass resolution and accuracy can be improved to more than 10 000 and less than 10 ppm, respectively, when using an extraction delay between the ion generation pulse and the high voltage acceleration. Furthermore, an electrostatic mirror, also called *reflectron*, consisting of a series of ring electrodes creating a linear voltage gradient, is often introduced into the ion flight path. The reflectron counterbalances the difference in the velocity of ions with the same m/z and thus further improves resolution and mass accuracy. Both delayed extraction and the use of reflectron are nowadays standard in commercial ToF mass spectrometers.

It was later shown that singly charged molecular ions and cationized species could also be generated from aromatic compounds and nonvolatile species, respectively, by laser ablation [8]. Molecular ions mainly result from direct photoionization (PI) of the chemical compounds at the wavelength of the laser, whereas cationized species originate from the attachment of protons or inorganic cations, that is, mainly Na^+ or K^+, to neutral organic compounds. The LAMMA technique is usually considered as semi-quantitative because ionization yields differ for each species and each material. Relative detection limits in the parts per million range were claimed for inorganic species [1].

13.2.2
Matrix-Assisted Laser Desorption/Ionization (MALDI)

The main drawback of LAMMA experiments was the limited m/z range due to the difficulty in directly desorbing and ionizing large biomolecular species without fragmentation. A huge breakthrough was simultaneously achieved at the end of the 1980s by two groups – that of Hillenkamp and Karas in Germany [2] and that of Tanaka (Nobel Prize in Chemistry, 2002) in Japan [3]. Both groups were experimenting with additives and special sample preparation methods for large molecules in LDMS, and developed the MALDI. The key concept of MALDI is to mix fragile biomolecules with a chemical matrix, at a molar ratio between 10^{-2} (small molecules) and 10^{-4} (large molecules). One to five microliters of a solution containing a mixture of the sample and the matrix is then deposited on a metallic surface and allowed to dry. This standard sample preparation is called the *dried droplet technique*. Small crystals (Figure 13.4), with a size between one and several hundreds of micrometers, are formed and introduced into the vacuum of the ionization chamber. The chemical structure of the matrix is always chosen to exhibit a high absorption coefficient at the wavelength of the laser. The choice of the matrix (Table 13.1) is absolutely crucial and mainly depends on the type of

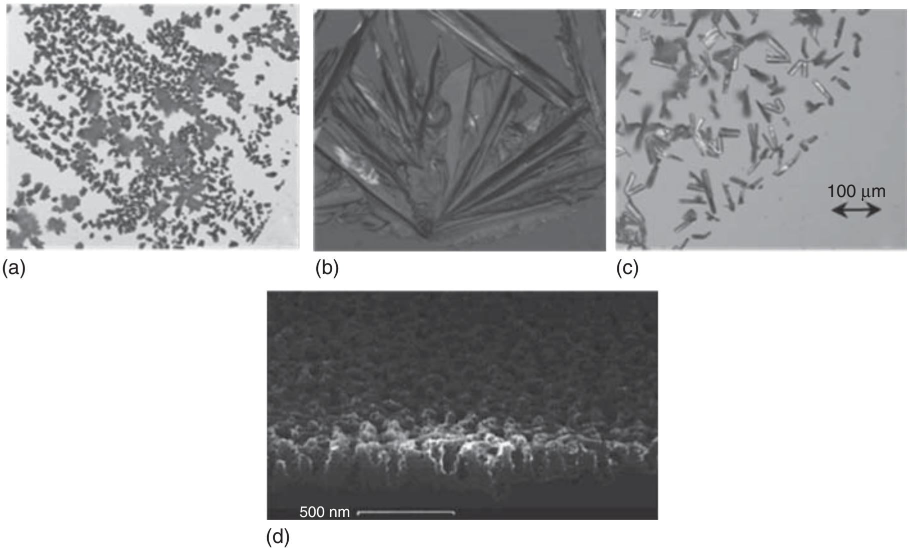

Figure 13.4 Microscopic views of (a) HCCA, (b) DHB, and (c) SA. (d) SEM (scanning electron microscopy) analysis of the ''double-etched'' porous silicon (DIOS) surface prepared from low-resistivity $n \pm$ Si material ($0.001 - 0.005\,\Omega$ cm) [9]. (From [9]. Copyright American Chemical Society.)

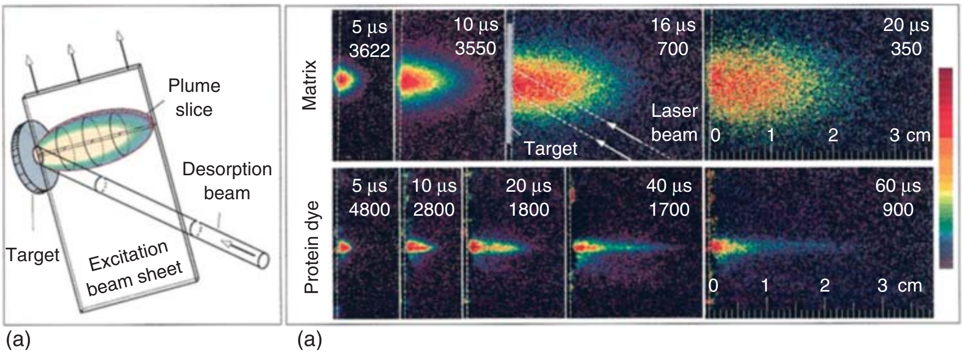

Figure 13.5 (a) Schematic of MALDI plume irradiation geometry. Desorption was induced with a KrF laser beam ($3.1 \times 3.6\,\text{mm}^2$ elliptical beam spot). LIF (laser-induced fluorescence) excitation utilizes a sheet beam from a second laser fired at variable time delay after the desorption laser pulse. (b) CCD (charge-coupled device) images (100 ns gate width, opened 50 ns prior to the LIF laser pulse) of LIF from matrix and dye-tagged protein molecules. Each image represents a different desorption event. Time delays after desorption and the maximum intensity (red, see palette) of each image are listed. Dashed lines show the target position. (Upper row) LIF images of 3-HPA matrix vapor plume (excitation: 308 nm XeCl, $1.6 \times 35.0\,\text{mm}^2$ rectangular beam spot); (lower row) LIF images of TMR-dye labeled DNase I protein (3.1×10^{-5} M) embedded within 3-HPA matrix and desorbed with a KrF laser (excitation: 532 nm, second harmonic of Nd:YAG laser, $0.3 \times 35\,\text{mm}^2$ beam spot). A 550 nm long-pass filter was used to cut off 532 nm scattered laser light [10]. (From [10]. Copyright American Physical Society.)

analytes and the polarity of the analysis. However, there is still no general rule to design an efficient matrix and to prepare the best matrix/analyte mixture, that is, MALDI sample preparation is still a kind of ‘‘art’’ (Figure 13.4).

For MALDI, a low irradiance (10^6 W cm^{-2}), which prevents nonvolatile, labile molecules from fragmentation, is used for the desorption/ionization process. (We note in passing that removal of a bulk volume is observed in MALDI when the laser hits the sample, that is, the term *desorption* is somehow misleading, and strictly speaking should be replaced by ‘‘ablation.’’) For infrared matrix-assisted laser desorption/ionization (IR-MALDI) with 100 ns-long erbium-doped yttrium aluminum garnet (ER:YAG)-laser pulses or for UV-MALDI (ultraviolet matrix-assisted laser desorption/ionization) [11], the ablation process is due to superheating of the sample to a temperature which is higher than the boiling temperature and to the ejection of material by heterogeneous nucleation in a plume (Figure 13.5). For 6 ns-long optical parametric oscillator (OPO)-laser pulses, the ablation mainly involves a strong thermoelastic wave, which is reflected at the sample vacuum surface, travels back through the sample, and leads to an explosion of the sample by homogeneous nucleation [11, 12]. In all cases, multiply charged clusters of the matrix and the analyte are extensively formed.

The exact mechanism leading to the formation of desolvated singly charged analyte ions is still unclear [11]. MALDI spectra in the positive ion mode are characterized by the presence of protonated/cationized molecules and radical cations of the matrix in the low m/z range, whereas deprotonated and radical anions of the matrix are detected in the negative mode. A characteristic of MALDI, as opposed to electrospray ionization (ESI), is that singly charged ions dominate in MALDI mass spectra. Sensitivity in the negative ion mode is usually lower compared to the positive ion mode. When an equimolar mixture of analytes is analyzed, different signal intensities are obtained for each compound (Figure 13.6), a phenomenon called *ion suppression effect*. During the crystallization step, exclusion of compounds from the crystal lattice is often observed, leading to different relative ion intensities at different locations of the MALDI sample crystals.

Several models for ion generation in MALDI have been thus proposed. The model developed by Knochenmuss and Zenobi [14] assumes that proton transfer occurs between neutral analyte molecules and primary ions formed from matrix molecules. However, with the typical UV-laser wavelength of 337 or 355 nm, the energy of more than two photons is needed for matrix PI, but the usual laser irradiance is too low for direct PI of the matrix in the gas phase. Energy pooling of excited matrix species in clusters has been suggested as a pathway for primary (matrix) ion formation. Another model for ion formation in MALDI, the ‘‘lucky survivor’’ model developed by Karas *et al.* [15], proposes that large biological analytes retain their solution charge state even when they are incorporated in the matrix crystals. After the desorption process, clusters are ejected, and desolvation, that is, loss of the neutral matrix molecules, occurs. Photoelectrons, presumably from PI of matrix molecules, are suggested to be captured by the free multiply charged analytes ions, leading to an extensive charge reduction. Most analytes should thus be reduced to charge state 0, but some analytes, called *lucky survivors*, can survive

Table 13.1 Commonly used MALDI matrices.

Matrix	Structure	Laser	Main applications
Nicotinic acid		266 nm	Peptides, proteins
2,5-Dihydroxybenzoic acid (DHB)		337, 353 nm	Peptides, proteins, carbohydrates, synthetic polymers
Sinapinic acid (SA)		337, 353 nm	Peptides, proteins
α-cyano-4-hydroxycinnamic acid (HCCA)		337, 353 nm	Peptides
2,4,6-Trihydroxyacetophenone (THAP)		337, 353 nm	Nucleic acids
3-Hydroxy-picolinic acid (HPA)		337, 353 nm	Nucleic acids
Dithranol (DIT)		337, 353 nm	Carbohydrates, synthetic polymers
6-Aza-2 thiothymine (ATT)		337, 353 nm	Peptides, proteins
Succinic acid	$HOOC{-}CH_2{-}CH_2{-}COOH$	2.79, 2.94 μm	Peptides, proteins
Glycerol	 $CH_2(OH){-}CH(OH){-}CH_2(OH)$	2.79, 2.94 μm	Peptides, proteins

as singly charged ions. One issue that remains unclear is that photoelectrons cannot be formed in the gas phase. The probability that photoelectrons interact with desolvated multiply charged analytes in the gas phase is thus very low, and the neutralization process should not be so complete. Until now, no model can explain all the experimental observations. Most likely, several different ion pathways operate simultaneously, depending on the matrix and the sample. What is clear is that quantitative studies with MALDI-MS are difficult because of the number of parameters that must be controlled. Semiquantitative or mass fingerprinting studies, however, are very successfully done by MALDI. The sensitivity of MALDI analysis is normally in the low picomole range; some results were obtained that show a sensitivity down to the attomole range. The main applications are mass fingerprinting of peptides for proteomics, of lipids for lipidomics, carbohydrates, or drugs for industry and imaging MS. Some among them are described in Section 13.6.

Standard MALDI is a vacuum ionization technique. A general trend in modern MS, however, is to do ion production at atmospheric pressure outside the MS and guide the ions into the mass analyzer through a differentially pumped interface (''atmospheric pressure ionization,'' API). In 2000, the group of Burlingame introduced an atmospheric pressure-matrix-assisted laser desorption/ionization source (AP-MALDI) [16] using a specially designed interface. Even if the transfer leads to ion losses, the total ionization yield is probably at least as high as in vacuum MALDI because of the fast thermalization of ions at atmospheric pressure. AP-MALDI makes sample preparation easier, and allows direct analysis of very fragile analytes. Moreover, online coupling with high-performance liquid chromatography (HPLC) or capillary electrophoresis (CE) has been recently described [17]. Nevertheless, the m/z range is often limited to 2000, making the analysis of intact large biological analytes impossible.

13.2.3
Small-Molecule Desorption/Ionization

As described before, matrix ions give rise to intense peaks in the low m/z range in MALDI mass spectra, leading to unwanted effects such as detector saturation and analyte ion suppression effect. There have been a number of efforts to develop a matrix-free variant of MALDI. The earliest such attempt was in fact the particle matrices of Tanaka [3]. In 1999, a novel and very promising matrix-free desorption/ionization method was introduced by the group of Siuzdak [18]. The idea is to deposit the analyte onto a porous silicon surface and to desorb/ionize it by UV-laser. UV photons are absorbed by the silicon surface and the energy is transferred to the analyte molecules. This method, dubbed desorption/ionization on silicon (DIOS) is essentially background free (Figure 13.7) and quite soft, thus offering the possibility to analyze low molecular weight analytes ($m/z < 100$) with a very low yield of fragmentation. In addition, the sample preparation is very easy. DIOS-MS has been used to develop quantitative methods for the analysis of pharmaceutical compounds [19] and for complex matrices such as biological or environmental samples [20]. DIOS was further refined by using silicon nanowires grown on the surface of solid silicon as an LDI substrate [21]. The laser irradiance required is lower than for conventional DIOS-MS, leading to a very low background and an increase in sensitivity. Very recently, another DIOS variant called nanostructure-initiator mass spectrometry (NIMS) was introduced by the Siuzdak group [22]. NIMS works with a nanoporous Si surface, obtained by electrochemical etching of crystalline silicon using hydrofluoric acid, which serves to trap a liquid ''initiator.'' The ''initiator'' is transparent, whereas the nanostructured silicon surface has a high

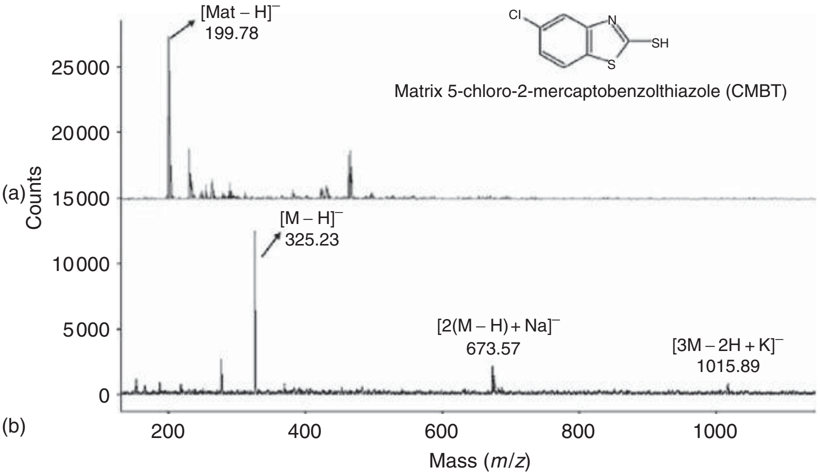

Figure 13.7 Negative ion mass spectra recorded for $C_{21}H_{42}O_2$ at 3 nmol µl^{-1} in (a) MALDI mode using the 5-chloro-2-mercaptobenzothiazole matrix (CMBT) and (b) in DIOS mode [23]. (From [23]. Copyright Wiley.)

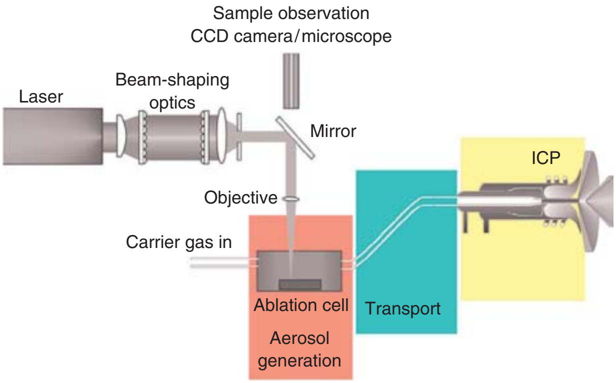

Figure 13.8 General scheme of a LA-ICP mass spectrometer [26]. (From [26]. Copyright American Chemical Society.)

absorption coefficient at the wavelength of the UV laser. A significant improvement in the signal-to-noise ratio was demonstrated for small organic compounds and peptide mixture compared to DIOS. Many other materials have been tried to enhance ion formation in LDI, including carbon nanotubes, functionalized carbon nanotubes, micro- and nanoparticles, sol–gels, ionic liquids, and so on. The main limitation of all these techniques is the low accessible m/z range, which is limited to a few thousands. Thus, studies of intact large biomolecules are usually conducted with MALDI-MS, whereas DIOS-MS and associated techniques are interesting alternatives for low mass compounds.

In parallel, bioaffinity MALDI formats were developed by several research teams, such as the groups of Nelson *et al.* [24] and of Chen [25]. These ‘‘assays’’ usually consist of a capture surface, for example, an antibody functionalized MALDI sample target or chemically modified particles, which is used for the concentration of specific analytes in a suspension of graphite particles in a mixture of glycerol, sucrose, and methanol. In the case of an antibody-functionalized MALDI target, a conventional matrix is applied to release the antigen. In the case of modified particles, they can be used as a ‘‘matrix’’ by themselves, thus serving not only for sample enrichment but for desorption/ionization as well.

13.3
Laser Ablation

In MALDI and DIOS, desorption and ionization steps are coupled and it is quite difficult to perfectly control both phenomena at the same time. Thus, several research laboratories have pursued the separation of the volatilization and ionization steps. Lasers, as spatially well-defined energy sources, can be easily focalized onto different surfaces in order to only ablate organic or inorganic materials. It is well known that the number of neutral species desorbed from an irradiated surface is much higher than the number of ions. Post-ionization of neutrals is therefore also attractive, especially for the detection of new analytes that cannot be analyzed by MALDI. Laser ablation has been successfully coupled to a large variety of ionization techniques [27]: electron ionization (EI), CI, Na^+-cationization, corona discharge atmospheric pressure chemical ionization (APCI), ^{63}Ni APCI, resonance-enhanced multiphoton ionization (REMPI), inductively coupled plasma (ICP), and vacuum-UV PI. At the present time, LA-ICP-MS (laser ablation inductively coupled plasma mass spectrometry; Figure 13.8) [28] is probably the most widely used among these techniques. In fact, it offers the unique possibility to combine the analysis of a very small volume of a sample with the simultaneous concentration determination of all chemical elements. Sensitivity is down to the parts per billion range for most elements, which makes it an efficient tool for ultratrace analysis of metals, semiconductors, or long-lived radionuclides.

Specific applications were developed for laser ablation followed by other post-ionization techniques, but most studies were restricted to the low mass range. To overcome this limitation, electrospray-assisted laser desorption/ionization (ELDI) was developed by Shiea *et al.* [27]. The idea was to couple an atmospheric MALDI source with an ESI source (Figure 13.9). In this case, the sample is directly deposited on a target plate and a laser is used for desorption of large biomolecules, which are then post-ionized by extensive proton exchanges with the charged solvent droplets formed by ESI. Typical ESI charge state distributions of proteins are observed, and found to be correlated with the initial conformation of proteins in solution, leading to the possibility of studying native proteins and noncovalent complexes by ELDI MS. The sensitivity of ELDI is comparable to that of ESI but still some orders of magnitudes worse than that of MALDI. ELDI was also applied to the analysis of drugs directly desorbed from tablets. A variant, called matrix-assisted laser desorption electrospray ionization, MALDESI, was developed by the group

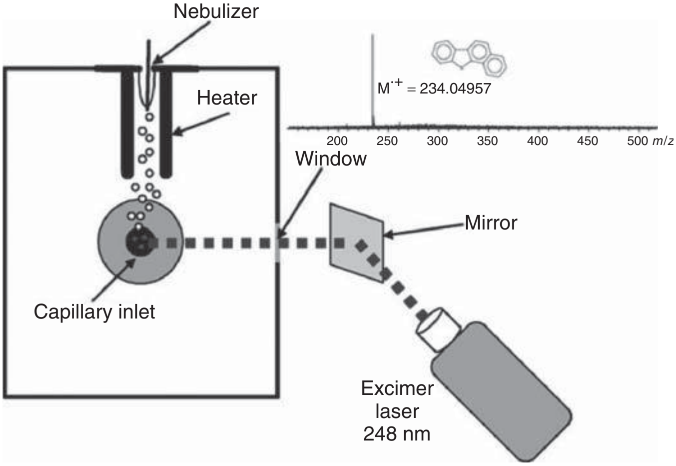

Figure 13.9 General scheme of a ELDI source coupled to a Fourier transform-ion cyclotron resonance (FT-ICR). Inset: typical mass spectrum obtained for benzonaphthothiophene [37]. (From [37]. Copyright 2008 The Royal Society of Chemistry.)

of Muddiman (Figure 13.10) [29]. The setup is actually the same as in the case of ELDI, but in MALDESI the analytes are mixed with a matrix solution prior to deposition on the sample plate. A better sensitivity was achieved. Nevertheless, both ELDI and MALDESI are still in their infancy and need to prove their benefits compared to standard ESI or MALDI.

13.4
Laser Postionization

Lasers can be used for specific post-ionization of neutral gas-phase species in the nonresonant and resonant modes. Neutral species can be produced by laser ablation (two-step laser mass spectrometry, L2MS) [31], ion impact on a surface (laser secondary neutral mass spectrometry, SNMS) [32], evaporation (resonance ionization mass spectrometry, RIMS) [33], or thermospray/ESI (atmospheric pressure laser ionization mass spectrometry, APLI-MS) [34]. For L2MS, an IR-laser is first used for ablation of neutral molecules from the sample surface. Second, a pulse from a tunable UV laser is used for resonance-enhanced two-photon ionization (1+1 REMPI) of the desorbed species. The mass spectra are dominated by intact radical cations of those mixture components that strongly absorb the selected ionization laser wavelength. Little or no sample preparation is necessary, and direct analysis of complex matrices is possible with sensitivity in the picogram range. L2MS was extensively used for the quantitative analysis of polycyclic aromatic hydrocarbons in biological matrices or aerosols. SNMS and RIMS are based on laser post-ionization of neutrals desorbed by sputtering from a sample surface with 10–20 keV ion (Ga^+, In^+, Ar^+) beam, or by evaporation, respectively. A large variety of lasers have been employed, depending on the chemical structure of the analyte, to achieve high selectivity and efficiency in the ionization step. The main reported applications are quantitative elemental analysis of semi-conductors, ceramics, or biological samples, with sensitivities in the parts per billion to parts per trillion range. Instruments are generally home-made and SNMS and RIMS are only used in very few laboratories. Finally, APLI-MS was recently developed for the postionization of liquid samples, such as petroleum. Nonvolatile analytes that are not easily protonated are brought into the gas phase by an APCI probe, with no or little ionization taking place. A KrF ($\lambda = 248$ nm) laser then interacts with these neutrals, leading to specific 1+1 REMPI, for example, of aromatic compounds. Better sensitivity was achieved for this class of analytes compared to ESI or conventional atmospheric pressure photoionization (APPI); the latter is based on direct or indirect PI of the gaseous samples with a Xe ($\lambda = 147.6$ nm), Kr ($\lambda = 123.6$ nm), or Ar ($\lambda = 110.7$ nm) lamp.

13.5
Laser Ion Excitation

Photoexcitation of gaseous ions can be achieved using pulsed IR or UV–vis (ultraviolet–visible) lasers, or continuous IR laser irradiation. Absorption of UV–vis photons by ions leads to a population of excited electronic states and to photodissociation of the excited ion. With IR excitation, ions are slowly heated, that is, their internal energy increases by small steps. IR multiphoton absorption is required to reach the quasi-continuum of the vibrational states and to induce fragmentation of the gaseous ions. The so-called IRMPD (infrared multiphoton dissociation) is now widely used for efficient fragmentation of multiply charged ions from peptides, proteins, or oligonucleotides [35]. This technique is usually operated on Fourier transform ion cyclotron resonance mass spectrometers, or on RF ion trap instruments, and structural information can be obtained from the analysis of the fragments. The main drawback of IRMPD is that the required irradiation time is quite long – hundreds of milliseconds. Therefore, fragment ions that are produced early on can also absorb further IR photons leading to the formation of low mass secondary fragments, and generally to a loss of structural information. IRMPD with tunable lasers, such as free electron lasers, is also used as a spectroscopic tool. In this manner, a vibrational ‘‘action’’ spectrum of gaseous ions can be obtained by recording the photofragmentation rate as a function of irradiation wavelength. Comparisons between *ab initio* calculations and experimental results have yielded very interesting results on structural features of ions (e.g., Figure 13.11) [36].

13.6
Typical Applications of Laser Mass Spectrometry

Key application areas of laser MS that are focused on in this section are the application of MALDI-MS in proteomics, and the use of MS imaging with laser assistance, which is an emerging field in MS.

13.6.1
MALDI-MS in Proteomics

As described above, MALDI is suitable for the analysis of a wide range of compounds. Applications range from quantification of small compounds and analysis of digested or intact proteins, to sequencing of oligonucleotides, and to lipidomics. *Proteomics* is defined as the study of the entire complement of proteins, including their chemical modifications, that is posttranslational modifications, produced by a living object in a specific condition. Proteomes are of extremely high complexity. If all the modifications are counted, the number of different proteins contained in the human body is estimated to be around several millions. Furthermore, the protein content of a cell depends directly on cell activity, stimuli, or disease state. In fact, it is not possible to identify all these proteins and modifications in a single experiment. The classical approach consists in the specific extraction of a set of proteins. This can be done using acidic or basic extraction, immunochemical precipitation, centrifugation, microdissection, and so on. The second step is usually a chromatographic separation of the protein set using HPLC or two-dimensional gel electrophoresis. In the latter case, proteins are separated by migration in a polyacrylamide gel. The first separation dimension is related to the isoelectric point whereas the second dimension depends on the molecular weight. In order to find the proteins on the gel, chemical staining by coomassie blue or silver nitrate is done. All bands of interest are then cut out, the proteins are removed from the gel by various chemical procedures, and digested by enzymes such as pepsin and trypsin. Pepsin cleaves nonspecifically whereas trypsin cleaves peptide chains at the carboxyl side of the amino acids lysine and arginine, except when either of them is followed by proline. The peptides that are generated by this digestion are finally analyzed by MALDI-MS(/MS) or ESI-MS(/MS). In MALDI, a ‘‘peptide mass fingerprint’’ is obtained, that is, each peptide gives a single signal that corresponds to its protonated form in the positive ion mode. The high mass resolution and accuracy available on modern mass spectrometers allow the interrogation of online databases and often the unambiguous identification of proteins from their peptide mass fingerprint. MS/MS data are of interest in order to confirm the assigned peptides and to precisely localize posttranslational modifications on protein structures. Nowadays, high throughput analysis is possible owing to the high repetition rate of commercial N_2 or Nd:YAG lasers and the continuous improvement of electronics and informatics. Proteomics combined with MS has many potentially very interesting applications, such as the detection of protein markers of cancer [38, 39], predicting the effects of treatments [40], and helping to understand many biological processes [41].

13.6.2
Imaging Mass Spectrometry

Molecular imaging is of great interest in biology for understanding the spatial location of biomolecules at the tissue or cellular levels. Most widely used methods

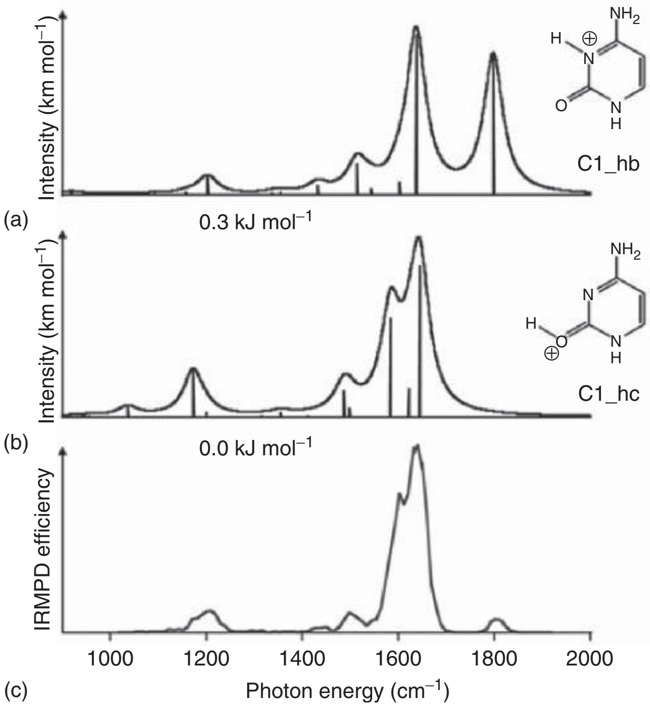

Figure 13.11 IR spectra of protonated cytosine. DFT calculated IR absorption spectra of the two lowest isomers C1_hb (a) and C1_hc (b) compared to the experimental IRMPD spectrum (c) recorded with two IR-FEL macropulses using our quadrupole ion trap device [42]. (From [42]. Copyright Wiley.)

are based on fluorescence, radiochemical tracers, positron emission tomography (PET), nuclear magnetic resonance (NMR), and so on. Nevertheless, all these techniques need chemical modifications of the interesting compounds and are related to very few chemical signals.

MS is more direct for chemical imaging, requiring no labels or tracers, and offering high spatial resolution by virtue of its sensitivity. One way to perform mass spectrometric imaging is by using laser ablation ICP-MS. LA-ICP-MS has in fact become of increasing interest in such different research areas as (i) physiology, pathophysiology, and anatomy, where trace elements play a role; (ii) development and *ex vivo* calibration of molecular imaging methods which use molecular probes carrying appropriate elements; (iii) development of metal-containing drugs; (iv) individual and environmental toxicology, and (v) gene–environment interactions concerning trace elements. Imaging LA-ICP-MS has been introduced and is being applied in several laboratories for the quantitative analysis of element distributions in biological tissue and in proteomics with a lateral resolution in the range of 10–200 μm, for example, for the mapping of Cu and Zn in sections of sheep liver or human brain tissue. An example of application area (ii) is given in Figure 13.12.

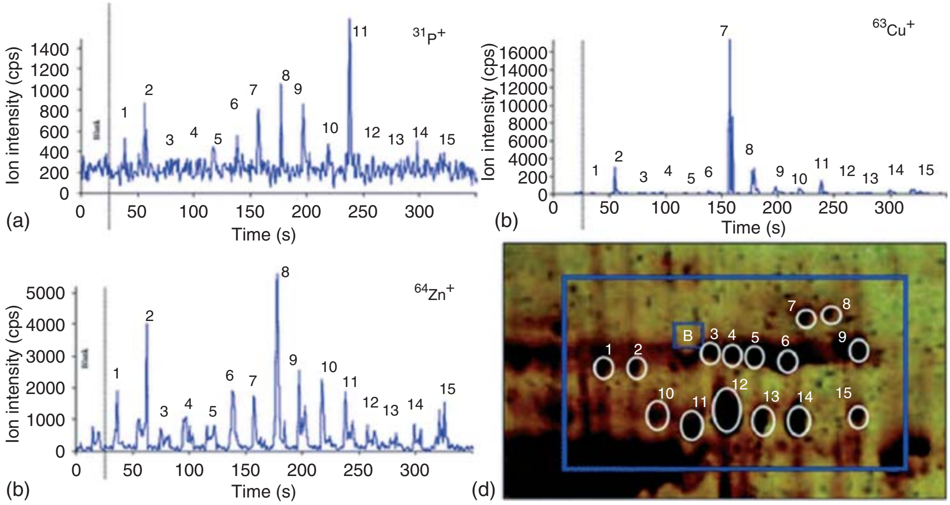

Figure 13.12 Example of LA-ICP-MS imaging [43]. Transient signals of (a) $^{31}\mathrm{P}^+$, (b) $^{63}\mathrm{Cu}^+$, and (c) $^{64}\mathrm{Zn}^+$, respectively, for protein spots 1–15 imaged directly in a 2D gel of human brain sample (d). The area marked with B in panel (d) is the blank. (From [43]. Copyright Royal Society of Chemistry.)

Imaging by molecular MS, for example, using MALDI-MS, offers the unique capability of analyzing several tens or hundreds of compounds at the same time on tissue surface. Modern MALDI mass spectrometers are equipped with lasers that have spot size of about 50 μm, allowing chemical imaging close to the cellular level.

MALDI-MS imaging was first described by Caprioli in 1997 [44]. The first step is to homogeneously deposit the matrix on the tissue section (Figure 13.13). This can be done manually with an air brush or automatically with a spotter or sprayer robot. It is absolutely crucial to control the matrix deposition in order to avoid delocalization of compounds. The sample is then introduced into vacuum. A first spectrum is recording at the top left of the sample. The sample plate is then moved in order to record a spectrum on the next position. The step between two locations will define the pixel size of the final images. At the end, a collection of spectra is recorded on the sample. Using these spectra it is then possible subsequently to plot the relative intensity of the individual m/z peaks in the mass spectrum across the tissue, and thus to visualize the distribution of the individual molecular ions. Depending on the matrix, spectra are focalized on the low mass range ($m/z < 2000$) or the high mass range ($m/z > 2000$). In the low mass range, the main information is related to lipid composition and localization [45]. This is why MALDI imaging in the low mass range is sometimes called a *lipid microscope*. Some studies are also linked to the distribution of drugs in different organs of a whole body mouse (Figure 13.14) [46] but high doses are usually needed because of a lack of sensitivity. MS/MS imaging can also be performed in order to improve the selectivity of the method. In the high mass range, peptides and light proteins can be localized. For example, markers of cancer have been identified on different tissues by the mean of

MALDI imaging [47]. Recently some attempts at local digestion by enzymes, such as trypsin, have been described [48]. Only fragments of highly abundant proteins were detected, limiting the interest in this approach. This technique is gaining attention in biology even if very careful sample preparation is needed in order to get reproducible data and to avoid false conclusions.

X-ray Fluorescence Analysis

Koen Janssens

14.1
X-ray Fluorescence Analysis – Outline

XRF (X-ray fluorescence) analysis is a powerful analytical tool for the spectrochemical determination of almost all the elements present in a sample. XRF radiation is induced when photons of sufficiently high energy, emitted from an X-ray source, impinge on a material. These primary X-rays undergo interaction processes with the analyte atoms. High-energy photons induce ionization of inner-shell electrons by the photoelectric effect and thus electron vacancies in inner shells (K, L, M, . . .) are created. The prompt transition of outer shell electrons into these vacancies within some 100 fs can cause the emission of characteristic fluorescence radiation. Not all transitions from the outer shells or subshells are allowed, only those obeying the selection rules for electric dipole radiation. The creation of a vacancy in a particular shell results in a cascade of electron transitions, all correlated with the emission of photons with a well-defined energy corresponding to the difference in energy between the atomic shells involved. The family of characteristic X-rays from each element, including all transitions, allows the identification of the element. Next to this radiative form of relaxation, a competing process can take place: the emission of Auger electrons. Both processes have Z-dependent probabilities that are complementary: the Auger yield is high for light elements and the fluorescence yield is high for heavy elements.

The working principle of XRF analysis is the measurement of wavelength or energy and intensity of the characteristic photons emitted from the sample. This allows the identification of the elements present in the analyte and the determination of their mass or concentration. All the information for the analysis is stored in the measured spectrum, which is a line spectrum with all characteristic lines superimposed above a certain fluctuating background. Other interaction processes, mainly the elastic and inelastic scattering of the primary radiation on the sample and substrate, induce the background.

Measurement of the spectrum of the emitted characteristic fluorescence radiation is performed using wavelength-dispersive (WD) and energy-dispersive (ED) spectrometers. In wavelength-dispersive X-ray fluorescence analysis (WDXRF), the

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

result is an intensity spectrum of the characteristic lines versus wavelength measured with a Bragg single crystal as dispersion medium while counting the photons with a Geiger–Müller, a proportional or scintillation counter. In energy-dispersive X-ray fluorescence analysis (EDXRF), a solid-state detector is used to count the photons, simultaneously sorting them according to energy and storing the result in a multichannel memory. The result is an X-ray energy versus intensity spectrum. The range of detectable elements ranges from Be ($Z = 4$) for the light elements and goes up to U ($Z = 92$) on the high atomic number Z side. The concentrations that can be determined with standard spectrometers of WD or ED type are situated in a wide dynamic range: from the percent to the microgram per gram level. In terms of mass, the nanogram range is reached with spectrometers having the standard excitation geometry.

By introducing special excitation geometries, optimized sources, and detectors, the picogram and even femtogram range of absolute analyte detection capacity can be reached; in terms of concentrations, the same improvement factor can be attained, that is, from the microgram per gram toward the pictogram per gram level under the best conditions.

In principle, XRF analysis is a multielement analytical technique and, in particular, the simultaneous determination of all the detectable elements present in the sample is inherently possible with EDXRF. In WDXRF, both the sequential and the simultaneous detection modes are possible.

The most striking feature of XRF analysis is that this technique allows the qualitative and quantitative analysis of almost all the elements (Be–U) in an unknown sample. The analysis is, in principle, nondestructive, has high precision and accuracy, has simultaneous multielement capacity, requires only a short irradiation time so that a high sample throughput is possible; online analysis is also possible and the running costs are low. The technique is extremely versatile for applications in many fields of science, research, and quality control; has low detection limits; and a large dynamic range of concentrations covering up to nine orders of magnitude. The physical size of an XRF spectrometer ranges from handheld, battery-operated field units to high-power laboratory units with compact tabletop units and larger ones requiring several cubic meters of space including a 10–20 kW electrical power supply and efficient cooling units with high-pressure water and a heat sink.

In contrast to all these attractive properties, there are some disadvantages. The absorption effects of the primary radiation and the fluorescence radiation created in the analyte result in a shallow layer a few tenths of a millimeter deep that provides information on its composition. This requires a perfectly homogeneous sample, which often occurs naturally but must sometimes be produced by acid dissolution into liquids or by grinding and the preparation of pressed pellets. In both examples, the feature of nondestructiveness is lost. Most ideally, thin films or small amounts of microcrystalline structure on any substrate are the ideal analytes, where the quantification process is also simple because there is linearity between fluorescence intensity and concentration. In thick samples, corrections for absorption and enhancement effects are necessary.

While the roots of the method go back to the early part of this century, where electron excitation systems were employed, it is only during the past 30 years or so that the technique has gained major significance as a routine means of elemental analysis.

14.2
Basic Principles

14.2.1
X-ray Wavelength and Energy Scales

The X-ray or Röntgen region of the electromagnetic spectrum starts at about 10 nm and extends toward the shorter wavelengths. The energies of X-ray photons are on the same order of magnitude as the binding levels of inner-shell electrons (K, L, M, . . . levels) and therefore can be used to excite and/or probe these atomic levels. The wavelength λ of an X-ray photon is inversely related to its energy *E* according to:

$$\lambda(\mathrm{nm}) = \frac{1.24}{E(\mathrm{keV})}$$

where 1 eV is the kinetic energy of an electron that has been accelerated over a voltage difference of 1 V ($1\,\mathrm{eV} = 1.602 \cdot 10^{-19}\,\mathrm{J}$). Accordingly, the X-ray energy range starts at 100 eV and continues toward higher energies. X-ray analysis methods most commonly employ radiation in the 1–50 keV (1–0.02 nm) range.

14.2.2
Interaction of X-rays with Matter

When an X-ray beam passes through matter, some photons will be absorbed inside the material or scattered away from the original path, as illustrated in Figure 14.1.

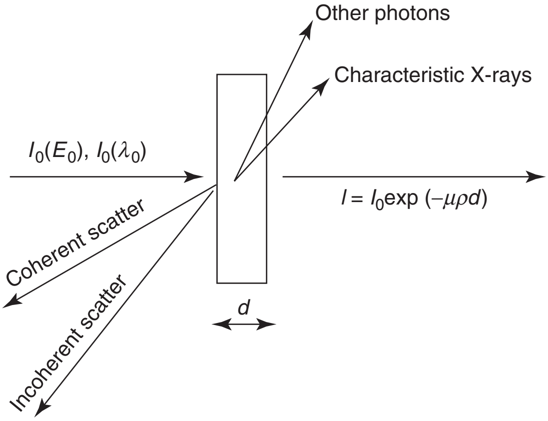

Figure 14.1 Interaction of X-ray photons with matter.

The intensity I_0 of an X-ray beam passing through a layer of thickness d and density ρ is reduced to an intensity I, according to the well-known law of Lambert–Beer:

$$I = I_0 e^{-\mu\rho d} \tag{14.1}$$

The number of photons (the intensity) is reduced but their energy is generally unchanged. The term μ is called the *mass attenuation coefficient* and has the dimension $\mathrm{cm}^2\,\mathrm{g}^{-1}$. The product $\mu_L = \mu\rho$ is called the *linear absorption coefficient* and is expressed in cm^{-1}. $\mu(E)$ is sometimes also called the *total cross section* for X-ray absorption at energy E.

Figure 14.2 shows a log–log plot of the energy dependence of the mass attenuation coefficient of several chemical elements in the X-ray energy range between 1 and 100 keV. The absorption edge discontinuities (due to photoelectric absorption – see subsequent text) are clearly visible. Low-Z materials attenuate X-rays of a given energy less than high-Z materials. A given material will attenuate high-energy (i.e., hard) X-rays less than low-energy (soft) X-rays.

The mass absorption coefficient $\mu(\mathbf{M})$ of a complex matrix $\mathbf{M}$ consisting of a mixture of several chemical elements (e.g., an alloy such as brass), can be calculated from the mass attenuation coefficient of the n constituting elements:

$$\mu(\mathbf{M}) = \sum_{i=1}^{n} w_i \mu_i \tag{14.2}$$

where μ_i is the mass attenuation coefficient of the ith pure element and w_i its mass fraction in the sample considered. This is called the *mixture rule*.

The mass absorption coefficient μ plays an important role in quantitative XRF analysis. Both the exciting primary radiation and the fluorescence radiation are attenuated in the sample. To relate the observed fluorescence intensity to the concentration, this attenuation must be taken into account.

As illustrated in Figure 14.1, the absorption of radiation in matter is the cumulative effect of several types of photon–matter interaction processes that take

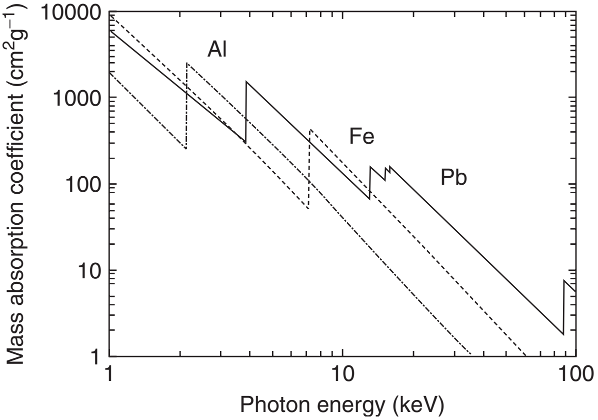

Figure 14.2 Energy dependence of the mass absorption coefficient μ of several elements.

place in parallel. Accordingly, in the X-ray range, the mass attenuation coefficient μ_i of element i can be expressed as

$$\mu_i = \tau_i + \sigma_i \tag{14.3}$$

where τ_i is the cross section for photoelectric ionization and σ_i the cross section for scattering interactions. All the above-mentioned cross sections are energy (or wavelength) dependent. Except at absorption edges (see subsequent text), μ is more or less proportional to $Z^4\lambda^3$.

14.2.3
Photoelectric Effect

In the photoelectric absorption process (Figure 14.3), a photon is completely absorbed by the atom and an (inner-shell) electron is ejected. Part of the photon is used to overcome the binding energy of the electron and the rest is transferred in the form of kinetic energy. After the interaction, the atom (actually an ion now) is left in a highly excited state as a vacancy has been created in one of the inner shells. The atom will almost immediately return to a more stable electron configuration by emitting an Auger electron or a characteristic X-ray photon. The latter process is called *X-ray fluorescence*. The ratio of the number of emitted characteristic X-rays to the total number of inner-shell vacancies in a particular atomic shell that gave rise to it is called the *fluorescence yield* of that shell (e.g., ω_K). For light elements ($Z < 20$), predominantly Auger electrons are produced during the relaxation upon K-shell ionization ($\omega_K < 0.2$), while the medium to heavy elements are preferentially relaxing in a radiative manner ($0.2 < \omega_K < 1.0$).

Photoelectric absorption can only occur if the energy of the photon E is equal to or higher than the binding energy ϕ of the electron. For example, an X-ray photon with an energy of 15 keV can eject a K-electron ($\phi_K = 7.112$ keV) or an L_3-electron ($\phi_{L_3} = 0.706$ keV) out of a Fe atom. However, a 5 keV electron can only eject L-shell electrons from such an atom.

Because photoelectric absorption can occur at each of the (excitable) energy levels of the atom, the total photoelectric cross section τ_i is the sum of (sub)shell-specific contributions:

$$\begin{aligned}\tau_i &= \tau_{i,\mathrm{K}} + \tau_{i,\mathrm{L}} + \tau_{i,\mathrm{M}} + \ldots \\ &= \tau_{i,\mathrm{K}} + (\tau_{i,\mathrm{L}_1} + \tau_{i,\mathrm{L}_2} + \tau_{i,\mathrm{L}_3}) + (\tau_{i,\mathrm{M}_1} + \ldots + \tau_{i,\mathrm{M}_5}) + \ldots\end{aligned} \tag{14.4}$$

In Figure 14.4, the variation of τ_{Mo} with energy is plotted. At high energy, for example, above 50 keV, the probability of ejecting a K-electron is rather low and that of ejecting an L_3-electron is even lower. As the energy of the X-ray photon decreases, the cross section increases, that is, more vacancies are created. At the binding energy $\phi_K = 19.99$ keV, there is an abrupt decrease in the cross section because X-rays with lower energy can no longer eject electrons from the K-shell. However, these photons continue to interact with the (more weakly bound) electrons in the L- and M-shells. The discontinuities in the photoelectric cross section are called *absorption edges*. The ratio of the cross section just above and just below the absorption edge

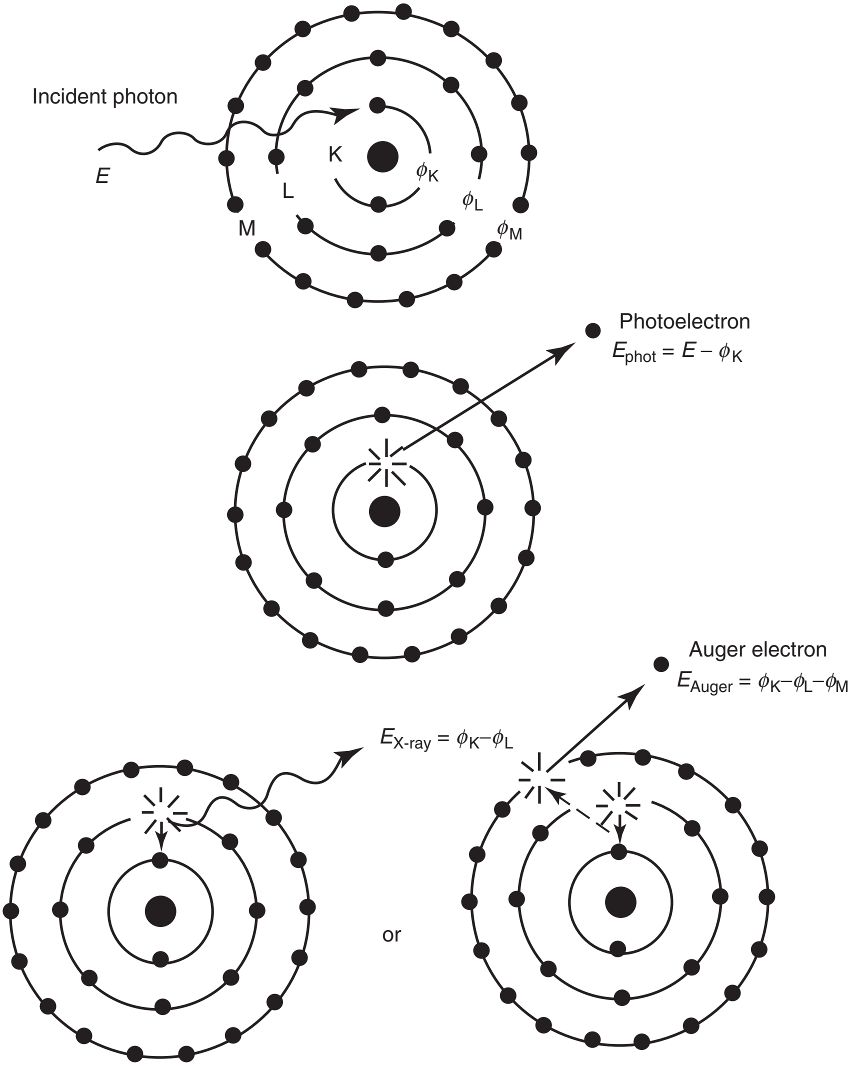

Figure 14.3 Photoelectric ionization can be followed by either radiative relaxation, causing the emission of characteristic fluorescent X-rays or nonradiative relaxation, involving the emission of Auger electrons.

is called the *jump ratio*, *r*. As XRF is the result of selective absorption of radiation, followed by spontaneous emission, an efficient absorption process is required. An element can therefore be determined with high sensitivity by means of XRF when the exciting radiation has its maximum intensity at an energy just above the K-edge of that element.

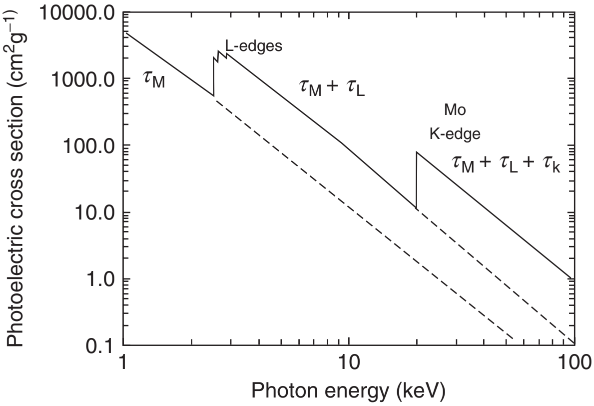

Figure 14.4 Variation of τ_{Mo} as a function of X-ray photon energy. The K, L_1, L_2, and L_3 absorption edges are clearly visible.

14.2.4
Scattering

Scattering is the interaction between radiation and matter that causes the photon to change direction. If the energy of the photon is the same before and after scattering, the process is called *elastic* or *Rayleigh scattering*. Elastic scattering takes place between photons and bound electrons and forms the basis of X-ray diffraction. If the photon loses some of its energy, the process is called *inelastic* or *Compton scattering*.

Accordingly, the total cross section for scattering σ_i can be written as the sum of two components:

$$\sigma_i = \sigma_{R,i} + \sigma_{C,i} \tag{14.5}$$

where $\sigma_{R,i}$ and $\sigma_{C,i}$, respectively, denote the cross sections for Rayleigh and Compton scattering of element i.

Compton scattering occurs when X-ray photons interact with weakly bound electrons. After inelastic scattering over an angle ϕ, a photon (Figure 14.5), with initial energy E, will have a lower energy E' given by the Compton equation:

$$E' = \frac{E}{1 + \frac{E}{m_0c^2}(1 - \cos\phi)} \tag{14.6}$$

where m_0 denotes the electron rest mass.

14.2.5
Bremsstrahlung

When an energetic electron beam impinges upon a (high-Z) material, X-rays in a broad wavelength band are emitted. This radiation is called *bremsstrahlung* because it is released during the sudden deceleration of the primary electrons, as a result

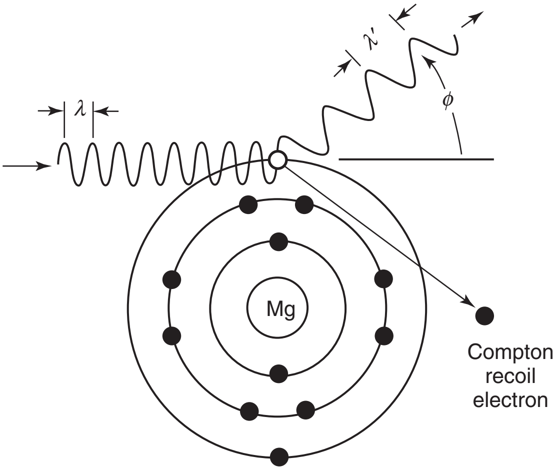

Figure 14.5 Geometry for Compton scattering of X-ray photons.

of their interaction with the electrons of the lattice atoms in the target. At each collision, the electrons are decelerated and part of the kinetic energy lost is emitted as X-ray photons. (In addition, characteristic X-ray lines (see subsequent text) of the target materials are produced.) As, during one collision, an electron of energy E can lose any amount between 0 and E, the resulting *bremsstrahlung* continuum features photons with energies in the same range. On a wavelength scale, the continuum is characterized by a minimal wavelength λ_{min} (nm) $= 1.24/E_{\mathrm{max}}$ (keV) $= 1.24/V$ (kV), where E_{max} is the maximum energy of the impinging electrons and V the potential used to accelerate them. The continuum distribution reaches a maximum at $1.5-2\lambda_{\mathrm{min}}$ so that an increase in the accelerating potential V causes a shift of the continuum toward shorter wavelengths. In Figure 14.6 *bremsstrahlung* spectra emitted by X-ray tubes operated at different accelerating potentials are shown.

14.2.6
Selection Rules, Characteristic Lines, and X-ray Spectra

Characteristic X-ray photons are produced following the ejection of an inner orbital electron from an excited atom, and the subsequent transition of atomic orbital electrons from states of high to low energy. Each element present in the specimen will produce a series of characteristic lines making up a polychromatic beam of characteristic and scattered radiation coming from the specimen. The systematic (IUPAC, International Union of Pure and Applied Chemistry) name of the X-ray line arising from a vacancy in the K-shell of an atom, which is filled by an electron originally belonging to the L_3-shell of that atom, is the $K-L_3$ transition. However, this transition is more commonly referred to as the $K_{\alpha 1}$-line (nonsystematic or Siegbahn nomenclature); similarly, fluorescent X-rays resulting from L_3-M_5 transitions are better known as $L_{\alpha 1}$*-photons*. Table 14.1 lists a number of observed X-ray lines and their corresponding IUPAC Siegbahn names.

Moseley first established the relationship between the wavelength λ of a characteristic X-ray photon and the atomic number Z of the excited element (Figure 14.7). Moseley's law is written as

$$\frac{1}{\lambda} = K(Z-s)^2 \tag{14.7}$$

where Z is atomic number and K and s are constants. s is the shielding constant and takes a value close to 1. K has a different value for each of the line series considered (e.g., the K_α-lines, the L_α-lines – see Table 14.1). Each unique atom has a number of available electrons that can take part in the transfer and, as millions of atoms are typically involved in the excitation of a given specimen, all possible de-excitation routes are taken. These de-excitation routes can be defined by a simple set of selection rules that account for the majority of the observed wavelengths.

Each electron in an atom can be defined by four quantum numbers. The first of these quantum numbers is the principal quantum number n, which can take all integral values. When n is equal to 1, the level is referred to as the *K level*; when n is 2, the L level, and so on. ℓ is the angular quantum number and this can take all values from $(n-1)$ to 0. m is the magnetic quantum number and can take values from $+\ell$ to $-\ell$. s is the spin quantum number with a value of $\pm\frac{1}{2}$. The total momentum J of an electron is given by the vector sum of $\ell + s$. As no two electrons within a given atom can have the same set of quantum numbers, a series of levels or shells can be constructed. Table 14.2 lists the atomic structures of the first three principal shells. The first shell, the K-shell, has a maximum of two electrons and these are both in the 1s level (orbital). As the value of J must

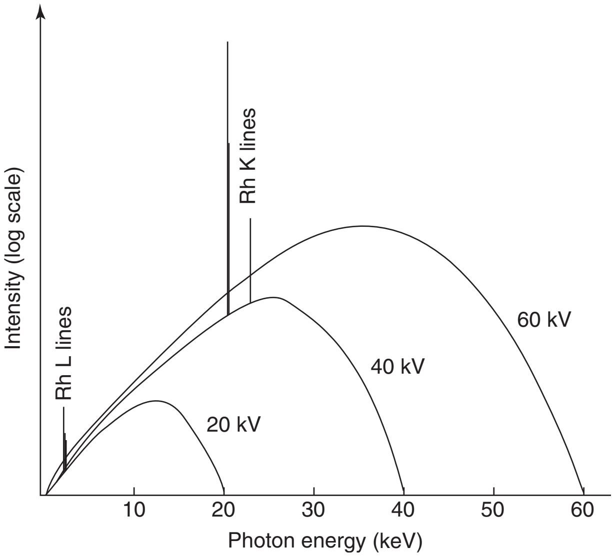

Figure 14.6 Polychromatic excitation spectra emitted by a Rh X-ray tube operated at various accelerating voltages. The excitation spectrum consists of a *bremsstrahlung* continuum upon which the characteristic lines of the anode material are superimposed.

Table 14.1 Principal X-ray lines (IUPAC and Siegbahn notations) and their approximate relative intensities relative to the major line in each subshell.

Series	IUPAC name	Siegbahn name	Relative intensity

be positive in this instance, the only allowed value is $+\frac{1}{2}$. In the second shell, the L-shell, there are eight electrons: two in the 2s level and six in the 2p levels. In this instance, J has a value of $\frac{1}{2}$ for the 1s level and $\frac{3}{2}$ or $\frac{1}{2}$ for the 2p level, thus giving a total of three possible L transition levels. These levels are referred to as L_1, L_2, and

Table 14.2 Atomic structures of the first three principal shells.

Shell (number of electrons)	*n*	*ℓ*	*m*	*s*	Orbitals	*j*
K (2)	1	0	0	$\pm 1/2$	1s	$1/2$
L (8)	2	0	0	$\pm 1/2$	2s	$1/2$
	2	1	1	$\pm 1/2$	2p	$1/2$, $3/2$
	2	1	0	$\pm 1/2$	2p	$1/2$, $3/2$
	2	1	-1	$\pm 1/2$	2p	$1/2$, $3/2$
M (18)	3	0	0	$\pm 1/2$	3s	$1/2$
	3	1	1	$\pm 1/2$	3p	$1/2$, $3/2$
	3	1	0	$\pm 1/2$	3p	$1/2$, $3/2$
	3	1	-1	$\pm 1/2$	3p	$1/2$, $3/2$
	3	2	2	$\pm 1/2$	3d	$3/2$, $5/2$
	3	2	1	$\pm 1/2$	3d	$3/2$, $5/2$
	3	2	0	$\pm 1/2$	3d	$3/2$, $5/2$
	3	2	-1	$\pm 1/2$	3d	$3/2$, $5/2$
	3	2	-2	$\pm 1/2$	3d	$3/2$, $5/2$

L_3, respectively. In the M level, there are a maximum of 18 electrons: 2 in the 3s level, 6 in the 3p level, and 10 in the 3d level. Again, with the values of $\frac{3}{2}$ or $\frac{1}{2}$ for J in the 3p level and $\frac{5}{2}$ and $\frac{3}{2}$ in the 3d level, a total of five M transition levels are possible (M_1 to M_5). Similar rules can be used to build up additional levels: N, O, and so on.

The selection rules for the production of normal (diagram) lines require that the principal quantum number must change by at least 1 ($\Delta n \geq 1$), the angular quantum number must change by only one ($\Delta \ell = \pm 1$), and the J quantum number must change by 0 or 1 ($\Delta j = 0, \pm 1$). Application of the selection rules indicates that in, for example, the K series, only $L_2 \rightarrow K$ and $L_3 \rightarrow K$ transitions are allowed for a change in the principal quantum number of one. There are equivalent pairs of transitions for $n = 2$, $n = 3$, $n = 4$, and so on. Figure 14.8 shows the lines that are observed in the K series. Three groups of lines are indicated. The normal lines are shown on the left-hand side, consisting of three pairs of lines from the L_2/L_3, M_1/M_3, and N_2/N_3 subshells. While most of the observed fluorescent lines are normal, certain lines may also occur in X-ray spectra that, at first sight, do not abide by the basic selection rules. These lines are called *forbidden lines*; they arise from outer orbital levels where there is no sharp energy distinction between orbitals. As an example, in the transition elements, where the 3d level is only partially filled and is energetically similar to the 3p levels, a weak forbidden transition (the β_5) is observed. The satellite lines arising from dual ionizations form the third type. Following the ejection of the initial electron in the photoelectric process, a short, but finite, period of time elapses before the vacancy is filled. This time period is called the *lifetime* of the excited state. For the lower atomic number elements, this lifetime increases to such an extent that there is a significant probability that a second electron can be ejected from the atom before the first vacancy is filled. The

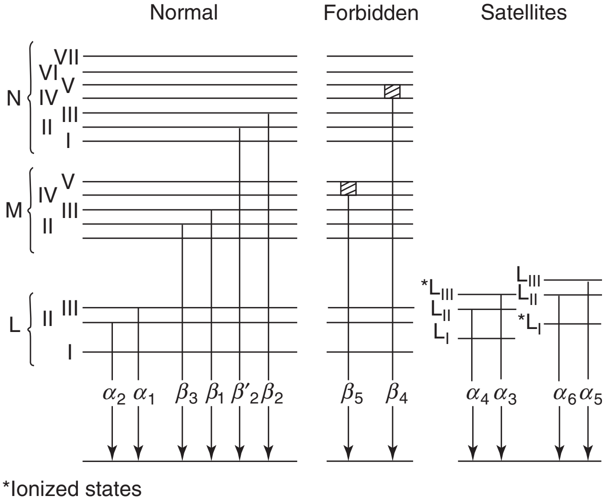

Figure 14.8 Observed lines in the K series.

loss of the second electron modifies the energies of the electrons in the surrounding subshells, and thus X-ray emission lines with other energies are produced. For example, instead of the Kα_1/Kα_2 line pair, a double ionized atom will give rise to the emission of satellite lines such as the Kα_3/Kα_4 and the Kα_5/Kα_6 pairs. As they are relatively weak, neither forbidden transitions nor satellite lines have great analytical significance; however, they may cause some confusion in the qualitative interpretation of spectra and may sometimes be misinterpreted as being analytical lines of trace elements.

14.2.7
Figures-of-Merit for XRF Spectrometers

14.2.7.1 Analytical Sensitivity

When XRF analysis of thin-film samples is performed (i.e., in samples where the product ρd of sample thickness d and sample density ρ is so small that absorption of the incoming exciting and of the outgoing fluorescent radiation in the material can be neglected – see Section 14.4), there is a linear relation between the collected net X-ray intensity N_{i} of a given characteristic line of element i and the irradiated mass m_i, which usually is also proportional to the concentration c_i of that element in the sample:

$$N_i = S_i^* \cdot m_i \cdot t = S_i \cdot c_i \cdot t \tag{14.8}$$

The proportionality constants S_i for the various elements are called the *sensitivity coefficients* of the XRF spectrometer for determination of these elements (expressed in counts per second per gram per cubic centimeter) and are important figures-of-merit of the instrument. In Figure 14.9, the variation with the atomic number of the sensitivity of a WDXRF spectrometer is plotted, for the case where either the

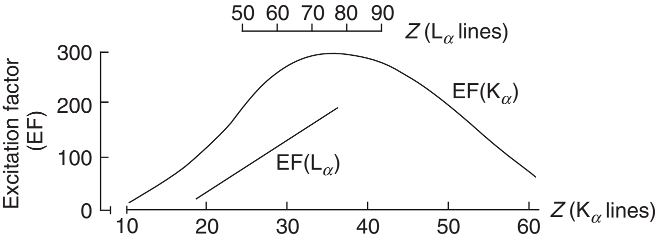

Figure 14.9 Variation in sensitivity coefficients with atomic number for a WDXRF spectrometer.

K_α ($10 < Z_i < 60$) or L_α ($40 < Z_i < 80$) peak intensities are used as analytical signals. By a selection of the excitation conditions (tube anode material, excitation voltage), the shape and location of the maximum in the sensitivity curve can be influenced to suit the needs of the application at hand.

Instead of using the X-ray intensity collected during a specific time t, it is often more convenient to use the net X-ray count rate R_i:

$$R_i = \frac{N_i}{t} = S_i \cdot c_i \tag{14.9}$$

14.2.7.2 **Detection and Determination Limits**

In reality, it is not possible to directly measure the net peak intensity N_i; rather, a total intensity $T_i = N_i + B_i$ is measured (see also Figure 14.27). The background intensity B_i can be written as the sum of various contributions:

$$B_i = B_i^{\text{scatter}} + B_i^{\text{detector}} + \sum_{j \neq i} B_{i,j}^{\text{overlap}} + B_i^{\text{blank}} \tag{14.10}$$

where B_i^{scatter} denotes the contribution to the spectral background below the analytical line of element i due to scattering of the primary radiation in the sample itself, in the sample environment gas (air or Helium, if any) and (in some cases) on the sample holder materials. These phenomena cause a continuous background upon which the characteristic peaks are superimposed. B_i^{detector} denotes the background contribution in the same energy/wavelength region due to detector artifacts, $B_{i,j}^{\text{overlap}}$ is the contribution to the peak intensity resulting from unresolved overlap between lines of an element $j \neq i$ and the analytical line of element i, and B_i^{blank} denotes the contributions to the peak intensity of element i not originating from the sample, that is, a blank value.

When the magnitude of B_i is experimentally determined and this measurement is repeated n times, the results will be distributed around a mean value $<B_i>$ with a standard deviation s_B. In modern instruments, most sources of systematic and random errors (e.g., due to mechanical or electrical instabilities) are small compared to the inherent uncertainty on the intensity measurements resulting from counting statistics. When B_i is obtained by means of a counting procedure (which usually is the case), Poisson (or counting) statistics govern the measurements so that $s^2{}_B = <B_i>$.

The IUPAC defines the limit of detection as "the lowest concentration level than can be determined to be statistically significant from an analytical blank." The lowest net X-ray intensity $N_{i,\mathrm{LD}}$ that still can be distinguished in a statistically significant manner from the average background level can be written as

$$N_{i,\mathrm{LD}} =< B_i > + k s_\mathrm{B} \tag{14.11}$$

where k is an integer constant depending on the significance level considered.

The limit of detection concentration $c_{i,\mathrm{LD}}$ corresponding to $N_{i,\mathrm{LD}}$ can be written as

$$c_{i,LD} = \frac{N_{i,LD} - \langle B_i \rangle}{S_i \cdot t} = \frac{k s_\mathrm{B}}{S_i \cdot t} = \frac{k\sqrt{R_\mathrm{B}}}{S_i \cdot \sqrt{t}} \tag{14.12}$$

where $R_\mathrm{B} = <B_i>/t$ is the background count rate. When the irradiation of a standard sample (with known concentration c_i) during a time t results in net and background intensities N_i^{std} and B_i^{std}, so that the sensitivity S_i can be approximated by the ratio $N_i^{\mathrm{std}}/c_i^{\mathrm{std}}/t$, it follows that the lowest detectable concentration (or relative detection limit) $c_{i,\mathrm{LD}}$ can be estimated from this measurement by using the relation:

$$c_{i,\mathrm{LD}} \cong c_i^{\mathrm{std}} \frac{k\sqrt{B_i^{\mathrm{std}}}}{N_i^{\mathrm{std}}} \tag{14.13}$$

When, during such an experiment, a known mass m_i^{std} was irradiated, the lowest detectable mass (or absolute detection limit) $m_{i,\mathrm{LD}}$ can be calculated by means of

$$m_{i,\mathrm{LD}} \cong m_i^{\mathrm{std}} \frac{k\sqrt{B_i^{\mathrm{std}}}}{N_i^{\mathrm{std}}} \tag{14.14}$$

Relative detection limits are useful figures-of-merit for bulk XRF equipment, where it usually is relevant to know the lowest concentration level at which the spectrometer can be used for qualitative or quantitative determinations. In instruments where very small sample masses are being irradiated (e.g., in the picogram range for microscopic X-ray fluorescence (μ-XRF) and total-reflection X-ray fluorescence (TXRF)), the absolute detection limit is another useful figure-of-merit as it provides information on the minimal sample mass than can be analyzed in a given setup.

In the literature, usually detection limit values for $k = 3$ (corresponding to a statistical confidence level of 99%) are reported. A related figure-of-merit is the *determination limit*, which is defined as the lowest concentration (or mass) at which a quantitative determination with a relative uncertainty of at least 10% is possible. This quantity can be calculated by setting $k = 10$ in the given expressions.

In Table 14.3, as an example, relative LD values for trace elements obtained by means of WDXRF in different matrices are listed. In Figure 14.10, a plot of typical absolute LD values for TXRF spectrometers is shown.

Table 14.3 WDXRF-obtained relative detection limits ($\mu g\,g^{-1}$) in various matrix and using different instruments.

14.3
Instrumentation

While most of the early work in X-ray spectrometry was carried out using electron excitation, the present-day use of electron-excited X-radiation is restricted mainly to X-ray spectrometric attachments to electron microscopes. Most modern stand-alone X-ray spectrometers use X-ray excitation sources rather than electron excitation. All conventional X-ray spectrometers comprise three parts: the primary source unit, the spectrometer itself, and the measuring electronics.

XRF spectrometry typically uses a polychromatic beam of short-wavelength/high-energy photons to induce the emission of longer wavelength/lower energy characteristic lines in the sample to be analyzed. Modern X-ray spectrometers may use either the diffracting power of a single crystal to isolate narrow *wavelength* bands (WDXRF) or an energy-selective detector may be employed to isolate narrow *energy* bands (EDXRF) from the polychromatic radiation (including characteristic radiation) that is produced in the sample.

Because the relationship between emission wavelength and atomic number is known, isolation of individual characteristic lines allows the unique identification of

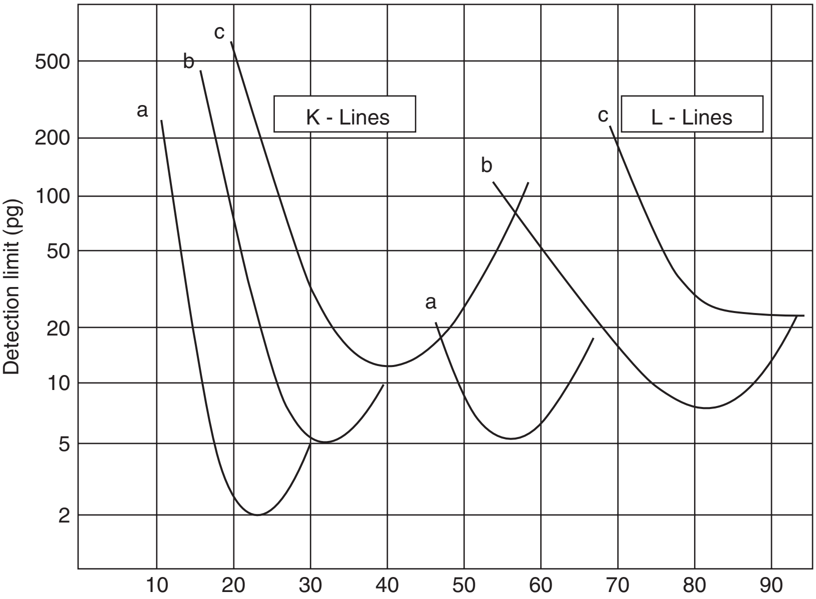

Figure 14.10 Typical absolute detection limit values for TXRF spectrometers. The labels a–c refer to different instrument settings.

an element to be made and elemental concentrations can be estimated from characteristic line intensities. Thus, this technique is a means of material characterization in terms of chemical composition.

WDXRF instrumentation is almost exclusively used for (highly reliable and routine) bulk analysis of materials, for example, in industrial quality control laboratories. In the field of EDXRF instrumentation, next to the equipment suitable for bulk analysis, several important variants have evolved in the past 20 years. Both TXRF and micro-XRF are based on the spatial confinement of the primary X-ray beam so that only a limited part of the sample (+support) is irradiated. This is realized in practice by the use of dedicated X-ray sources, X-ray optics, and irradiation geometries.

14.3.1
X-ray Sources

Four different types of X-ray sources are being employed in X-ray analysis: (i) sealed X-ray tubes and (ii) radioactive sources are the most commonly employed, while to a lesser extent primary X-rays produced in (iii) rotating anode tubes, and (iv) synchrotron radiation (SR) facilities are also utilized for analytical purposes.

Most commercially available X-ray spectrometers utilize a sealed X-ray tube as an excitation source, and these tubes typically employ a heated tungsten filament to induce the emission of thermionic electrons in a vacuum chamber. After acceleration by means of a high voltage V, the electrons are directed toward a layer of high purity metal (e.g., Cr, Rh, W, Mo, Rh, and Pd) that serves as the anode. In the metal layer, a *bremsstrahlung* continuum is produced, onto which the characteristic lines of the anode material are superimposed. The broad band radiation is well suited for the excitation of the characteristic lines of a wide range of atomic numbers. The higher the atomic number of the anode material, the more intense is the beam of radiation produced in the tube. Figure 14.11 shows a schematic cross section of a sealed X-ray tube.

In typical X-ray tubes employed in XRF spectrometers, accelerating voltages of 25–50 kV are used, while electron currents in the range 20–50 mA are employed. For WDXRF, frequently, 3 kW X-ray tubes are used; in EDXRF spectrometers, depending on the manner of sample excitation, tubes in the 50–1000 W range are employed. The efficiency of an X-ray tube is relatively low: only about 1% of the electric power is converted into X-rays, the rest is dissipated as heat. Accordingly, the tube anode of high-power tubes (>100 W) usually is water cooled to about meltdown of the metal block. A key factor in the design of an X-ray tube is the maximum powder loading (expressed in W mm^{-2}) it can stand. The high-voltage power supplies used together with X-ray tubes are highly stable so that a wide conical X-ray beam of nearly constant intensity (to within a small percentage relative) is emitted. For applications requiring higher power levels as 3 kW, rotating rather than fixed anode tubes are employed. In these devices, the anode is a fast-spinning water-cooled metal cylinder covered with the desired anode material. During each revolution of the anode, only a small area on the surface is bombarded by the electrons in a short fraction of the time, so that the rest of the period can be used for heat removal. Rotating anode tubes that can be operated up to a total power of 18 kW are commercially available.

The emission spectrum of an X-ray tube (Figure 14.6) consists of two components: a *bremsstrahlung* continuum upon which the characteristic lines of the anode material (that becomes ionized as a result of the electron bombardment) are

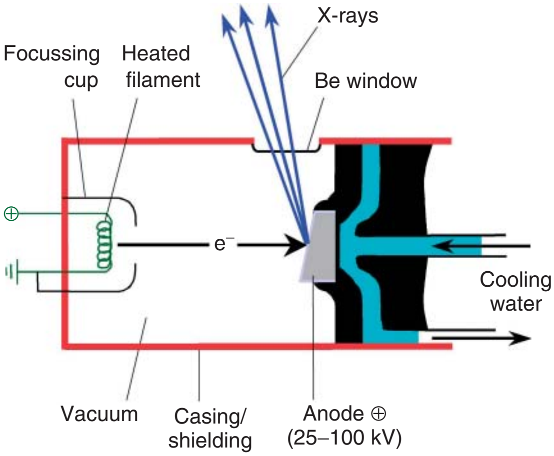

Figure 14.11 Cross section of a sealed X-ray tube.

superimposed. The shape of the emission spectrum can be modified by changing the electron acceleration voltage.

Radioactive α-, β-, and γ-sources may also be employed for (ED)XRF analysis. Generally, these sources are compact compared to X-ray tubes and can, for example, be used in portable analysis systems. α-sources are suited for the analysis of low atomic number elements. Frequently used sources are ^{244}Cm, with a half-life ($t_{\frac{1}{2}}$) of 17.8 years that emits 5.76 and 5.81 MeV α-particles, and ^{210}Po, having a half-life of 138 days and emitting 5.3 MeV α's.

β-sources can also be employed, either for direct EDXRF excitation of a sample or for producing *bremsstrahlung* radiation in a target to be used for subsequent sample excitation. ^{22}Na ($t_{\frac{1}{2}} = 2.6$ years), ^{85}Kr ($t_{\frac{1}{2}} = 10.7$ years), and ^{63}Ni ($t_{\frac{1}{2}} = 100$ years) are β-emitters that can be used for the former purpose, emitting, respectively, β^--particles of about 550, 670, and 66 keV. For *bremsstrahlung* production, ^{147}Pm ($t_{\frac{1}{2}} = 2.6$ years, 225 keV) in combination with a Zr target and ^{3}H ($t_{\frac{1}{2}} = 12.4$ years, 19 keV, Ti target) are useful.

In Table 14.4, some characteristics of radio sources emitting X-ray or γ-ray lines are listed. The X-ray emitting sources usually contain nuclides that decay by means of the electron-capture mechanism. During the decay, an inner-shell electron is captured by the neutron-deficient nucleus, transforming a proton in a neutron. This results in a daughter nuclide that has a vacancy in one of its inner shells, which results in the emission of corresponding characteristic radiation. For example, when a ^{55}Fe-nucleus (26 protons and 29 neutrons) captures a K-electron and becomes a ^{55}Mn nucleus, a Mn K-$L_{3,2}$ (Mn-K_α) or K-$M_{3,2}$ (Mn-K_β) photon will be emitted. Other sources (such as ^{241}Am or ^{57}Co) emit γ-rays of suitable energy as a result of different nuclear transformations.

In Figure 14.12, the range of elements that can be usefully analyzed by means of various radioactive and X-ray tubes sources is summarized.

In a number of specialized cases, XRF experiments also make use of synchrotron sources. SR is produced by high-energy (GeV) relativistic electrons or positrons circulating in a storage ring. This is a very large, quasi-circular vacuum chamber where strong magnets force the particles on closed trajectories. X-radiation is produced during the continuous acceleration (change in velocity vector in this case) of the particles. SR sources are several (six to twelve) orders of magnitude more

Table 14.4 Radioactive sources used for XRF analysis (flux in photons/s/sr).

Radio isotope	Half-life (years)	X-ray or γ-ray energy (keV)	Flux
^{55}Fe	2.7	5.9–6.5 (Mn-K X-rays)	7×10^6
^{244}Cm	88	14.6–22 (U L X-rays)	—
^{109}Cd	1.3	22–25 (Ag K X-rays)	8×10^6

^{241}Am	433	59.6 (γ-ray)	6×10^7
^{153}Gd	0.66	41.48 (Eu-K X-rays)	4×10^8
^{57}Co	0.74	122.136 (γ-ray)	4×10^6

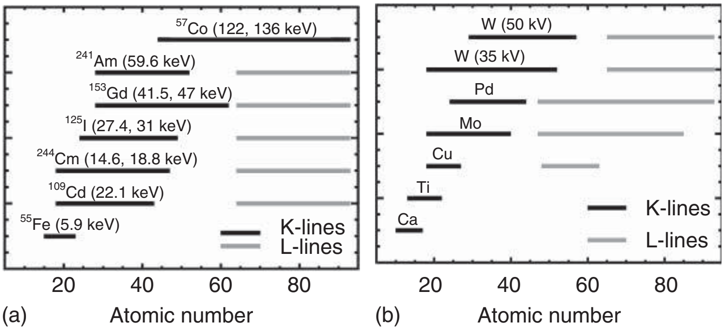

Figure 14.12 Range of elements that can be analyzed using (a) radioactive sources and (b) X-ray tubes with different anodes, showing excitation of K- and L-lines.

bright than X-ray tubes, have a natural collimation in the vertical plane, and are linearly polarized in the plane of the orbit. The spectral distribution is continuous or shows sharp maxima at a limited number of energies, called *harmonics*. By monochromatization of the continuum or by selection of one of the harmonics, it is possible to employ selective excitation of a series of elements in the sample, yielding optimal detection conditions (see subsequent text – TXRF). Because the SR originates from a source point of small dimensions and is released in a very narrow angular range, it is easily focusable into micro- and/or nanobeam (see subsequent text – micro-XRF). An additional advantage is the high degree of polarization of SR, causing spectral backgrounds due to scatter to be greatly reduced when the detector is placed at 90° to the primary beam and in the storage ring plane. The combination of a high primary beam intensity and a low spectral background causes DL values of SRXRF to go down to the parts per billion level (see, e.g., Figure 14.24).

14.3.2
X-ray Detectors

As any radiation detector, an X-ray detector is a transducer for converting X-ray photon energy into easily measurable and countable voltage pulses. All detector types work through a process of photoionization, in which interaction between the entering X-ray photon and the active detector material produces a number of electrons. By means of a capacitor and a resistor, the current produced by the electrons is converted to a voltage pulse, in such a way that one digital voltage pulse is produced for each X-ray photon that enters the detector.

Next to being sensitive to photons of the appropriate energy range, there are two other important properties that the ideal detector should possess: proportionality and linearity. A detector is said to be proportional when the height of the voltage pulse that is produced upon entry of a photon is proportional to the energy of the photon. Proportionality is needed when, through pulse-height selection, only pulses of a particular height, that is, corresponding to X-ray photons within a specific energy band, are to be measured.

When the rate with which voltage pulses are being recorded is the same as the rate with which X-ray photons enter the detector, the latter is said to have a linear response. This property is important when the recorded count rates of various X-ray lines are to be used as measures of the photon intensities of these lines produced in a sample.

The detector resolution is the precision/repeatability with which the energy of a specific type of X-ray photons (e.g., the Mn-K_α-line at 5.9 keV) can be determined and is therefore a measure of the capability of the detector to distinguish between X-rays of very similar energy but different origin (e.g., the As-$K_{\alpha 1}$-line at 10.543 keV and the Pb-Lα1-line at 10.549 keV).

In WD spectrometers, gas-flow proportional counters (for long wavelengths, $\lambda > 0.2$ nm) and scintillation counters (for wavelengths shorter than 0.2 nm) are used to count X-rays. Both types of detectors usually are combined in a tandem detector that covers the entire wavelength range used in WDXRF spectrometry. As neither of these detectors has sufficient resolution to separate multiple wavelengths/energies on its own, they are employed together with an analyzing crystal. In case of ED spectrometry, solid-state detectors of higher resolution are used.

A gas-flow proportional counter (Figure 14.13a) consists of a cylindrical tube about 2 cm in diameter, carrying a thin (25–50 mm) wire along its radial axis. The tube is filled with a mixture of inert gas and quench gas – typically 90% argon/10% methane (P-10). The cylindrical tube is grounded and a voltage of about 1400–1800 V is applied to the central wire. The wire is connected to a resistor shunted by a capacitor. An X-ray photon entering the detector produces a number of ion pairs (n), each comprising one electron and one Ar^+ ion. The first ionization potential for argon is about 16 eV, but competing processes during the conversion of photon energy to ionization cause the average energy required to produce an ion pair to be greater than this amount. The fraction relating the average energy to produce one ion pair, to the first ionization potential, is called the *Fano factor F*. For argon, F is between 0.5 and 0.3 and the average energy ε required to produce one primary ion pair is equal to 26.4 eV. The number of ion pairs produced by a photon of energy E will equal:

$$n = \frac{E}{\varepsilon} \tag{14.15}$$

Following ionization, the charges separate, with the electrons moving toward the (anode) wire and the argon ions to the grounded cylinder. As the electrons approach the high-field region close to the anode wire, they are accelerated sufficiently to produce further ionization of argon atoms. Thus, a much larger number N of electrons will actually reach the anode wire. This effect is called *gas gain* or *gas multiplication*, and its magnitude is given by $M = N/n$. For gas-flow proportional counters used in X-ray spectrometry, M typically has a value of around 10^5. Provided that the gas gain is constant, the size of the voltage pulse V produced is directly proportional to the energy E of the incident X-ray photon. In practice, not all photons arising from photon energy E will be exactly equal to V. There is a random process associated with the production of the voltage pulses and the resolution of a

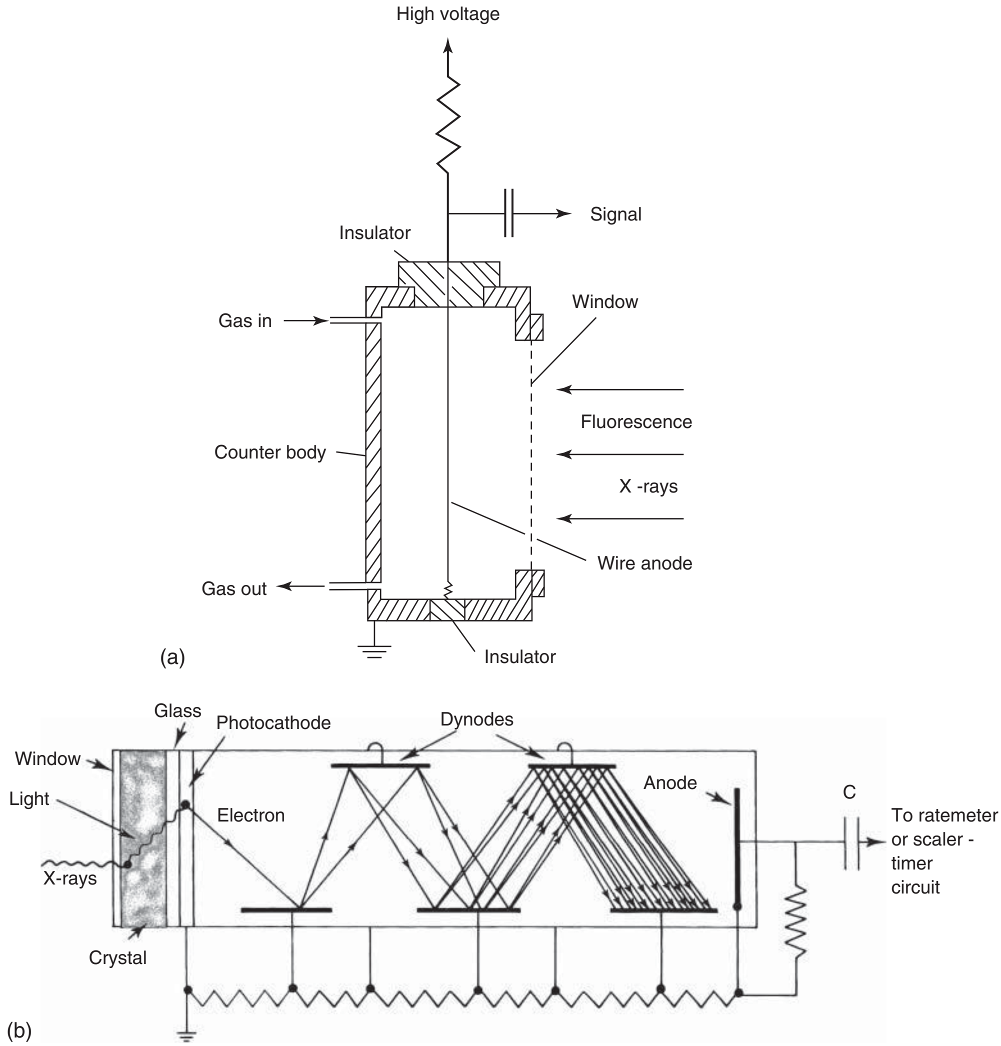

Figure 14.13 Schematic drawings of (a) a gas-filled proportional counter and (b) a scintillator detector.

counter is related to the variance in the average number of ion pairs produced per incident X-ray photon.

While the gas-flow proportional counter is ideal for measurement of longer wavelengths, it is rather insensitive to wavelengths shorter than about 0.15 nm. For this shorter wavelength region, it is common to use a scintillation counter (Figure 14.13b). The scintillation counter consists of two parts, the phosphor (scintillator) and the photomultiplier. The phosphor is typically a large single crystal of sodium iodide that has been doped with thallium, denoted as a NaI(Tl) crystal. When X-ray photons fall onto the phosphor, blue light photons are produced (with a wavelength of 410 nm), where the number of blue light photons is related to the energy of the incident X-ray photon. These visual light photons produce electrons by interaction with the surface of the photocathode in the photomultiplier, and the number of electrons is linearly increased by a series of secondary surfaces, called *dynodes*, inside the photomultiplier. The current produced by the photomultiplier is then converted to a voltage pulse, as in the case of the gas-flow proportional counter. As the number of electrons is proportional to the energy of the incident X-ray photon, the scintillation counter also has a proportional response. Because of inefficiencies in the X-ray/visual light/electron conversion processes, the average energy to produce a single event within a scintillation counter is more than a magnitude greater than the equivalent process in a flow counter. For this reason, the resolution of scintillation counters is much worse than that of flow counters.

The output pulses produced by both the above-mentioned detectors are further processed by a linear amplifier and a discriminator circuit. Usually the number of pulses is counted during a preset amount of time and the accumulated counts stored in computer memory for display and further processing. The processing of an X-ray event by the detector and its associated electronics takes a finite amount of time. After the arrival of one X-ray, the detection system is said to be ''dead'' during this length of time because X-rays arriving within this dead period will not be counted. The dead time is of the order of 200–300 ns after the arrival of each photon; this implies that count rates up to 10^6 photons per second can be handled.

The detectors used in the various forms of EDXRF are semiconductor detectors. Conventionally, two types, that is, lithium-drifted silicon (Si(Li)) and hyperpure germanium (HPGe) detectors are used. Their main advantages are their compact size, the nonmoving system components, and relatively good energy resolution, which optimally is of the order of 120 eV at 5.9 keV. Because of their operation principles, these detectors have an inherent simultaneous multielement capacity, which leads to a short measuring time for all elements as the detectors select the energy and collect counts at the same time. Disadvantages include the need for liquid nitrogen (LN_2) cooling during operation, the necessity of having a relatively thin (8–25 μm) Be window and the fact that the maximum processable number of counts is limited to about 40.000 cps. This figure can be increased to 100 000 cps, but with loss of optimal performance characteristics.

The detector crystal itself is a disk of very pure Si or Ge with dimensions of 4–10 mm diameter and 3–5 mm thickness. Even careful production of the Si ingots the disk are cut from will still leave some trace impurities in the Si lattice. To compensate for and bind all free electrons, lithium ions are drifted (allowed to diffuse at elevated temperature) into the silicon crystal to neutralize the Si crystal defects in a particular zone, the so-called intrinsic zone. Afterwards, Au contacts are evaporated onto the crystal and a reverse voltage applied. In the crystal, the energy difference ε (band gap) between the valence and conduction band is 3.8 eV. At room temperature, the conduction band is partially populated so that the crystal is a (semi)conductor. To keep the leakage current as low as possible, the crystal is cooled with LN_2 by placing it in a vacuum cryostat. At $-196\,^{\circ}$C, almost all electrons remain in the valence band. The radiation to be measured needs to enter the cryostat through a thin entrance window, usually made of Be. By applying a reverse voltage to the charge-carrier-free intrinsic zone, an absorbed X-ray photon is converted into charge by ionization. Electrons are promoted from the valence to the conduction band, leaving ''positive holes'' in the valence band; thus, the crystal temporarily becomes conducting. $n = E/\varepsilon$ of electron–hole pairs are created. The electrons and holes are quickly swept to the contact layers by the electric field created by the applied reverse bias on the crystal.

Figure 14.14 shows the operation principle schematically. The charge induces a signal at the gate of a cooled field-effect transistor (FET) that is the input stage of a charge-sensitive preamplifier. The output signal is fed to a pulse processor that shapes the pulse and amplifiers it further. This signal is in the range up to 10 V and is proportional to the energy of the absorbed photon. The pulse height is digitized by means of an analog-to-digital converter (ADC) and the resulting digital value stored in a multichannel analyzer (MCA). This is an array of memory cells called *channels*; by using the digital value associated with a single event as address offset into the memory array, the content of the appropriate channel is incremented with one count. Thus, all detector events having the same pulse height are stored in the same channel. For example, upon entry in the detector of a Cu-K$_{\alpha1}$ photon ($E = 8.05$ keV), 2117 electron–hole pairs will be generated, which may lead to the formation of a preamplifier voltage pulse of, for example, 42.0 mV. After further amplification and shaping, this is converted into a bell-shaped pulse of 4.20 V; the pulse height is then digitized by an ADC, resulting, for instance, in a digital number of 420. Ultimately, this causes the content of channel 420 to be incremented with one count. After readout, the MCA memory (typically 1024 or 2048 channels in size, each corresponding to a 10–20 eV wide energy range)

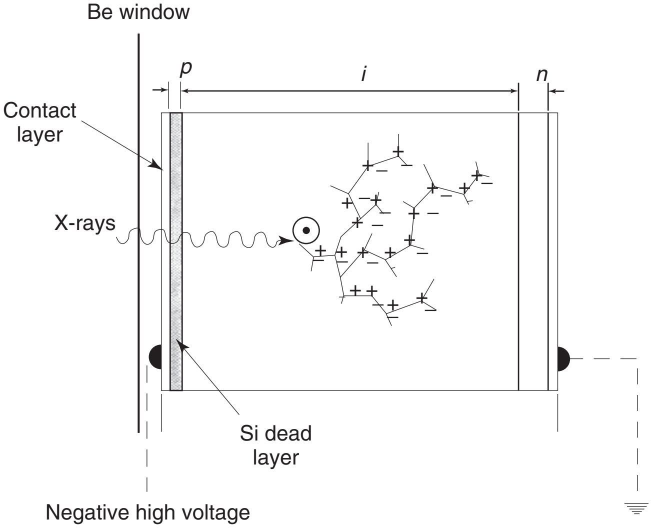

Figure 14.14 Scheme of the working principle of a Si(Li) detector.

yields a pulse-height distribution of the detected events or an ED X-ray spectrum, as shown in Figure 14.15.

In the spectra, a broadening of the X-ray lines can always be observed, that is, the counts associated with photons of a specific energy, which normally should end up in a single channel, are distributed in a quasi-Gaussian manner over several adjacent channels in the spectrum, thus giving rise to a bell-shaped X-ray peak in the spectrum. This line broadening is caused by statistical fluctuations in the number of electron–hole pairs created when an X-ray photon of a given energy enters the detector; electronic noise in the amplifiers causes the uncertainty on the pulse height to increase further. Even under conditions in which all noise contributions in the electronics are minimized, the line broadening remains a significant phenomenon, causing a frequent peak overlap to occur in X-ray spectra, for example, between lines of adjacent elements such as the Mn-K_β and Fe-K_α peaks. The resolution of ED detectors conventionally is expressed as the full width at half maximum (FWHM) of the Mn-K_α (Mn K-$L_{2,3}$) peak (at 5.98 keV) and typically is around 150 eV. In the most optimal case, this value can be also as low as 120 eV. The time to process an X-ray event (dead time) is of the order of 10–30 μs; conventional EDXRF spectrometers can therefore only operate at count rates up to 40 000 cps. In view of the presence of a Be window in the detector cryostat, X-ray photons below 2 keV are hard to detect in a conventional Si(Li) detector, although thin-window models are commercially available.

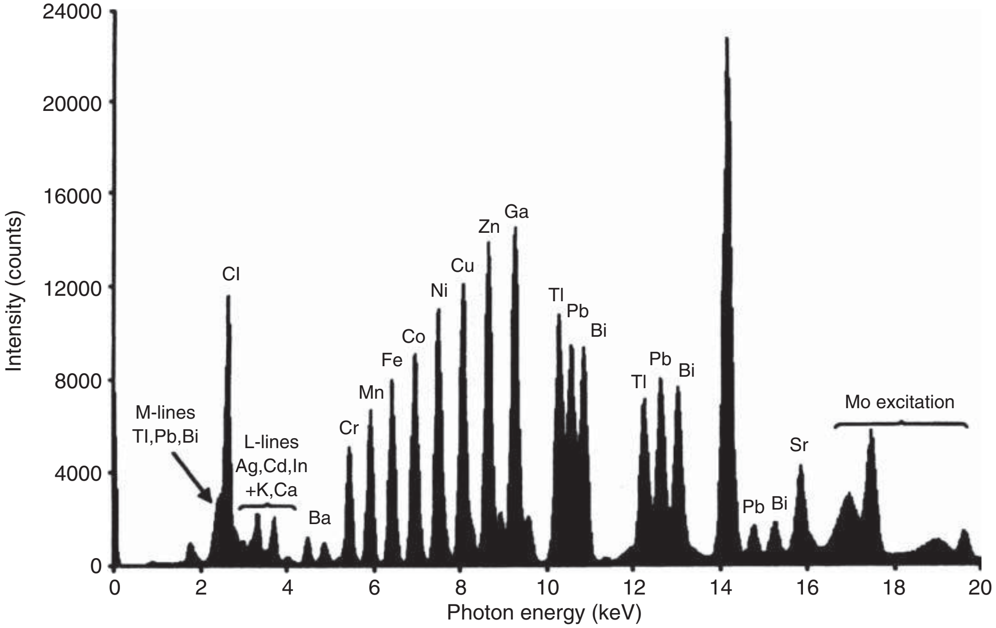

Figure 14.15 Energy-dispersive XRF spectrum of a multielement standard, obtained in a TXRF spectrometer.

Roughly since 1995, several types of compact and thermoelectrically cooled ED detectors have become available. The most significant advantage of these detectors is that they do not require LN_2 cooling, allowing the instrument they are incorporated in to be much smaller. These types of detectors are suitable for employment in portable equipment.

Thermoelectrically cooled Si-PIN, $Cd_{1-x}Zn_xTe$ (CZT), and HgI_2 detectors are fairly inexpensive devices. The currently available Si-PIN diode detectors mostly have a thickness of about 300 μm, which makes the detector useful up to X-ray energies of 20 keV and an energy resolution in the range of 180–200 eV at Mn-K_α, that is, slightly worse than that of Si(Li) or HPGe detectors. Some versions with 500 μm thickness or larger active areas (up to 25 mm^2 vs the standard 5–10 mm^2) are available as well. CZT detectors are targeted toward the higher energy range with a thickness of up to 2 mm and allow efficient detection of X-rays up to 150 keV with a resolution of about 250 eV at Mn-K_α (5.9 keV) and 1 keV at 60 keV. Similarly, HgI_2 detectors (with thicknesses of a few millimeters) can also be used in this range with a resolution of about 200 eV at Mn-K_α.

A high-quality type of solid-state detector is the solid-state drift (SSD) chamber detector, featuring excellent energy resolution at high count rates. An FWHM below 140 eV at 5.9 keV can be achieved by means of thermoelectrical cooling (Peltier effect). SSDs exist in a large variety of sizes up to 2 cm^2 diameter. They still show adequate spectroscopical behavior at count rates as high as several million counts per centimeter square per second. The compact design, the relatively low price, the absence of the need for LN_2 for cooling, the high count rate capability and the nonsensitivity to noise pickup make these systems attractive alternatives to conventional semiconductor detectors.

The resolution of a number of different X-ray detectors in the range 1–100 keV (about 1–0.01 nm) is compared in Figure 14.16. It is clear that scintillators and proportional counters are not even able to separate the K_α-lines of adjacent elements, whereas this is the case for most of the solid-state detectors.

14.3.3
Wavelength-Dispersive XRF

A typical WDXRF system consists of an X-ray tube, a specimen support holder, a primary collimator, an analyzing crystal, and a tandem detector. The typical WDXRF irradiation/detection geometry is shown in Figure 14.17. WD spectrometers employ diffraction by a single crystal to separate characteristic wavelengths emitted by the sample. A single crystal of known interplanar spacing d is used to disperse the collimated polychromatic beam of characteristics wavelengths coming from the sample, such that each wavelength λ will diffract at a specific angle θ, given by Braggs law:

$$n\lambda = 2d\sin\theta \tag{14.16}$$

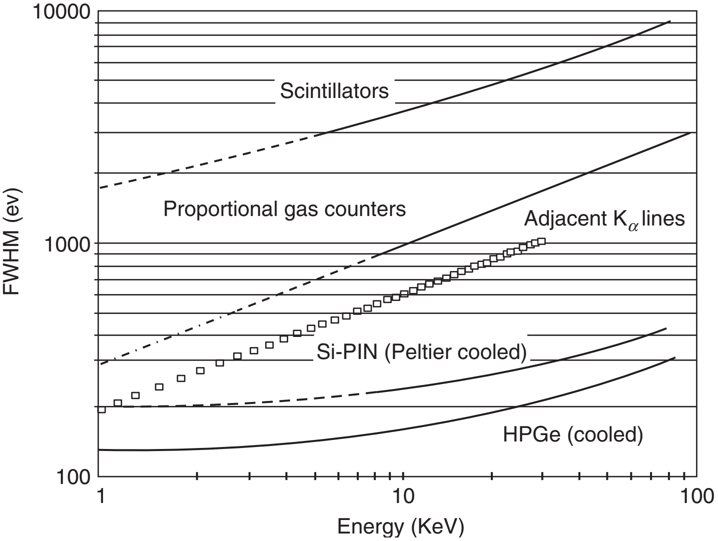

Figure 14.16 Energy resolution (expressed as FWHM of the K_α-line of a given energy), of different X-ray detectors in the 1–100 keV range. The difference in the K_α-line energy between adjacent elements is also shown (symbols).

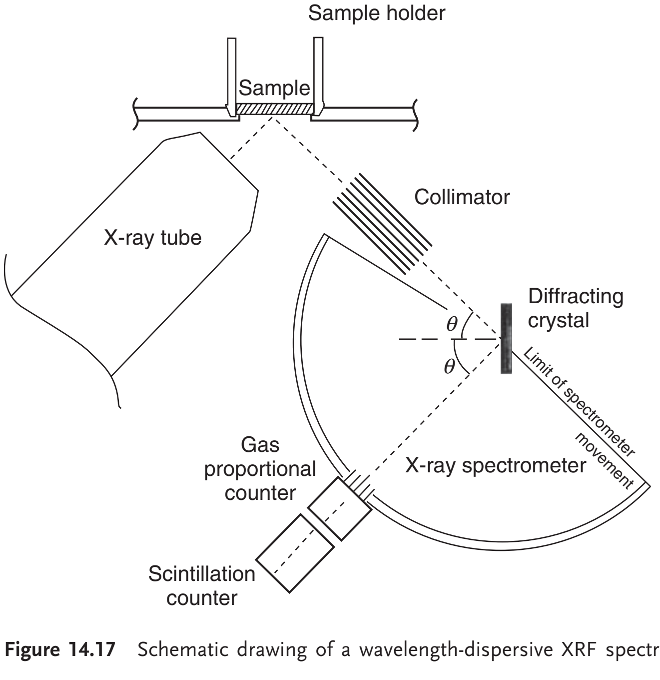

Figure 14.17 Schematic drawing of a wavelength-dispersive XRF spectrometer.

where n is an integer number denoting the order of the diffracted radiation. A goniometer is used to maintain the required $\theta/2\theta$ relationship between sample and crystal/detector.

Before impinging on the analyzer crystal, by means of a collimator or a slit, the spread in initial directions of the sample-to-crystal beam is limited. As the maximum achievable angle on a typical WDXRF spectrometer is around 73°, the maximum *wavelength* that can be diffracted by a crystal of spacing d is equal to about $1.9d$.

The angular dispersion $\mathrm{d}\theta/\mathrm{d}\lambda$ of a crystal with spacing $2d$ is given by

$$\frac{\mathrm{d}\theta}{\mathrm{d}\lambda} = \frac{n}{2d\cos\theta} \tag{14.17}$$

and is therefore inversely proportional to its d-spacing. Thus, high dispersion can only be obtained at the expense of reducing the wavelength range covered by a particular crystal. Several crystals therefore are likely to be employed for covering a number of analyte elements. Typically, four to six different analyzer crystals (with different d-spacings) and two different collimators are provided in this type of instrument, allowing for a wide choice in dispersion conditions. The smaller the d-spacing of the crystal, the better is the separation of the lines, but the smaller the wavelength range that can be covered. The separating power of the crystal spectrometer is dependent on the divergence allowed by the collimators (which mainly determine the width of the diffracted lines) in the 2θ spectrum, but the angular dispersion of the analyzing crystal itself and the intrinsic width of the diffraction lines also play a role.

In Table 14.5, some characteristics of a few commonly employed analyzer crystals are listed. Classically, large single crystals have been used as dispersive elements. For dispersion of long wavelengths (>0.8 nm), only a limited number of natural materials are available; the most commonly employed is thallium acid phthalate (TAP, $2d = 2.63$ nm), allowing measurement of the Mg-, Na-, F-, and O-K-lines. As an alternative, several other materials with large $2d$-spacings have been used and since the 1980s layered synthetic multilayers (LSMs) are in use. These consist of stacks of alternate electron-rich (e.g., W) and electron-poor (e.g., graphite) layers of atoms or molecules, deposited on a sufficiently smooth substrate. As the composition and interplanar distance of the LSM can, to a certain extent, be

Table 14.5 Analyzing crystals used in wavelength-dispersive X-ray spectrometry.

Crystal	Planes	2*d* (nm)	K-line range	L-line range
Lithium fluoride (LiF)	220	0.2848	>Ti	>La
Lithium fluoride (LiF)	200	0.4028	>K	>Cd
Pentaerythritol (PET)	002	0.8742	Al–K	—
Thallium acid phthalate (TAP)	001	2.64	F–Na	—
LSMs	—	5–12	Be–F	—

optimized for particular applications, a factor 4–6 improvement in peak intensities compared to TAP crystals can be achieved.

Among WD spectrometers, a distinction can be made between single-channel instruments and multichannel spectrometers. In the former type of instrument, a single dispersive crystal/detector combination is used to sequentially measure the X-ray intensity emitted by a sample at a series of wavelengths when this sample is irradiated with the beam from a high-power (2–4 kW) X-ray tube. In a multichannel spectrometer, many crystal/detector sets are used to measure many X-ray lines/elements simultaneously.

Single-channel instruments are also referred to as *scanning spectrometers*; this type is the most common. During an angular scan, the angle θ between sample and analyzer crystal is continuously varied; in order to maintain an identical angle between analyzer crystal and detector, the latter moves at the double angular speed as the crystal. In this manner, X-ray intensity versus 2θ diagrams are obtained. By means of tables, the recorded peaks can be assigned to the characteristic lines of one or more elements. In Figure 14.18, a typical 2θ spectrum obtained from a brass sample is shown.

Simultaneous WD spectrometers were introduced in the early 1950s, and sequential systems about a decade later. At this time, about 30 000 or so WD instruments have been supplied commercially. The two major categories of WD X-ray spectrometers differ mainly in the type of source used for excitation, the number of elements that they are able to measure at one time, the speed at which they collect data and their price range. For high-specimen throughput quantitative

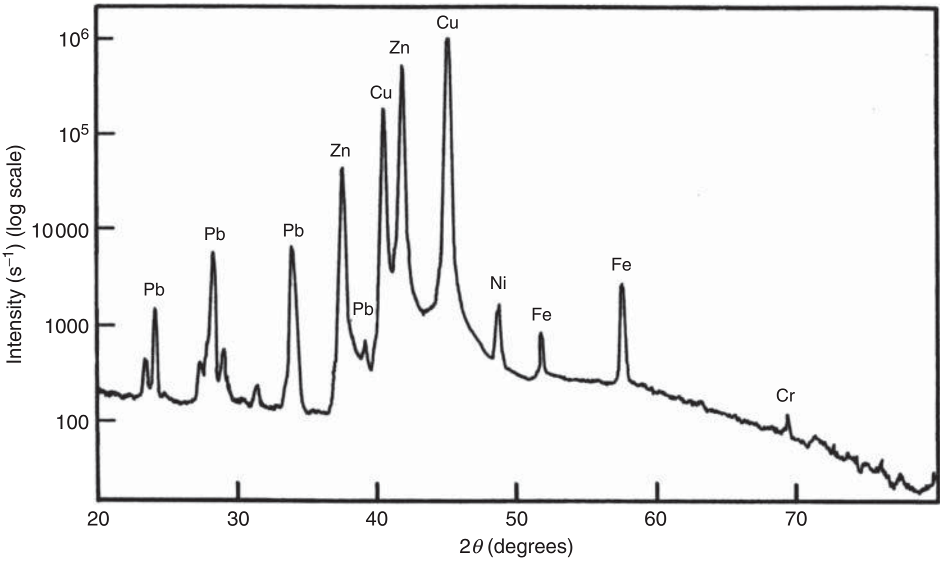

Figure 14.18 Wavelength-dispersive XRF of a brass sample recorded with a LiF analyzer crystal, showing the characteristic lines of the major elements Cu and Zn and the lines of Cr, Fe, Ni, and Pb superimposed on a continuous background.

analysis where speed is of the essence, and where a high initial cost can be justified, simultaneous WD spectrometers are optimal. For more flexibility, where speed is important but not critical and where a moderately high initial cost can be justified, sequential WD spectrometers are probably more suited. Both of the instruments are, in principle at least, capable of measuring all elements in the periodic classification from $Z = 9$ (F) and upwards, and most modern WD spectrometers can do some useful measurements down to $Z = 6$ (C). Both can be fitted with multiple sample-handling facilities and automated. Both are capable of precision of the order of a few tenths of 1% and both have sensitivities down to the parts per million level. Single-channel WD spectrometers are typically employed for both routine and nonroutine analysis of a wide range of products, including ferrous and nonferrous alloys, oils, slags and sinters, ores and minerals, and thin films. These systems are flexible but, relative to multichannel spectrometers, are somewhat slow. The multichannel WD instruments are used almost exclusively for routine, high-throughput analyses where there is need for fast accurate analysis, but where flexibility is of no importance.

14.3.4
Energy-Dispersive XRF

ED spectrometers became commercially available in the early 1970s, with the advent of high-resolution solid-state detectors; currently, there are of the order of 20 000 units in use. In principle, EDXRF instruments have a much simpler mechanical design than WDXRF instruments, as the detection system does not include any moving parts and the solid-state detector (most commonly a Si(Li) detector) itself acts as a dispersion agent. The high geometrical efficiency of the semiconductor detector permits a great variety in excitation conditions. The manner in which the radiation that originally exits from the X-ray tube is ‘‘pretreated’’ before it reaches the sample varies according to the type of EDXRF instrument. The final analytical capabilities and, in particular, the LD values that can be attained by the instrument strongly depend on the sophistication with which this is done.

In Figure 14.19a, the most simple of EDXRF instrumental configurations is shown. A low-power X-ray tube (e.g., 50 W) and a Si(Li) detector are both placed at an angle of 45° with respect to the sample. Collimators are used to confine the excited and detected beam to a sample area between 0.5 and 2 cm^2. In such a ‘‘direct-excitation’’ configuration, the distance between the components can be fairly small (typically a few centimeters) and as both the tube anode lines and the *bremsstrahlung* component of tube output spectrum are used to irradiate the sample, only a limited tube power is required. As the *bremsstrahlung* continuum not only ensures a uniform excitation of many elements but also causes a significant scatter background to be present in the recorded EDXRF spectra, most direct-excitation systems are equipped with a set of primary beam filters to alter the tube spectrum. By selection of an appropriate filter, the excitation conditions for a particular range of elements can be optimized. In order to facilitate the determination of low-Z

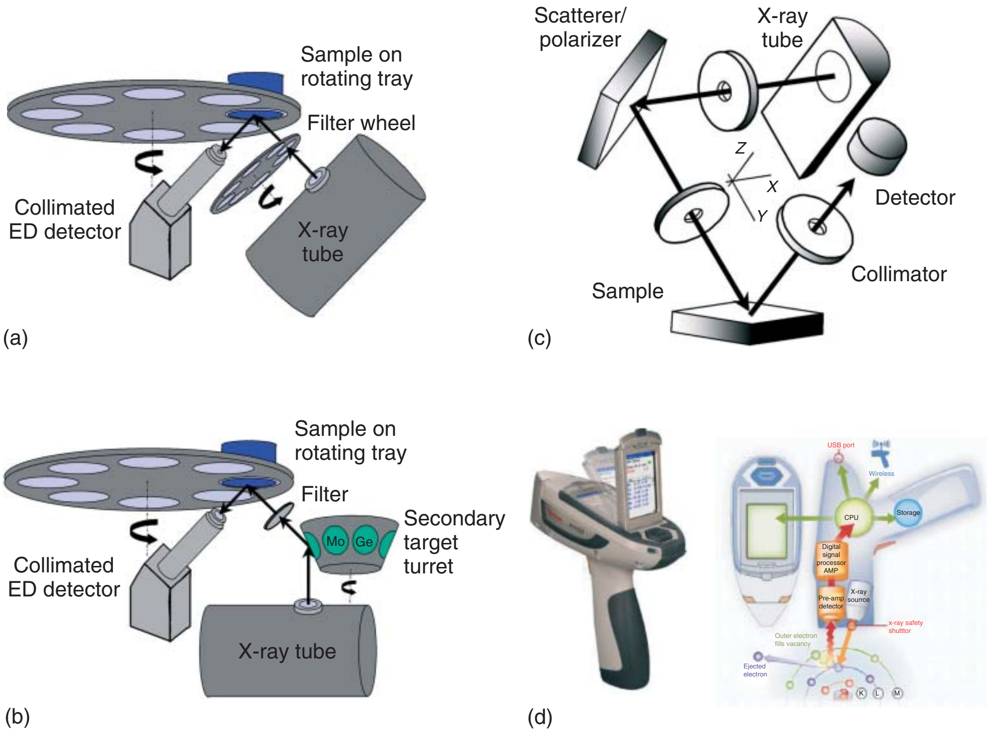

Figure 14.19 Schematic drawings of (a) a direct-excitation XRF instrument, (b) a secondary target XRF instrument, (c) a polarized XRF instrument employing a Cartesian (XYZ) irradiation geometry, and (d) a photograph a and schematic representation of a portable XRF device.

elements, commercial systems can be either evacuated or flushed with He, thus reducing the absorption of low-energy radiation and scatter.

The schematic of a ‘‘secondary target’’ EDXRF system is shown in Figure 14.19b. In such a configuration, a high-power (1 kW) X-ray tube irradiates a metal disk (the secondary target, e.g., made of Mo), causing it to emit its own characteristic radiation lines (Mo-K_α and Mo-K_β). This ‘‘bichromatic’’ fluorescent radiation is then used to excite the sample to be examined. The advantage of the secondary target scheme is that, as a result of the bichromatic excitation, the background in the resulting EDXRF spectra is significantly lower, as in the direct-excitation case. This leads to better detection limits. By using a filter that preferentially absorbs the K_β component of the secondary target radiation (e.g., a Zr foil in case of a Mo target), a quasi-monochromatic form of sample excitation can be realized. By interchanging the target (and matching filter), different element ranges can be excited optimally. For example, to obtain the best conditions for determination of trace concentrations of the elements Rb-Nb in geological samples, a Rh secondary target may be selected while for optimal detection of Cr in the same material, a Cu target would be more beneficial.

The ability to simultaneously measure a wide range of elements is one of the greatest advantages of EDXRF. This advantage is strongly reduced when the count rate limitation of the ED detection electronics is taken into consideration. This is due to simultaneous recording of the entire primary source radiation scattered on the specimen and is especially true for examinations on samples with light matrices.

The stationary arrangement of components used in EDXRF is ideally suited for geometrical configurations that exploit polarization phenomena to reduce background and thereby improve signal-to-noise ratios.

Figure 14.19c shows a configuration employed to achieve a reduction in the background level of EDXRF spectra obtained in direct-excitation conditions. In this case, one or more energy bands of the tube emission spectrum are scattered and/or diffracted under (nearly) 90° by means of a suitable scatterer material and/or diffraction crystal. Because scattering rather than fluorescence is used to ''reflect'' the primary tube spectrum onto the sample, the X-ray beam that impinges on the sample is linearly polarized in the plane perpendicular to the tube–scatterer–sample plane. When the Si(Li) detector is also positioned in the former plane at 90° relative to the scatterer–sample axis, the lowest background level will be recorded. The reason for this background reduction is that the polarized photons will preferentially be scattered out of the plane of polarization and therefore will not reach the detector. The optimal geometrical configuration is therefore that tube, scatterer, sample, and detector are arranged in an XYZ (also called ''*Cartesian*'') geometry, as shown in Figure 14.19c. For polarization of medium-to-hard radiation ($E > 10\,\mathrm{keV}$) by Barkla scattering, fairly thick slabs of low-Z materials such as Al_2O_3, B_4C, and B_3N are suitable materials. For polarization of softer radiation, the above-mentioned materials are not suitable given that for $E < 10\,\mathrm{keV}$, photoelectric absorption dominates over scattering. In the region 1–10 keV, radiation can be polarized through Bragg diffraction over $2\theta \approx 90^\circ$ by using a suitable crystal. For example, HOPG (highly oriented pyrolithic graphite) is an excellent Bragg polarizer for the (002) reflection of the Rh-L_α radiation ($\theta = 43.2^\circ$). Multiple-layer scatterers, for example, consisting of a thin layer of HOPG glued on top of an Al_2O_3 substrate, in combination with a Rh tube, are useful to determine a wide range of elements simultaneously with good detection limits and sensitivities.

In Figure 14.20, the spectra that result from direct-excitation, secondary excitation, and polarized direct excitation of a standard oil sample, containing 21 elements at the $30\,\mu\mathrm{g\,g}^{-1}$ level, are compared. The relative detection limits obtained from the three spectra are summarized in Table 14.6; they indicate that the DL values by means of polarized excitation are on average five times better than those determined by direct excitation. The secondary target results are factor 2.5 better than the polarized excitation values for elements efficiently excited by the Mo-Ka-line (e.g., Pb); however, elements such as Sn and Cd cannot be determined using the Mo secondary target, while they are well excited by the polarized *bremsstrahlung* radiation.

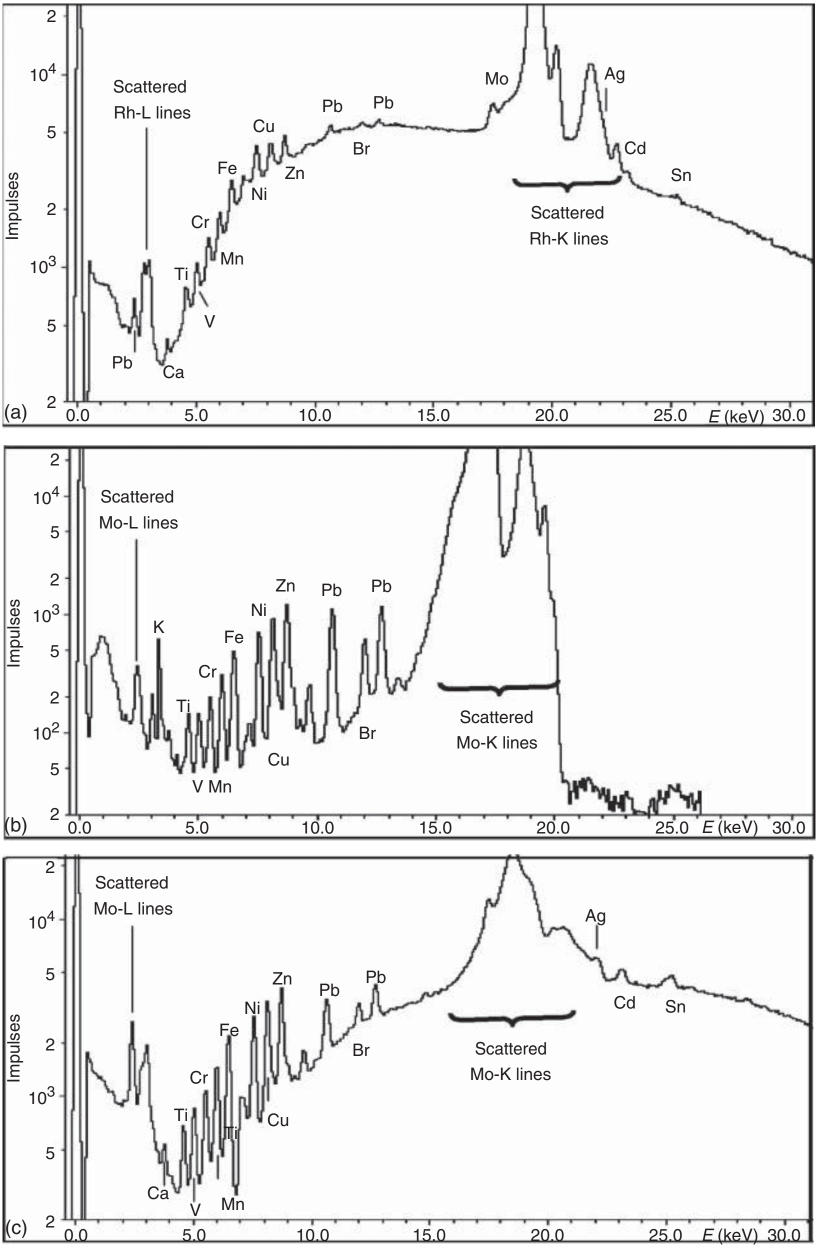

Figure 14.20 Comparison of EDXRF spectra of an oil standard containing 21 elements (e.g., Ca, Ti, V, Cr, Mn, Fe, Ni, Cu, Zn, Mo, Ag, Cd, Sn, Ba, and Pb) with concentrations of 30 μg g^{-1}. The spectra (log scale) are (a) nonpolarized, direct excitation by radiation from rhodium anode X-ray tube; (b) molybdenum secondary excitation; and (c) polarized excitation by scatter from a HOPG/Al_2O_3 target. The measuring time amounts 200 s for each spectrum. In all cases, a Rh end-window tube was used.

Table 14.6 Limits of detection (LD) (n.d. = not detectable), for some elements in base oil using direct excitation, monochromatic excitation using a Mo secondary target and direct excitation with linearly polarized X-rays (175 W for a measuring time of 200 s and a incident pulse density of about 60 000 cps).

Element	Limits of detection, ($\mu g\, g^{-1}$)		
	Direct excitation	Mo secondary target	Polarization
Ca	13	8.8	4.1
Ti	3.8	2.9	1.6
Cr	3.1	2	0.78
Mn	2.6	1.2	0.51
Cu	1.7	0.31	0.34
Zn	1.7	0.3	0.33
Mo	2.3	n.d.	0.95

14.3.5
Portable and Radioisotope XRF

Next to EDXRF spectrometers that are intended for use in the laboratory, a number of portable EDXRF instruments are also available. These devices are used in various fields for on-site analysis of works of art, environmental samples, forensic medicine, industrial products and waste materials, and so on. In its simplest form, the instruments consist of one or more radioisotope sources combined with a scintillation or gas proportional counter. However, combinations of radio sources with thermoelectronically cooled solid-state detectors are also available in compact and lightweight packages (below 1 kg). In Figure 14.21, schematics of various types of radio-source-based EDXRF spectrometers are shown. In Figure 14.21a, the X-ray source is present in the form of a ring; radiation from the ring irradiates

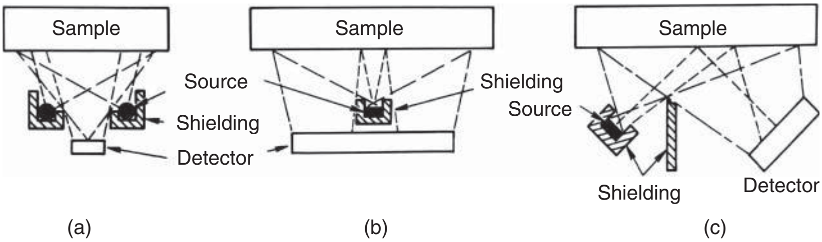

Figure 14.21 Radioisotope-excited X-ray fluorescence analysis by means of (a) an annular source, (b) a central source, and (c) a side-looking source.

the sample from below while the fluorescent radiation is efficiently detected by a solid-state detector positioned at the central axis. Shielding prevents radiation from the source entering the detector. In Figure 14.21b,c, the X-ray source has another shape, requiring a different type of shielding. Portable XRF analyzers (Figure 14.19d), however, have more or less completely replaced radioisotope-based XRF instruments. Figure 14.19d shows a photograph and the functional diagram of a portable or handheld XRF instrument. A miniaturized X-ray tube is combined with a compact Si-PIN or SDD detector into a lightweight enclosure. This type of XRF analyzers more or less have the dimensions and weight of a (lightweight) drilling machine and can run on batteries. They usually are controlled by means of a PDA (personal digital assistant)-style computer that is responsible for spectrum collection and storage, and on which spectrum evaluation software and quantification procedures can also be run.

14.3.6
Total Reflection XRF

When X-rays impinge (optically) upon a flat material under a very small angle (typically a few milliradians), that is, nearly grazing the surface, total external reflection occurs. This means that instead of penetrating the material, the X-ray photons will only interact with the top few nanometers of the material and then be reflected. Material that is present on top of the reflecting surface will be irradiated in the normal manner, and will interact with both the primary and the reflected X-rays. The major difference between conventional EDXRF and TXRF therefore is the excitation geometry. In the standard case of EDXRF, the angle between the primary incident radiation and the sample is 45°, while the detector is placed normal to the incident beam so that the angle between sample and detector is also 45°. The principle setup of TXRF is shown in Figure 14.22. A narrow, almost parallel beam impinges at angles below the critical angle on the surface of the

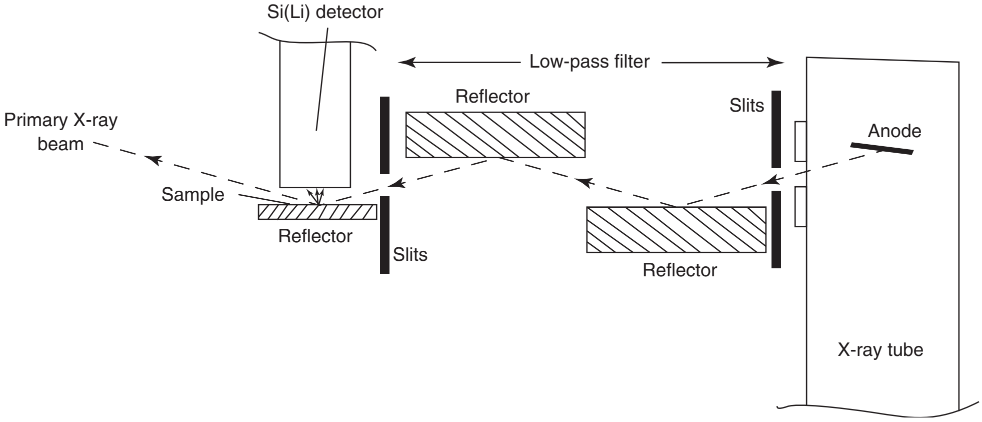

Figure 14.22 Schematic layout of a TXRF spectrometer.

reflector that carries the sample as randomly distributed microcrystals in the center part of its surface. As the X-rays scarcely penetrate the reflector, the contribution from scattered primary radiation from the substrate is minimized. As a result of the double excitation of the sample by both the primary and the reflected beam, the fluorescent signal is practically twice as intense as in the standard EDXRF excitation mode. The largest angle at which total external reflection still takes place is called the *critical angle* of total reflection ϕ_{crit}. The critical angles are in the range of a few milliradians for typical reflector materials such as quartz or Si and primary radiation of 9.4 keV (from a W-L tube) or 17.5 keV (from a Mo-anode X-ray tube). With higher energies in the exciting spectrum, adjustments must be made for the proper incident angle below the critical angle, which is given by

$$\phi_{\text{crit}}(\text{mrad}) = 20.7/E\ (\text{keV})\rho^{\frac{1}{2}}(\text{g}\,\text{cm}^{-3}) \tag{14.18}$$

The main advantages of TXRF are as follows:

1) The background caused by scattering of the primary radiation on the substrate is reduced.
2) The fluorescence intensity is doubled as the primary and reflected beams pass through the sample giving efficient excitation.
3) The distance between the sample on the reflector surface and the detector can be made small, and thus the solid angle for detection is large.
4) All these advantages lead to lower limits of detection (LD) compared to the standard EDXRF mode.

Depending on the X-ray source and the spectral modification devices, the LD are in the picogram range for 2–3-kW X-ray tubes and in the femtogram range with excitation by means of SR. Figure 14.15 shows a typical TXRF spectrum; the absolute detection limit values of typical TXRF instruments are shown in Figure 14.10. Thus, TXRF permits to simultaneously determine trace elements in samples of small volume. Additional advantages are insensitivity to matrix effects, easy calibration, fast analysis times, and low costs. In practice, the method is, in particular, applied to multielement determinations in water samples of various natures and for the routine analysis of Si-wafer surfaces employed in the microelectronics industry.

14.3.7
Microscopic XRF

The basic measuring strategy of μ-XRF analysis is illustrated in Figure 14.23. This microanalytical variant of bulk EDXRF is based on the localized excitation and analysis of a microscopically small area on the surface of a larger sample, providing information on the lateral distribution of major, minor, and trace elements in the material under study. Essentially, a beam of primary X-rays with (microscopically) small cross sections irradiates the sample and induces the emission of fluorescent X-rays from a microspot. A suitable detector system collects the fluorescent radiation that carries information on the local composition of the sample. When

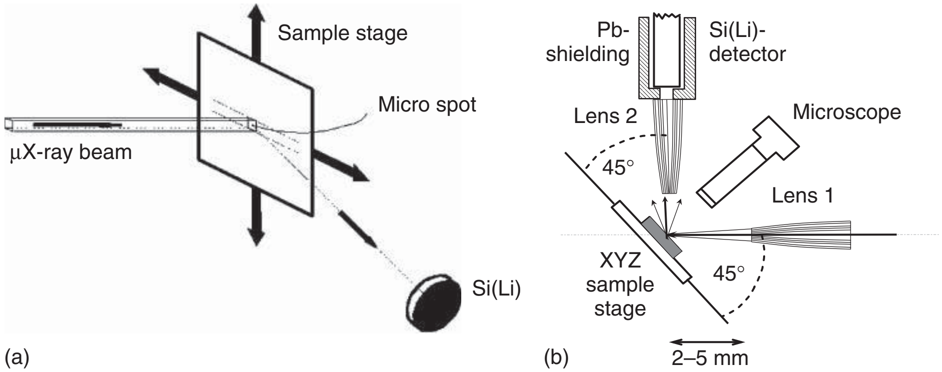

Figure 14.23 Principle of (a) conventional and (b) confocal μ-XRF.

the sample is moved either manually or under computer control in the X-ray beam path, spot analysis, line analysis, or image collection is possible.

The difficulties in the exploitation of this method reside in the production of sufficiently intense X-ray beams to allow sensitive microanalysis. Techniques to do this have only recently appeared; in the past, X-rays were considered to be notably difficult to focus to a small dimension beam. Any variants on the basic mode of operation either reside with the method employed for X-ray beam concentration/focusing or with the source type employed: conventional X-ray tubes or SR sources. Especially the increased performance of compact and relatively inexpensive X-ray focusing devices and in particular the development of (poly)capillary X-ray focusing optics, permitting X-ray beams to be focused to below 10 μm diameter spots, has made the development of μ-XRF possible. When used in combination with X-ray tubes, absolute detection limits in the picogram area are obtained for thin samples. In massive samples, relative LD values around 10 ppm have been reported. At synchrotron facilities, the capabilities of the μ-XRF method (both regarding spot sizes and detection limits) are significantly better: femtogram to lower attogram-level absolute detection limits are obtained with beams that are between 0.1 and 2 μm in diameter. Using monochromatic beams of polarized radiation, optimal peak-to-background ratios in the resulting EDXRF spectra can be obtained, resulting in relative LD levels in the 1–100 ppb range in biological materials. As an example, Figure 14.24 shows the LD values obtained within the 1000 section by using 14 and 21 keV synchrotron microbeams (of $2 \times 15\,\mu m^2$ diameter) to irradiate NIST SRM (standard reference material) 1577 bovine liver. At synchrotrons, the dimensions of the primary beams continuously shrink and currently (2010) beams with about 50 nm diameter and of sufficient intensity can be produced using various optical technologies. In recent years, the technique of confocal μ-XRF has been developed, where a secondary optic, placed between sample and detector prevents all XRF radiation, except that originating from a specific depth below the surface of the sample, to reach the detector. This allows to perform analysis of heterogeneous samples in three dimensions, with a resolution of about 10–50 μm.

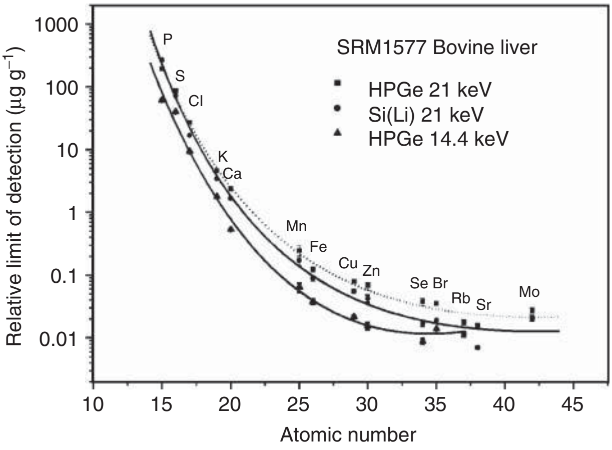

Figure 14.24 Relative LD values obtained by irradiation of NIST SRM 1577 bovine liver by means of 14.4 and 21 keV synchrotron microbeams and Si(Li) or HPGe detectors.

The application of μ-XRF to a great variety of problems and materials has been described, including geochemistry, archeology, industrial problems, and environmental studies. Especially the fact that quantitative data on (trace) constituents can be obtained at the microscopic level without sample damage is of use in many different circumstances. At synchrotron sources, (μ-)XRF investigations of heterogeneous materials is also frequently combined with other methods, providing speciation information on major, minor, and/or trace constituents.

14.4
Matrix Effects

14.4.1
Thin and Thick Samples

The simple linear relation between observed count rate R_i of analyte element i and its concentration c_i shown in Eq. (14.9) is only valid in a limited number of cases. In general, for monochromatic forms of excitation (with energy E_0) and in the absence of enhancement phenomena, the observed XRF count rate R_i of an element i (with energy E_i) is related to the sample thickness d and its concentration c_i is the following manner (see also Eqs. (14.34–14.36)):

$$R_i = S_i c_i \frac{1 - \mathrm{e}^{-\chi(E_0,E_i)\rho d}}{\chi(E_0, E_i)\rho d} = S_i c_i A_i \quad \text{with}$$
$$\chi(E_0, E_i) = \mu(E_0)\csc\alpha + \mu(E_i)\csc\beta \tag{14.19}$$

where α and β are the angles under which the X-rays impinge and takeoff relative to the sample surface (Figure 14.25) and ρ is the sample density. The absorption factor A_i is obtained by adding all contributions to R_i produced in a series of infinitesimal sample volumes at various depths z inside the sample and by considering an

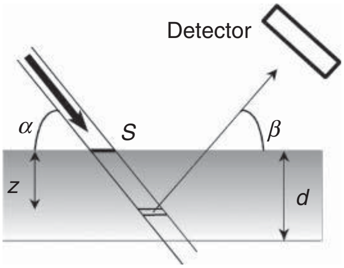

Figure 14.25 Basic XRF irradiation geometry.

attenuation factor $\exp[-\mu(E_0)\rho z \csc \alpha]$ for the primary radiation while penetrating into the sample until this depth and an attenuation factor $\exp[-\mu(E_i) z \csc \beta]$ for the fluorescent radiation when emerging from the sample toward the detector. When polychromatic forms of excitation are used, Eq. (14.19) is more complicated and involves an integral over the intensity distribution of the X-ray source (see subsequent text, Eq. (14.36)).

As a result of the attenuation of both primary and fluorescent radiation within the sample, these is a critical depth in the sample, d_{thick}, below the surface, beyond which any emitted photon is essentially absorbed and therefore will not make a significant contribution to the detected fluorescent intensity. This critical penetration depth varies as a function of matrix composition and is also strongly dependent on the energy of the (primary and) fluorescent radiation. Samples that have a thickness greater than the critical penetration depth for a specific kind of fluorescent radiation are sometimes referred to as ''*infinitely thick*'' or ''*massive*'' samples. In Table 14.7 values for d_{thick} in a geological (a silicate rock) and metallurgical (steel) matrix are listed for various fluorescent line energies. For low-energy photons (e.g., the K_α-photons of low-Z elements such as Al or Na), the critical penetration depth is very small (a fractional to a few micrometers), so that compositional information that exclusively pertains to the surface layers of the sample is obtained. When more penetrating fluorescent radiation is used (e.g., Rb-K_α at 13.39 keV), having d_{thick} values of several millimeters, compositional information from much deeper in the sample is obtained.

In many practical situations, it is important to ensure that the sample presented for analysis is sufficiently thick (i.e., thicker than the highest critical penetration depth among the various fluorescent signals being used), so that the observed analytical signals no longer depend on sample thickness but only on analyte concentration.

Next to the critical penetration depth, d_{thick}, it is also useful to define a critical thickness, d_{thin}, below which absorption and enhancement effects can be neglected. For analysis of such ''thin-film'' samples, the calibration relations of Eqs. (14.8) and (14.9) are valid and matrix effect corrections need not be applied. By convention, d_{thin} corresponds to the situation where the total attenuation in the sample is equal to 1%. Table 14.7 lists typical d_{thin} values for various fluorescent line energies in two matrices.

Table 14.7 Critical penetration depth and thin-film thickness of various fluorescent lines in two matrices.

Element	Energy/wavelength of K_α-line		Excitation spectrum tube anode	Critical penetration depth d_{thick} (μm)		Thin-film thickness d_{thin} (μm)	
	E (keV)	λ (nm)		Silicate	Steel	Silicate	Steel

From [2].

14.4.2
Primary and Secondary Absorption, Direct and Third-Element Enhancement

In the context of XRF analysis, matrix effects are caused by attenuation and enhancement phenomena that influence the intensity of the fluorescent X-ray lines observed from a sample. As the magnitude of the matrix effects varies with elemental composition, the observed XRF intensity is no longer linearly proportional to the concentration of the analyte (Eq. (14.9)). Corrections must therefore be applied to the measured intensity data to account for the following:

1) *Primary absorption* (Figure 14.26a): this occurs because all atoms of the specimen matrix will absorb photons from the primary source. As there is competition for these primary photons by the atoms making up the specimen, the intensity/wavelength distribution of these photons available for the excitation of a given analyte element may be modified by other matrix elements. In this manner, the intensity and spectral distribution of the X-ray flux available to excite the sample atoms can change with penetration depth. This phenomenon is known as "*beam hardening*."
2) *Secondary absorption*: this refers to the effect of the absorption of characteristic analyte radiation by the specimen matrix. As characteristic radiation passes out from the specimen in which it was generated, it will be absorbed by all matrix elements, by amounts relative to the mass absorption coefficients of these elements.
3) *Direct (or second-element) enhancement* (Figure 14.26b): in situations where the energy of a fluorescent photon (e.g., Ni-K_α at 7.47 keV) is immediately above

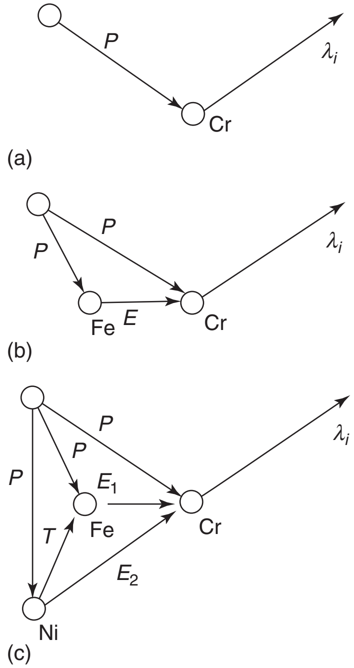

Figure 14.26 Primary excitation versus two-element and three-element enhancement. (a) Primary, (b) primary plus enhancement, and (c) primary, enhancement and third element.

the absorption edge of a second element (e.g., the K-edge of Fe at 7.11 keV), the fluorescence intensity of the second element (here, Fe-K_α and Fe-K_β radiation) will be enhanced as a result of the preferential excitation (here, by Ni-K_α radiation) within the sample. The magnitude of this effect is not always significant, but is readily observable in alloys of specific combinations of elements (e.g., Cr-Fe-Ni steels) and in multiplayer thin-film samples.

4) *Indirect (or third-element) enhancement* (Figure 14.26c): for example, in a stainless steel matrix, the observed intensity of the Cr-K characteristic radiation (Cr-K absorption edge at 5.99 keV) is enhanced by secondary excitation due to Fe-K (K_α at 6.40 keV) and Ni-K radiation. As the intensity of the Fe-K radiation is itself enhanced (see preceding text), part of the Cr enhancement due to Fe is a tertiary effect originating from Ni.

14.5
Data Treatment

The process of converting experimental XRF data into analytically useful information (usually in the form of concentration values of elemental constituents whose X-ray peaks are visible above the background in the spectrum) can be divided into two steps: first the evaluation of the spectral data, whereby the net height or the net intensity of the X-ray peaks is determined, taking care to correct for peak overlap (if any) between X-ray lines of different elements and, second, the conversion of the net X-ray intensities into concentration data, that is, the quantification. In this last step, especially, the appropriate correction of matrix effects is a critical issue.

14.5.1
Counting Statistics

The production of X-rays is a random process that can be described by a Gaussian distribution. As the number of photons counted is nearly always large, typically thousands of hundreds of thousands, rather than a few hundred, the properties of the Gaussian distribution can be used to predict the probable error for a given count measurement. There will be a random error, s_I, associated with a measured intensity value I, this being equal to $I^{\frac{1}{2}}$. As an example, if 10^6 counts are taken, the 1s standard deviation will be $[10^6]^{\frac{1}{2}} = 10^3$, or 0.1%. The measured parameter in WD X-ray spectrometry is generally the counting rate $R = I/t$ and, based on what has been already stated, the magnitude of the *relative* random counting error RSD(R) associated with a given measured rate R can be expressed as

$$\mathrm{RSD}(R)(\%) = 100\%\frac{s_R}{R} = 100\%\frac{s_I}{I} = 100\%\frac{\sqrt{I}}{I} = \frac{100\%}{\sqrt{Rt}} \tag{14.20}$$

Care must be exercised in relating the counting error (or indeed any intensity related error) with an estimate of the error in terms of concentration. Provided that the sensitivity of the spectrometer in counts per second per percent is linear, a count error can be directly related to a concentration error. However, where the sensitivity of the spectrometer changes over the range of measured response, a given fractional count error may be much greater when expressed in terms of concentration.

14.5.2
Spectrum Evaluation Techniques

Spectrum evaluation is a crucial step in X-ray analysis, as much as sample preparation and quantification. As with any analytical procedure, the final performance of X-ray analysis is determined by the weakest step in the process. Spectrum evaluation in EDXRF analysis is more critical than in WDXRF spectrometry because of the relatively low resolution of the solid-state detectors employed.

In general, it is possible to distinguish between amplitude and energy noise in (ED)X-ray spectra. Amplitude noise is the result of the statistical nature of the counting process in which random events (the arrival of X-ray photons in the detector) are observed during a finite time interval. Poisson statistics cause the typical channel-to-channel fluctuations observed in X-ray spectra. Energy noise, on the other hand, causes the characteristic X-ray lines in EDXRF spectra to appear much wider (on the order of 120–150 eV) than their natural line widths (typically

5–10 eV). It results partly from the photon-to-charge conversion process in the detector and partly from the electronic noise that is introduced in the amplification and processing steps that follow it. Accordingly, characteristic X-ray lines appear as nearly Gaussian peaks in EDXRF spectra.

In WDXRF spectra, where at least one of these noise contributions usually is absent (the noise in the energy/wavelength dimension is significantly lower as a result of the much higher resolution of the dispersion systems used), spectrum evaluation, in principle, is much more simple and sometimes can be discarded with altogether. Because the X-ray lines appear as narrow, well-defined peaks, their net X-ray intensities and that of the background in the same region can be determined with great accuracy. The few cases of peak overlap (e.g., between As-K_α and Pb-L_α, where the separation of 8 eV is less than the natural line width of As-K_α) can be dealt with on a case-by-case basis or avoided by the use of another, nonoverlapped, X-ray line of the elements involved as analytical signals (e.g., the As-K_β-line).

In both WDXRF and EDXRF, the net number of counts under a characteristic X-ray line (i.e., the integrated peak *intensity*) is proportional to the concentration of the analyte. At constant resolution, this proportionality also exists between concentration and net peak *height*. In EDXRF (where the detector resolution is low, and changes considerably with energy, and many peaks are low in intensity), the use of the net peak area as analytical signal is preferred, as this also results in a lower statistical uncertainty for the small peaks. In WDXRF (where the detector resolution is high and must be less dependent on the wavelength, while often sharp and intense peaks are encountered), the acquisition of the entire peak profile is often too time consuming so that the count rate is frequently measured only at the peak maximum.

14.5.2.1 **Data Extraction in WDXRF**

In WDXRF, most often the count rate, $R_{\max}$, at the angle of the peak maximum, corrected for background, is used as an analytical signal. In order to estimate the appropriate background below the line, the background count rate at slightly lower and higher 2θ values is measured and the average calculated. If T is the number of counts accumulated during a time interval t_T at the top of the peak and B is the corresponding background counts (during a time t_B), the net count rate R is given by the different of the total and background count rates R_T and R_B:

$$R = R_T - R_B = \frac{T}{t_T} - \frac{B}{t_B} \tag{14.21a}$$

and, considering that $s^2{}_T = T$ and $s^2{}_B = B$, the uncertainty s_R on the net count rate R is given by

$$s_R^2 = \frac{T}{t_T^2} + \frac{B}{t_B^2} = \frac{R_T}{t_T} + \frac{R_B}{t_B} \tag{14.21b}$$

Accordingly, in WDXRF, several counting strategies may be employed to keep this number as low as possible. In the "optimum fixed time" strategy, the minimum uncertainty is obtained within a time interval $t = t_T + t_B$ when t_T and t_B are chosen in such a way that

$$\frac{t_T^2}{t_B^2} = \frac{R_T}{R_B} \tag{14.22}$$

In this case, the uncertainty s_R can be written as

$$s_R = \frac{\sqrt{R_T} + \sqrt{R_B}}{\sqrt{t}} \tag{14.23}$$

14.5.2.2 Data Extraction in EDXRF – Simple Case: No Peak Overlap

The most straightforward method to obtain the net area of an isolated, nonoverlapped peak in an EDXRF spectrum is to interpolate the background under the peak and to sum the net channel contents in a window enclosing the peak. Thus, the net peak area N is given by

$$N = \sum_j [y_j - y_B(j)] = \sum_j y_j - \sum_j y_B(j) = T - B \tag{14.24}$$

where the summation runs over the spectral window (containing n_T channels) under consideration. Thus, the uncertainty s_N can be written as

$$s_N^2 = s_T^2 + s_B^2 = T + B \tag{14.25}$$

The background height $y_\mathrm{B}(j)$ in channel j of the peak window can be interpolated between the average background height to the left and right of the peak ($y_\mathrm{B,L} = B_\mathrm{L}/n_\mathrm{L}$ and $y_\mathrm{B,R} = B_\mathrm{R}/n_\mathrm{R}$, where B_L and B_R are the integrals of the left and right background windows and n_L, n_R their widths in channels) (Figure 14.27):

$$y_\mathrm{B}(j) = y_\mathrm{B,L} + \frac{y_\mathrm{B,R} - y_\mathrm{B,L}}{j_\mathrm{B,R} - j_\mathrm{B,L}} \cdot (j - j_\mathrm{B,L}) \tag{14.26}$$

where $j_\mathrm{B,L}$ and $j_\mathrm{R,L}$ represent the channels between which the background is linearly interpolated. When both background windows around the peak have equal

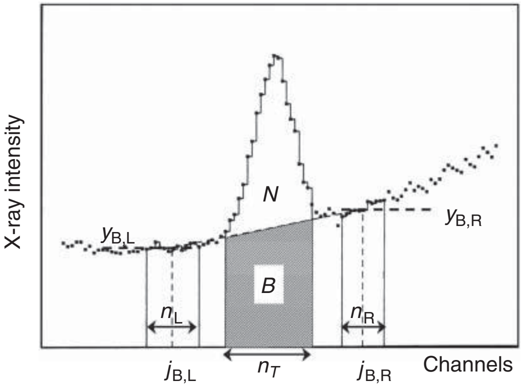

Figure 14.27 Background estimation below an isolated photo peak.

width (i.e., $n_\mathrm{L} = n_\mathrm{R} = n_\mathrm{B}/2$ channels) and are positioned symmetrically around the maximum, the uncertainty on N is given by

$$s_N^2 = T + \left(\frac{n_T^2}{n_\mathrm{B}^2}\right)\left(\frac{B_\mathrm{L}}{B_\mathrm{R}}\right) \tag{14.27}$$

14.5.2.3 **Data Extraction in EDXRF – Multiple Peak Overlap**

The above-described simple integration procedure is useful for explorative data analysis but implicitly assumes that within the energy window used, a single, nonoverlapped peak is present with a high peak-to-background ratio. In general, these assumptions are not valid: peak overlap frequently occurs in ED X-ray spectra when, especially for peaks corresponding to trace constituents, the background intensity below the peak may be on the same order or larger than the net peak intensity. In these cases, the use of too simple spectrum evaluation procedures may negate all the efforts that are made both during the data collection and during the further quantitative processing of the data to increase the reliability of the final (trace) element concentrations. An established way of proceeding is to use a nonlinear least squares strategy to minimize the weighted difference Π^2 between the experimental data y_i and a mathematical fitting function y_fit

$$\chi^2 = \frac{1}{n-m}\sum_i \left(\frac{\left[y_i - y_{\mathrm{fit},i}\,(i)\right]^2}{y_i}\right) \tag{14.28}$$

where y_i is the observed content of channel i in the spectrum being processed and $y_\mathrm{fit}(i)$ is the calculated fitting function in this channel. n is the total number of channels in the fitting window, while m represents the number of parameters in the fitting function. The latter consists of two parts, describing, respectively, the spectral background and the photo peaks:

$$y_\mathrm{fit}(i) = y_\mathrm{back}(i) + y_\mathrm{peak}(i) = y_\mathrm{back}(i) + \sum_j y_j(i) \tag{14.29}$$

where the index j runs over all characteristic line groups that appear in the spectrum. For each line group j (e.g., Fe-K, Pb-L$_3$), the contribution $y_j(i)$ to the ith channel is calculated as

$$y_j(i) = A_j \left(\sum_{k=1}^{N_j} r_{jk} G\left(E_{jk}, i\right) t(E_{jk})\right) \tag{14.30}$$

where A_j represents the total area of all photo peaks in line group j (comprised, e.g., of the Fe-K$_\mathrm{V}$- and -K$_\exists$-lines); these are optimizable parameters during the least squares fitting process. The index k runs over all lines in group j, each line having a relative abundance r_{jk} (with $\Gamma_k\, r_{jk} = 1$). G_{jk} represents a Gaussian function centered around E_{jk}; $t(E_{jk})$ denotes the total attenuation factor for X-rays with energy E_{jk} as defined by the absorption of radiation in the detector, in absorbers placed between sample and detector and in the sample itself. This model can also be expanded to account for spectral artifacts that are generated in the solid-state detector. In

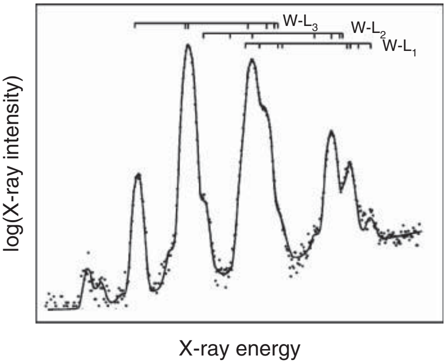

Figure 14.28 Spectral deconvolution in case of complex multiplets.

Figure 14.28, the result of nonlinear deconvolution of the complex multiplets constituted by the W-L$_1$-, L$_2$-, and L$_3$-lines is shown.

The background in the EDXRF spectra is the result of many processes and therefore can have a fairly complex shape. Although it is not impossible to calculate/predict this shape, during spectrum evaluation, usually a more empirical (and faster) approach is favored. Either the background shape is estimated a priori so that it can be subtracted from the experimental data before the actual fitting (‘‘background estimation’’) or it is described by a suitable mathematical function (usually a polynomial of some kind), of which the coefficients are optimized together with the other parameters of the fitting model (‘‘background modeling’’).

14.5.3
Quantitative Calibration Procedures

In the X-ray analytical laboratory, the quantitative method of analysis employed will be typically determined by a number of circumstances of which probably the four most common are the complexity of the analytical problem, the time allowable, the data processing and calibration software present, and the number of standards available. It is convenient to break quantitative analytical methods down into two major categories: single-element methods and multiple-element methods.

Single element methods	Internal standardization Standard addition
Multiple-element methods	Type standardization Use of influence coefficients Fundamental parameter techniques

The simplest quantitative analysis situation to handle is the determination of a single element in a known matrix. A slightly more difficult case might be the determination of a single element where the matrix is unknown. As shown in the table, three basic methods are commonly employed in this situation: use of internal standards, use of standard addition, or use of a scattered line from the X-ray source.

The most complex case is the analysis of all, or most, of the elements in a sample, about which little or nothing is known. In this case, a full qualitative analysis would be required before any attempt is made to quantify the matrix elements. Once the qualitative composition of the sample is known, again, one of three general techniques is typically applied: use of type standardization, use of an influence coefficient method, or use of a fundamental parameter technique. Both the influence coefficient and fundamental parameter technique require a computer for their application.

The correlation between the characteristic count rate, R_i, of an analyte element and the concentration c_i of that element is typically nonlinear over wide ranges of concentration because of interelement effects between the analyte element and other elements making up the specimen matrix. However, the situation can be greatly simplified in the case of homogeneous specimens, where severe enhancement effects are absent; here, the slope of a calibration curve S_i is inversely proportional to the total absorption factor A_i of the specimen for the analyte wavelength:

$$S_i = \frac{R_i}{c_i A_i^{-1}} \tag{14.31}$$

As an example, the data in Table 14.8 show how the net intensity of the Fe-K$_\alpha$-line (Fe K-L$_{3,2}$ transition) resulting from a concentration of 1% iron strongly depends on the matrix composition: the Fe-intensity obtained from a graphite sample, in which virtually no absorption takes place ($A \approx 1$) of the Fe-K$_\alpha$ radiation is about 600 times higher than that obtained from the same Fe concentration in a strongly absorbing lead sample. With the Ni sample, a higher intensity than in the Cr sample is observed, even though the absorption in the Ni matrix is higher. This is caused by the enhancement effect due to the Ni characteristic X-rays that additionally excite the Fe atoms. The combination of matrix absorption and enhancement effects causes the calibration curves in XRF to be nonlinear. Figure 14.29 shows calibration curves for Pb and Sn in binary Pb-Sn alloys. Different quantitative analysis schemes are used depending on the type of matrix, the concentration range, and the availability of the standards.

Table 14.8 Intensity (cps) of the Fe-K$_\alpha$-line obtained from a 1% concentration of Fe in various matrices.

Matrix	Intensity
C	1200
Al	108
Cr	22
Ni	79
Pb	20

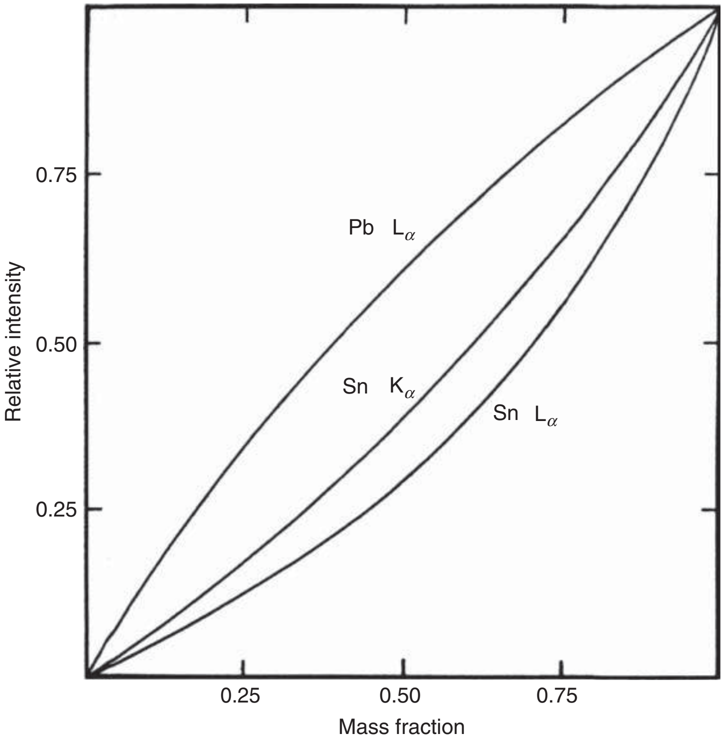

Figure 14.29 Calibration curves for Pb-L$_\alpha$, Sn-K$_\alpha$, and Sn-L$_\alpha$ in Pb-Sn binaries. The Pb-La intensity shows a slight enhancement effect (due to the Sn-K-lines); the Sn-K$_\alpha$ and Sn-L$_\alpha$ curves indicate different degrees of absorption in the sample. In case of Sn-L$_\alpha$, the absorption effect apparently dominates over the enhancement of the Sn-L$_\alpha$ intensity by both the Pb-L and Sn-K-lines.

14.5.3.1 **Single-Element Techniques**

Single-element techniques reduce the influence of the absorption term μ in Eq. (14.30), generally by referring the intensity of the analyte wavelength to a similar wavelength, arising either from an added standard or from a scattered line from the X-ray tube. In certain cases, limiting the concentration range of the analyte may allow the assumption to be made that the absorption value does not significantly change over the concentration range and the calibration curve is essentially linear.

Thin-film approach. Quantitative analysis of thin films, such as filters loaded with aerosol particles, can be done by simply comparing the count rate for a particular element in the sample with the count rate observed in a thin-film standard, because matrix effects are virtually absent. Special reference standards may be made up for particular purposes, and these may serve the dual purpose of instrument calibration as well as establishing working curves for analysis. As an example, two thin glass film SRMs specially designed for calibration of X-ray spectrometers are available from the National Institute of Standards and Technology in Washington as SRMs 1832 and 1833. They consist of a silica-based film deposited by focused ion-beam coating onto a polycarbonate substrate. SRM 1832 contains aluminum, silicon, calcium, vanadium, manganese, cobalt, and copper, and SRM 1833 contains silicon, potassium, titanium, iron, and zinc.

Internal standardization. One of the most useful techniques for the determination of a single-analyte element in a known or an unknown matrix is to use an internal standard. The technique is one of the oldest methods of quantitative analysis and is based on the addition of a known concentration of an element that features an X-ray line with a wavelength/energy close to that of the analyte wavelength. The assumption is made that the effect of the matrix on the internal standard is essentially the same as the effect of the matrix on the analyte element. Internal standards are best suited for the measurement of analyte concentrations below about 10%. The reason for this limit arises because it is generally advisable to add the internal standard element at about the same concentration level as that of the analyte. When more than 10% of the internal standard is added, it may significantly change the specimen matrix and introduce errors into the determination. Care must also be taken to ensure that the particle sizes of specimen and internal standard are about the same, and that the two components are adequately mixed. Where an appropriate internal standard cannot be found, it may be possible to use the analyte itself as an internal standard. This method is a special case of standard addition (spiking).

Type standardization. Provided that the total specimen absorption does not vary significantly over a range of analyte concentrations, and provided that enhancement effects are absent and that the specimen is homogeneous, a linear relationship will be obtained between analyte concentration and measured characteristic line intensity. Where these provisos are met, type standardization techniques can be employed.

In this way, linear calibration curves can be used to determine trace and minor element concentrations in alloys, mineral pellets, and liquids provided that the major element concentrations of standards and unknowns are very similar. In this case, the matrix effect remains the same.

It will also be clear from previous discussions that by limiting the range of analyte concentrations to be covered in a given calibration procedure, the range in absorption can also be reduced. Type standardization is probably the oldest of the quantitative analytical methods employed, and the method is usually evaluated by taking data from a well-characterized set of standards, and, by inspection, establishing whether a linear relationship is indeed observed. Where this is not the case, the analyte concentration range may be further restricted. The present-day analyst is fortunate in that many hundreds of good reference standards are commercially available. While the type standardization method is not without its pitfalls, it is nevertheless extremely useful and is especially useful for quality control type applications where a finished product is being compared with a desired product.

14.5.3.2 Multiple-Element Techniques

To determine major and minor elements in complex samples, more elaborate matrix correction algorithms need to be applied. They can be roughly divided into two categories: the influence coefficient and the fundamental parameter method.

14.5.3.2.1 Influence Coefficient Methods All these models have essentially the same form:

$$\frac{c_i}{R'_i} = K_i + \text{model-dependent term(s)} \tag{14.32}$$

describing the (empirical) relation between an analyte concentration c_i, its X-ray intensity ratio R'_i, an instrument-dependent term K_i that is equal to the inverse of the sensitivity of the spectrometer for the analyte in question ($K_i = 1/S_i$), and a term that corrects this sensitivity term for the effect of the matrix. R' is the ratio of the analyte intensity in the unknown sample to that obtained from a pure element standard, measured under identical circumstances. The different methods only vary in the form of the correction term. The relations used by some of the commonly employed influence methods are listed here:

$$\text{Linear model} \quad \frac{c_i}{R'_i} = K_i \tag{14.33a}$$

$$\text{Lachance–Traill} \quad \frac{c_i}{R'_i} = K_i + \sum_j \alpha_{ij} c_j \tag{14.33b}$$

$$\text{Claisse–Quintin} \quad \frac{c_i}{R'_i} = K_i + \sum_j \alpha_{ij} c_j + \sum_j \gamma_{ij} c_j^2 \tag{14.33c}$$

$$\text{Rasberry–Heinrich} \quad \frac{c_i}{R'_i} = K_i + \sum_j \alpha_{ij} c_j + \sum_{k \neq j} \beta_{ijk} \left[\frac{c_k}{(1 + c_i)} \right] \tag{14.33d}$$

$$\text{Lachance–Claisse} \quad \frac{c_i}{R'_i} = K_i + \sum_j \alpha_{ij} c_j + \sum_j \sum_{k>j} \alpha_{ijk} c_j c_k \tag{14.33e}$$

where all concentrations are expressed as mass fractions.

All the models are concentration correction models in which the product of the influence coefficient (α, β, or γ in the given equations) and the concentration of the interfering element are used to correct the slope of the analyte calibration curve. The Lachance–Traill model is the earliest model; after that, in the Rasberry–Heinrich model, the influence of the absorbing and enhancing elements is separated by the use of the α and β coefficients, respectively. When the physics of the X-ray excitation are thoroughly studied, it becomes clear that the above-mentioned models are too simple and that all binary coefficients (the α_{ij}'s and β_{ij}'s) systematically are dependent on the composition. Both the Claisse–Quintin and the Lachance–Claisse models use higher order cross-terms to correct for enhancement and third-element effects. Accordingly, these models are, in general, more suited for use in a very wide concentration range.

14.5.3.2.2 **Fundamental Parameter Method** The fundamental parameter method is based on the physical theory of X-ray production rather than on empirical relations between observed X-ray count rates and concentrations of standard samples. In general, the observed XRF count rate $R_{i,\mathrm{K}\alpha}$ of (the K_α-line of) an element i, obtained by polychromatic excitation of a sample with thickness d and density ρ, can be written as

$$\begin{aligned} R_{i,\mathrm{K}_\alpha} = &\int_{E=E_{i,\mathrm{abs}}}^{E_{\max}} \int_{z=0}^{d} I_0(E)\frac{G_1}{\sin\varphi}\sigma_{i,\mathrm{K}_\alpha}(E)c_i H_i(E)e^{-\chi(E,E_{i,\mathrm{K}_\alpha})\rho z} \\ &G_2 B(E, E_{i,\mathrm{K}_\alpha})\varepsilon(E_{i,\mathrm{K}_\alpha})\mathrm{d}z\mathrm{d}E \end{aligned} \tag{14.34}$$

where the quantity $\sigma_{i,\mathrm{K}_\alpha}$ is the effective cross section for production of K_α-radiation of element I:

$$\sigma_{i,K_\alpha}(E) = \tau_{i,K_\alpha}(E)\cdot\omega_{i,K}\cdot p_{i,K_\alpha} \tag{14.35}$$

(with p_{i,K_α} the probability of producing a K_α-fluorescent photon from a vacancy in the K-shell and $\omega_{i,\mathrm{K}}$ its fluorescence yield). $E_{i,\mathrm{abs}}$ is the absorption edge energy and E_{i,K_α} the K_α-line energy of element i, $I_0(E)\mathrm{d}E$ is the spectral distribution of the exciting radiation with $E_{\max}$ its maximum energy (see Figure 14.6), G_1 and G_2 are geometry constants, $\chi(E,E_{i,\mathrm{K}_\alpha})$ is defined in Eq. (14.19). $H_i(E,E_{i,\mathrm{K}_\alpha})$ is a factor describing secondary and higher order excitation (at low concentrations, $H_i = 1$), while the factor $B(E,E_{i,\mathrm{K}_\alpha})$ describes the absorption of the radiation in the medium between tube, sample, and detector (e.g., air, He). $\varepsilon(E_{i,\mathrm{K}_\alpha})$ is the efficiency of the detector. After integration over the sample depth, Eq. (14.34) becomes

$$\begin{aligned} R_{i,\mathrm{K}_\alpha} = &\int_{E=E_{i,\mathrm{abs}}}^{E_{\max}} I_0(E)\frac{G_1\rho d}{\sin\varphi}\sigma_{i,\mathrm{K}_\alpha}(E)c_i \times \frac{1-\mathrm{e}^{-\chi(E,E_{i,\mathrm{K}_\alpha})\rho d}}{\chi(E, E_{i,\mathrm{K}_\alpha})\rho d} \\ &\times G_2 B(E, E_{i,\mathrm{K}_\alpha})\varepsilon(E_{i,\mathrm{K}_\alpha})\mathrm{d}E \end{aligned} \tag{14.36}$$

This fundamental parameter equation relates the intensity of one element to the concentration of all elements present in the sample. A set of such equations can be written, one for each element to be determined. This set of equations can only be solved in an iterative way, making the method computationally complex. Moreover, an accurate knowledge of the shape of the excitation spectrum $I_0(E)\mathrm{d}E$, of the detector efficiency ε and of the fundamental parameters μ, τ, ω, and p is required. The fundamental parameter method is of interest because it allows for semiquantitative (5–10% deviation) analysis of completely unknown samples and is therefore of use in explorative phases of investigations. Several computer programs that allow to perform the necessary calculations at various levels of sophistication are available. As an example, in Table 14.9, the relative standard deviation between certified and calculated concentration of the constituents of series of tool steels are listed.

Table 14.9 Analysis of tool steels obtained by means of a fundamental parameter program and one calibration standard.

Element	Min (%)	Max (%)	Standard deviation (%)
Si	0.14	0.27	0.03
S	0.015	0.029	0.003
P	0.022	0.029	0.003
Mo	0.2	9.4	0.04
Mn	0.21	0.41	0.01
Cr	2.9	5	0.13
Co	0	10	0.2
C	0.65	1.02	0.16
W	1.8	20.4	0.52

Min., max.: minimum and maximum concentrations in the series of analyzed samples. Standard deviation on the basis of the difference between calculated and certified concentrations.

14.5.4
Error Sources in X-ray Fluorescence Analysis

Table 14.10 lists the four main categories of random and systematic errors encountered in XRF analysis. The first category includes the selection and preparation of the sample to be analyzed. Two stages are generally involved before the actual prepared specimen is presented to the spectrometer, these being sampling and specimen preparation. The actual sampling is rarely under the control of the spectroscopist and it generally has to be assumed that the container containing the

Table 14.10 Sources of error in X-ray fluorescence analysis.

	Source	Random (%)	Systematic (%)
1	Sample preparation	0–1	0–5
	Sample inhomogeneity	—	0–50
2	Excitation source fluctuations	0.05–0.2	0.05–0.5
	Spectrometer instability	0.05–0.1	0.05–0.1
3	Counting statistics	Time dependent	—
	Dead time correction	—	0–25
4	Primary absorption	—	0–50
	Secondary absorption	—	0–25
	Enhancement	—	0–15
	Third-element effects	—	0–2

material for analysis does, in fact, contain a representative sample. It will be seen from the table that, in addition to a relatively large random error, inadequate sample preparation, and residual sample heterogeneity can lead to very large systematic errors. For accurate analysis, these errors must be reduced by the use of a suitable specimen preparation method. The second category includes errors arising from the X-ray source previously discussed. Source errors can be reduced to less than 0.1% by the use of the ratio counting technique, provided that high-frequency transients are absent. The third category involves the actual counting process and these errors can be both random and systematic. System errors due to detector dead time can be corrected either by use of electronic dead time correctors or by some mathematical approach. The fourth category includes all errors arising from interelement effects. Each of the effects listed can give large systematic errors that must be controlled by the calibration and correction scheme.

14.5.5
Specimen Preparation for X-ray Fluorescence

Because X-ray spectrometry is essentially a comparative method of analysis, it is vital that all standards and unknowns be presented to the spectrometer in a reproducible and identical manner. Any method of specimen preparation must give specimens that are reproducible and that, for a certain calibration range, have similar physical properties including mass attenuation coefficient, density, particle size, and particle homogeneity. In addition, the specimen preparation method must be rapid and cheap and must not introduce extra significant systematic errors, for example, the introduction of trace elements from contaminants in a diluent. Specimen preparation is an all-important factor in the ultimate accuracy of any X-ray determination, and many papers have been published describing a multitude of methods and recipes for sample handling. In general, samples fit into three main categories:

1) Samples that can be handled directly following some simple pretreatment such as pelletizing or surfacing. For example, homogeneous samples of powders, bulk metals, or liquids.
2) Samples that require significant pretreatment. For example, heterogeneous samples, samples requiring matrix dilution to overcome interelement effects, and samples exhibiting particle size effects.
3) Samples that require special handling treatment. For example, samples of limited size, samples requiring concentration or prior separation, and radioactive samples.

The ideal specimen for XRF analysis is one in which the analyzed volume of specimen is representative of the total specimen, which is, itself, representative of the sample submitted for analysis. There are many forms of specimen suitable for XRF analysis, and the form of the sample as received will generally determine the method of pretreatment. It is convenient to refer to the material received for analysis as the sample, and that which actually is analyzed in the spectrometer as the specimen. While the direct analysis of certain materials is certainly possible, more often than not some pretreatment is required to convert the sample to the specimen. This step is referred to as *specimen preparation*. In general, the analyst would prefer to analyze the sample directly, because if it is taken as received, any problems arising from sample contamination that might occur during pretreatment are avoided. In practice, however, there are three major constraints that may prevent this ideal circumstance from being achieved: sample size, sample size homogeneity, and sample composition heterogeneity. Problems of sample size are frequently severe in the case of bulk materials such as metals, large pieces of rock, and so on. Problems of sample composition heterogeneity will generally occur under these circumstances as well, and in the analysis of powdered materials heterogeneity must almost always be considered. The sample as received may be either homogeneous or heterogeneous; in the latter case, it may be necessary to render the sample homogeneous before an analysis can be made. Heterogeneous bulk solids are generally the most difficult kind of sample to handle, and it may be necessary to dissolve or chemically react the material in some way to give a homogeneous preparation. Heterogeneous powders are either ground to a fine particle size and then pelletized, or fused with a glass-forming material such as borax. Solid material in liquids or gases must be filtered out and the filter analyzed as a solid. Where analyte concentrations in liquids or solutions are too high or too low, dilution or preconcentration techniques may be employed to bring the analyte concentration within an acceptable range.

14.6
Advantages and Limitations

14.6.1
Qualitative Analysis

Qualitative analysis is, in principle, very simple with XRF and is based on the accurate measurement of the energy, or wavelength, of the fluorescent lines observed. As many WDXRF spectrometers operate sequentially, a 2θ scan needs to be performed. The identification of trace constituents in a sample can sometimes be complicated by the presence of higher order reflections or ‘‘satellite’’ lines from major elements. With EDXRF, the entire X-ray spectrum is acquired simultaneously. The identification of the peaks, however, is rendered difficult by the comparatively low resolution of the ED detector. In qualitative analysis programs, the process is simplified by overplotting the so-called KLM markers onto an (unknown) spectrum. These markers indicate the theoretical position of the K-, L-, and M-lines of a specific element; when these observed peaks coincide with the line markers, an element is positively identified.

14.6.2
Detection Limits

For a particular element, the detection limit depends on the sensitivity and on the count rate of the continuum below the peak and is inversely proportional to the measurement time. Detection limits can be improved by increasing the sensitivity (optimization of the excitation and detection efficiency), by reducing the background (as is done in TXRF) or by counting a longer period of time. The value of the attainable detection limits thus depends very much on the sample, the element considered and the experimental conditions. In WD instruments, values range from 0.1 to 10 ppm are obtained for medium-Z elements (such as Fe) upto 1–5% for the lightest elements (B, Be). Detection limits for unpolarized EDXRF are typically a factor 5–10 worse, except for TXRF that has absolute detection limits in the picogram range. Using synchrotron sources, the detection limits of XRF are generally several orders of magnitude better than in cases where conventional X-ray sources are employed.

14.6.3
Quantitative Reliability

The great flexibility, sensitivity, and range of the various types of XRF spectrometers make them ideal for quantitative analysis. In common with all analytical methods, quantitative XRF analysis is subject to a number of random and systematic errors that contribute to the final accuracy of the analytical result. As with all instrumental methods of analysis, the potential high precision of X-ray spectrometry can only be translated into high accuracy if the various systematic errors in the analysis process are taken care of. The precision of a WD system for the measurement of a single, well-separated line is typically on the order of 0.1%, and about 0.25% for the ED system. A good rule of thumb that can be used in XRF analysis to estimate the expected standard deviation σ at an analyte concentration level c is given by

$$\sigma = K(c + 0.1)^{\frac{1}{2}}$$

where K varies between 0.005 and 0.05. For example, at a concentration level $c \approx 25\%$, the expected value of σ would be between about 0.025 and 0.25%. A K value of 0.005 would be considered very high-quality analysis and a value of 0.05 rather poor quality. The value of K actually obtained under routine laboratory conditions depends on many factors but with reasonably careful measurements a K value of around 0.02–0.03 can be obtained.

14.7
Summary

When an element is bombarded by high-energy particles, orbital electrons may be ejected creating inner orbital atomic vacancies. These vacancies may be filled by transition of outer-level electrons giving rise to characteristic X-radiation.

XRF spectrometry provides the means of the identification of an element by measurement of its characteristic X-ray emission wavelength of energy.

The method allows the quantization of a given element by first measuring the emitted characteristic line intensity and then relating this intensity of element concentration.

While the roots of the method go back to the early part of this century, where electron excitation systems were employed, it is only during the past 30 years or so that the technique has gained major significance as a routine means of elemental analysis. WD spectrometers employ diffraction by a single crystal to separate characteristic wavelengths emitted by the sample. At present, nearly all commercially available X-ray spectrometers use the fluorescence excitation method and employ a sealed X-ray tube as the primary excitation source. The first commercial X-ray spectrometer became available in the early 1950s and although these earlier spectrometers operated only with an air path, they were able to provide qualitative and quantitative information on all elements above atomic number 22 (titanium). Later versions allowed use of helium or vacuum paths that extended the lower atomic number cutoff to around atomic number 9 (fluorine). X-ray detectors used include the flow counter, the scintillation counter, and the Si(Li) detector.

The X-ray method has good overall performance characteristics. In particular, the speed, accuracy, and versatility of XRF are the most important features among the many that have made it the method of choice in over 30 000 laboratories all over the world.

Most WD spectrometers fall into two broad categories – single channel and multichannel. Single-channel spectrometers are typically employed for both routine and nonroutine analysis of a wide range of products, including ferrous and nonferrous alloys, oils, slags, and sinters, ores and minerals, thin films, and so on. These systems are very flexible but relative to multichannel spectrometers are somewhat slow. The multichannel WD instruments are used almost exclusively for routine, high-throughout analysis where the great need is for fast accurate analysis, but where flexibility is of no importance. ED spectrometers exist in various forms, some designed for (on-site or laboratory) bulk analysis, others for surface-specific or microscopic analysis.

Interelement (matrix) effects often complicate quantitative analysis by XRF. However, a wide selection of methods is now available for minimizing these effects, allowing excellent accuracy to be obtained in many cases. Detection limits are achievable down to the low parts per million (ppm) range and it is possible to obtain reasonable responses from as little as a few milligrams of material.

Atomic Absorption Spectrometry (AAS) and Atomic Emission Spectrometry (AES)

Erwin Rosenberg and Ulrich Panne

15.1

Introduction

Atomic absorption spectrometry (AAS) and atomic emission spectrometry (AES) were the first instrumental techniques to be established for elemental analysis. They are based on the pioneering work in the middle of the nineteenth century of Bunsen and Kirchhoff [1], who discovered that elements that are subjected to a hot flame emit light of a characteristic wavelength. On the other hand, this characteristic emission can be absorbed again by the vapor of the same element. These two discoveries formed the basis for atomic absorption and emission spectrometry and demonstrate the close interrelation and complementary nature of these two techniques. AAS and AES have many theoretical and practical considerations in common, and they can be described by the same formalism. The theory of AAS and AES will thus be treated together.

15.2

Theory of Atomic Spectroscopy

15.2.1

Basic Principles

The development of atomic spectroscopic techniques and their application to fundamental studies fostered the concurrent development of atomic theory and quantum mechanics. In turn, the better understanding of atomic theory led to the implementation of many beneficial techniques and instrumental features in atomic spectroscopy, particularly for the reduction or elimination of interferences and background.

A first step toward the interpretation of atomic spectra was made in 1885, when Balmer found a formula describing the different emission lines of hydrogen in the visible region:

$$\lambda = k \frac{n^2}{n^2 - 4} \tag{15.1}$$

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

where λ is the wavelength (in nanometers), k a constant, and $n = 2, 3, 4$, and so on, represents the spectroscopic lines H_α, H_β, H_γ, and so on.

Equation (15.1) may be expressed in wavenumbers as

$$\nu' = \frac{1}{\lambda} = R\left(\frac{1}{2^2} - \frac{1}{n^2}\right) \tag{15.2}$$

where ν' is the frequency of the radiation in wavenumbers ($\mathrm{cm^{-1}}$) and R the Rydberg constant ($109\,677\ \mathrm{cm^{-1}}$). Equation (15.2) may be generalized to give the wavelength of the lines in all series of the hydrogen atom:

$$\nu' = R\left(\frac{1}{n_1^2} - \frac{1}{n_2^2}\right) \tag{15.3}$$

where $n_1 > n_2$. The numbers $n_1 = 1, 2, 3$ represent the Lyman, Balmer, and Paschen series, respectively. Formula (15.3) was further extended by Rydberg to yield

$$\nu' = RZ^2\left(\frac{1}{n_1^2} - \frac{1}{n_2^2}\right) \tag{15.4}$$

where Z stands for the atomic number (equivalent to the number of protons) of the particular element, which now gives the possibility of calculating the wavelength of lines of atoms other than the hydrogen atom. The two numbers n_1 and n_2 are the so-called spectral terms of the particular atom. These terms describe the defined energy levels of the electrons in their orbits around the nucleus. According to Bohr's theory of the atomic structure, no energy is taken up or emitted as long as the electron remains in its given orbit. Energy (E) is only taken up or emitted in the form of electromagnetic radiation when the transition of an electron between two energetic states occurs. The wavelength of this radiation is given by

$$E = h\nu = \frac{hc}{\lambda} \tag{15.5}$$

(with $h = 6.626 \times 10^{-34}\ \mathrm{J\,s}$, i.e., Planck's constant, ν is the frequency (in $\mathrm{s^{-1}}$), $c = 3 \times 10^8\ \mathrm{m\,s^{-1}}$ the speed of light in vacuum, and λ is the wavelength (m). The energy difference accompanying such a transition is thus

$$\nu' = \frac{1}{\lambda} = \frac{E}{hc} = \frac{E_1}{hc} - \frac{E_2}{hc} = T_1 - T_2 \tag{15.6}$$

where T_1 and T_2 are the Bohr energy levels. Considering systems with a single valence electron, the energy of this electron can be expressed as

$$E = \frac{2\pi Z^2 e^4 \mu}{n^2 h^2} \tag{15.7}$$

where μ is the reduced mass of the system; $\mu = m \times M/(m + M)$ with m representing the mass of the electron and M the mass of the nucleus, and n is the principal quantum number ($n = 1, 2, 3, \ldots$).

The orbital quantum number l, with $l = 0, 1, 2 \ldots (n-1)$, determines the orbital angular momentum $\boldsymbol{L}$.

$$||\boldsymbol{L}|| = \frac{h}{2\pi} = \sqrt{l(l+1)} \tag{15.8}$$

For an elliptical orbit, the possible orientations relative to an external electric or magnetic field are

$$\boldsymbol{L}_z = \frac{h}{2\pi} m_l \tag{15.9}$$

where $\boldsymbol{L}_z$ is the component of the orbital angular momentum $\boldsymbol{L}$ that is parallel to the external field with $m_l = \pm 1; \pm(n-1); \ \ldots \ 0$. m_l has $(2l+1)$ values. When an absorbing or emitting atom is brought into a strong magnetic field, the spectral lines display a hyperfine structure, called the *Zeeman effect*. The explanation of this effect requires the assumption that the electron rotates around its axis, thus exhibiting a spin angular momentum $\boldsymbol{S}$.

$$||\boldsymbol{S}|| = \frac{h}{2\pi} = \sqrt{S(S+1)} \tag{15.10}$$

The spin quantum number m describes the orientation of the axis of rotation of the electron and the external field.

$$\boldsymbol{s}_z = \frac{h}{2\pi} \ m_s \tag{15.11}$$

m_s may assume the values of $\pm 1/2$.

The total angular momentum $\boldsymbol{J}$ of an electron results from the vector sum of the orbital angular momentum and the spin angular momentum:

$$\vec{\mathrm{J}} = \vec{\mathrm{L}} + \vec{\mathrm{S}} \ \text{ with } \ ||\boldsymbol{J}|| = \frac{h}{2\pi} = \sqrt{j(j+1)} \tag{15.12}$$

$j = l \pm s$ is the total internal quantum number.

All electrons of an atom must differ in their energetic states. These are given by the quantum number in the following notation:

$$n^m l_j \tag{15.13}$$

where n stands for the principal quantum number; m for the multiplicity of the signal ($m = 2s+1$), and l ($l = 0, 1, 2, \ldots$) for the orbital quantum number. The corresponding terms are denoted by the symbols s (sharp), p (principal), d (diffuse), f (fundamental), and so on, which were initially used to describe the appearance of the different spectral lines. j is the total internal quantum number.

These term schemes are useful for expressing the energy levels of each element. They also allow defining which transitions between energy levels are allowed and which are forbidden. This is expressed by the so-called selection rules. These are

- $\Delta n = 0; \pm 1; \pm 2$ (the principal quantum number may change by any integer value);
- $\Delta l = \pm 1$ (the orbital quantum number must change by one integer);
- $\Delta j = 0$ or ± 1 (the total internal quantum number may either remain unchanged or change by one integer, but the transition $J = 0 \rightarrow J = 0$ is forbidden);
- $\Delta s = 0$ (the spin quantum number must not change, transitions between singulett and triplett spin systems are not allowed).

For larger systems (heavy atoms), however, the selection rules $\Delta l = \pm 1$ and $\Delta s = 0$ are sometimes violated.

The spectroscopic notation is easy to derive for elements with one valence electron, for example, the Na atom. Its electronic configuration in the ground state is $1s^2 2s^2 2p^6 3s^1$, or $3^2 S_{1/2}$ which results from $l = 0$ (*s*); $m = 2 \times (1/2) + 1 = 2$ (with $s = 1/2$), and $j = ||l \pm s|| = ||0 \pm 1/2|| = 1/2$. The spectroscopic notation corresponding to the excited states with the 3s electron being lifted to the 3p level is $3^2 P_{1/2}$ and $3^2 P_{3/2}$ (since $l = 1$(p); $m = 2 \times (1/2) + 1 = 2$ (with $s = 1/2$), and $j = ||1 \pm s|| = ||1 \pm 1/2|| = 1/2$ and $3/2$).

The term schemes of the elements have been compiled by Grotrian [2]. Two examples are given in Figure 15.1. The energy level diagram of the singly charged magnesium ion differs very little from that of the uncharged sodium atom (or of other alkaline metal atoms). A significant difference, however, consists in the energy difference between the 3p and 3s states, which is almost double for Mg^+ in comparison to Na_0 as a consequence of the larger charge of the nucleus of Mg.

For atoms with more than one valence electron, coupling of the spin and orbital angular momentum must be considered (Russel–Saunders or L–S coupling). The

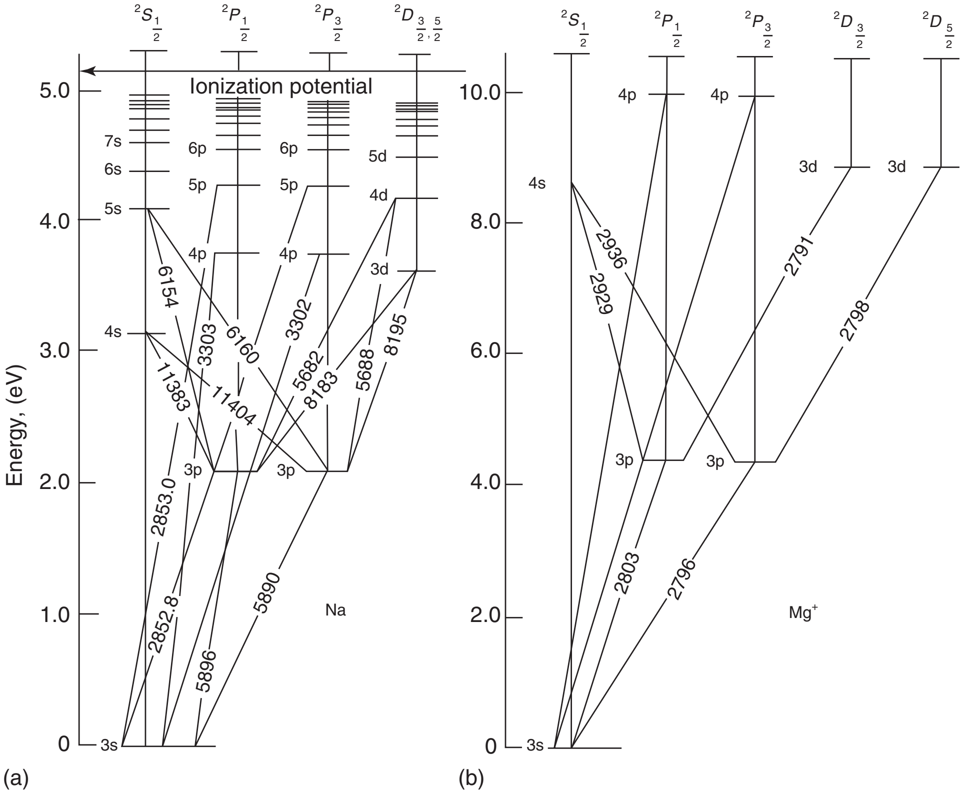

Figure 15.1 Energy level (Grotrian) diagrams for (a) atomic sodium and (b) magnesium (I) ion.

orbital momenta of all electrons have to be coupled to the total orbital momentum, and so are the spin momenta. The total quantum number L is obtained by replacing $L=\Sigma l$, $S=\Sigma s$, and $J=L-S, \ldots, L+S$. The term symbol thus becomes

$$^{\mathrm{M}}L_J \tag{15.14}$$

As an example, the ground state of Mg is denoted as 3^1S_0 (electron configuration: $1s^22s^22p^63s^2$, corresponding to $L=0$ as $l_1=0$ and $l_2=0$; $S=0$ as $s_1=1/2$ and $s_2=-1/2$; and $J=L+S=0$). The notation for the first excited state ($1s^22s^22p^63s^13p^1$) is, depending on the spin quantum number of the two valence electrons, 3^1P_1 (with $L=1$ as $l_1=0$ and $l_2=1$; $S=0$ as $s_1=1/2$ and $s_2=-1/2$; and $J=L+S=0$ and $J=|L\pm S|=1$) , as well as 3^3P_2, 3^3P_1, and 3^3P_0 (corresponding to parallel spins $s_1=1/2$ and $s_2=1/2 => S=1$ and consequently $J=0, 1, 2$). The energy level diagrams for ionic magnesium with one valence electron (Figure 15.1b) and atomic magnesium (Figure 15.2) differ significantly. For atoms with two outer electrons, two different term schemes exist upon excitation, the singlet and the triplet state with considerably different excitation energies. In the excited singlet state, the spins of the two electrons are of opposed orientation and they are paired. In the triplet state, the spins are parallel or unpaired. For this reason, the triplet excited state is of lower energy than the corresponding singlet state.

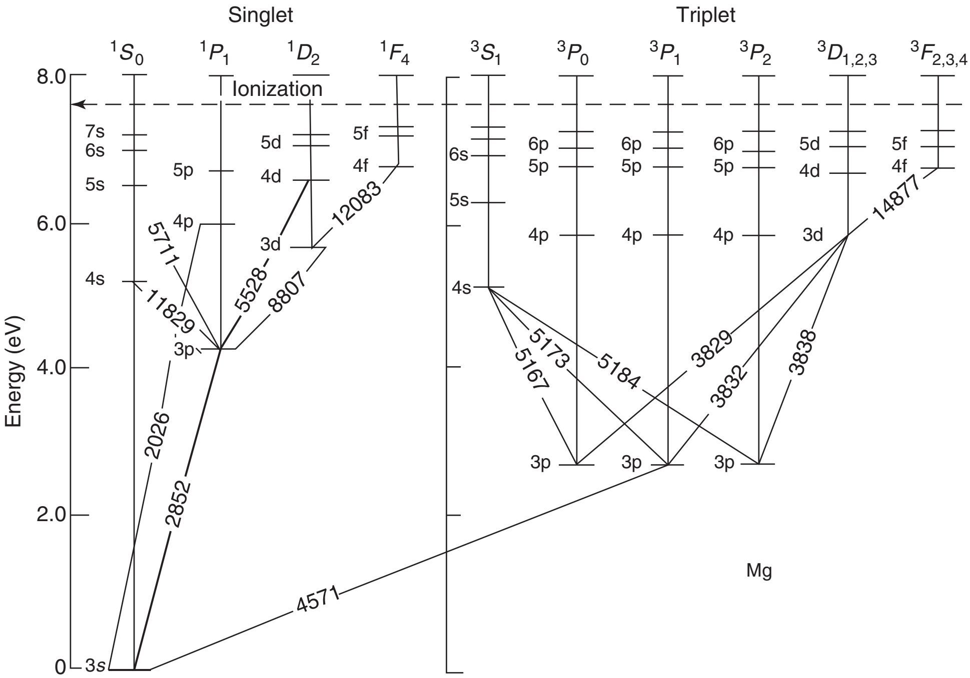

Figure 15.2 Energy level diagram for atomic magnesium. Strong lines indicate greater line intensities. The singlet/triplet transition has a significantly lower probability for occurrence than the singlet/singlet transition.

While the energy level diagrams and the corresponding spectroscopic transitions are relatively straightforward for light elements, they become very complex for heavier elements. The number of observed lines listed by Harvey [3] increases from the alkali metals with 30 (for lithium) to 645 (for cesium) to several thousand lines for the transition elements (chromium: 2277, iron: 4757, and cerium 5755).

15.2.2
Fundamentals of Absorption and Emission

Atomic absorption and emission require the prevalence of free atoms, which, in most instances, is achieved in a plasma or a plasma-like state. When a plasma is contained in a closed system and is in thermal equilibrium, the population of the excited levels may be described for one species by Boltzmann's law:

$$\frac{N_q}{N_0} = \frac{g_q}{g_0} \exp\left(\frac{-E_q}{kT}\right) \tag{15.15}$$

with N_q being the number of particles in the excited state, N_0 is the number of particles in the ground state, g_q and g_0 are the statistical weights of the corresponding energy levels, E_q is the excitation energy of the state q, k is the Boltzmann constant ($=1.38 \times 10^{-23}\ \mathrm{J\,K^{-1}}$), and T is the absolute temperature.

When the plasma is in the steady state, the number of particles that leave an energy level per unit time is equal to the number of particles that arrive at this level. A number of phenomena are responsible for the transition of species between energy levels in a plasma:

1) collisions of atoms, leading to the excitation of one species to a higher energy level (collisions of the first kind);
2) collisions of an excited species with another particle, leading to radiationless relaxation (collisions of the second kind);
3) excitation by collision with electrons;
4) de-excitation with the transfer of energy to an electron;
5) excitation of atoms or ions by the absorption of radiation;
6) de-excitation of atoms or ions by spontaneous or stimulated emission.

Assuming the presence of two species, with n being the concentration of one species and N that of the second species that is in large excess ($N \gg n$), we can set up the following equations:

$$\alpha N n_0 = \beta N n_q \tag{15.16}$$

$$\alpha_e n_e n_0 = \beta_e n_e n_q \tag{15.17}$$

$$B' \rho_\nu n_0 = (A + B\rho_\nu) n_q \tag{15.18}$$

A, B, and B' are the Einstein transition probabilities for spontaneous emission, stimulated emission, and absorption, respectively, and α_e, α, β_e, and β are the cross sections of the respective processes (which are also a function of the velocity distribution of the particles involved). n_e is the electron density and ρ_ν is the radiation density at a given frequency ν.

When the system is in thermodynamic equilibrium, the rate of formation and disappearance of charged particles and neutrals is equal, and at a given temperature T we can state

$$\frac{n_q}{n_0} = \frac{\alpha}{\beta} = \frac{\alpha_e}{\beta_e} = \frac{B'}{\frac{A}{\rho_\nu} + B} = \frac{g_q}{g_0} \exp\left(\frac{-E_q}{kT}\right) \tag{15.19}$$

The number of charged and uncharged species remains constant through excitation and de-excitation by collisions with neutrals, ions, and electrons. Absorption and emission, as they occur in a real radiation source, certainly also have to be considered, but they normally contribute only very little to the energy balance which is in the so-called local thermal equilibrium (LTE):

$$\alpha N n_0 + \alpha_e n_e n_0 + B' \rho_\nu n_0 = \beta N n_q + \beta_e n_e n_q + (A + B\rho_\nu) n_q \tag{15.20}$$

From Eq. (15.20), n_q/n_0 can be calculated. In the radiation source, the population of excited states is determined by the excitation process, as may be deduced from Eq. (15.20): Thus, for a DC arc source (which is said to be in LTE), $\alpha N \gg \alpha_e n_e + B' \rho_w$, and $\beta N \gg \beta_e n_e + (A + B\rho_\nu) n_q$.

As long as the radiation density is low (which is the case for the DC arc), the plasma can be assumed to operate under LTE. This is not the case for low-pressure discharges where both collisions with electrons and radiative de-excitation are very important. Also, for low-pressure plasmas, the assumption of a Maxwellian velocity distribution of the particles is no longer valid.

Species can decay from excited states through a number of processes, including collision with uncharged (molecules, atoms) or charged (ions, electrons) particles, or by the emission of electromagnetic radiation. In the case of radiative decay, the wavelength of emission is given by Planck's law. For the spontaneous decay from level q to level p, the number of events per unit time is

$$-\frac{\mathrm{d}N_q}{\mathrm{d}t} = A_{qp} N_q \tag{15.21}$$

A_{qp} is the Einstein coefficient for spontaneous emission (s^{-1}). Equation (15.21) must be adapted when several transitions starting from level q are to be considered.

$$-\frac{\mathrm{d}N_q}{\mathrm{d}t} = N_q \sum_p A_{qp} = N_q \nu_q \tag{15.22}$$

Here, ν_q is the lifetime of the excited state q. The typical lifetime of an excited state from which a species decays through an allowed radiative transition is of the order of 10^{-8} s. When radiative transitions are not allowed, the excited states are metastable (as is the case, e.g., for the Ar 11.5 and 11.7 eV states), and relaxation can only occur through collisions with other particles.

Absorption of electromagnetic radiation of frequency ν_{qp} and radiation density p increases the number density of excited particles N_q as

$$\frac{\mathrm{d}N_q}{\mathrm{d}t} = B'_{qp} N_q \rho_\nu \tag{15.23}$$

Stimulated emission takes place when atoms in the excited state q decay upon interaction with radiation of wavelength λ_{qp} and leads to a reduction in the number density of excited species according to

$$-\frac{\mathrm{d}N_q}{\mathrm{d}t} = B_{qp}N_q\rho_\nu \tag{15.24}$$

Under conditions of thermal equilibrium

$$g_q B_{qp} = g_p B_{pq} \tag{15.25}$$

where g_q and g_p are the statistical weights (degeneration factors) of levels p and q.

When species emit, the intensity of the emitted spectral line (denoted by the subscript a) is proportional to the number density of atoms in the excited state q:

$$I_{qp} = A_{qp}n_{aq}h\nu_{qp} \tag{15.26}$$

n_{aq} may be substituted using the Boltzmann equation

$$I_{qp} = A_{qp}h\nu_{qp}n_a\,\frac{g_q}{Z_a}\exp\left(\frac{-E_q}{kT}\right) \tag{15.27}$$

The sum $Z_a = \sum^{a} g_a \exp\left(\frac{-E_a}{kT}\right)$ is the partition function. It is a function of temperature, and the coefficients of this function are tabulated in the literature for a large number of atoms and ions. When the intensities of two emission lines a and b from the same ionization state of an element are used, the excitation temperature T may be calculated from

$$T = \frac{5040(V_a - V_b)}{\log[(g_aA_a)/(g_bA_b)] - \log(\lambda_a/\lambda_b) - \log(I_a/I_b)} \tag{15.28}$$

In this equation, energies are in electronvolts (eV), and V_a and V_b denote the excitation energies (eV) of lines a and b. The line pair Zn 307.206 nm/Zn 307.59 nm is very often used for calculating the excitation temperature. It is particularly suitable, as ionization of zinc is generally low (due to its high ionization energy), the difference between the two wavelengths is not too large, ensuring a uniform detector response, and the gA factors are precisely known.

15.2.2.1 **Absorption**

Between absorption and the number density of the absorbing atoms, the following relation holds:

$$\int K_\nu \mathrm{d}\nu = \frac{\pi e^2}{mc}Nf \tag{15.29}$$

where K_ν is the absorption coefficient at frequency ν, m is the electron mass and e its charge, c is the velocity of light, N is the number density of atoms, and f is the oscillator strength. As this relation is strictly valid only for monochromatic light, the use of a source that emits radiation with a very narrow spectral line width is required. Normally, atomic emission sources such as hollow cathode lamps (HCLs) or electrodeless discharge lamps (EDLs) fulfill this condition. The relation between the absorption A and the concentration c is given by the law of Lambert and Beer, which states that the intensity of incident radiation I_0 is diminished by the fraction dI by absorption in the incremental length dl (with l being the total optical path length):

$$-\mathrm{d}I = kI_0c\,\mathrm{d}l \tag{15.30}$$

Integration of Eq. (15.30) in the limits $I = I_0$ to I and $l = 0$ to l gives

$$-\int_{I=I_0}^{I} \frac{\mathrm{d}I}{I} = kc \int_{I=0}^{I} \mathrm{d}I \tag{15.31}$$

$$-\log\left(\frac{I}{I_0}\right) = kcl \tag{15.32}$$

As log I_0/I equals the absorbance A, Eq. (15.32) can finally be written as

$$A = kcl \tag{15.33}$$

The Lambert–Beer law is valid only within a restricted concentration range. Deviations from linearity are commonly observed – and most notably in atomic absorption – and may be due to a number of reasons.

15.2.2.2 **Line Broadening**

Because of the contribution from various broadening mechanisms, the line widths typically observed in atomic spectrometry are significantly larger than the natural width of a spectroscopic line that can be theoretically derived. The natural width of a spectral line is a consequence of the limited lifetime τ of an excited state. Using Heisenberg's uncertainty relation, the corresponding half-width expressed as frequency is

$$\Delta\nu_N = \frac{1}{2\pi\tau} \tag{15.34}$$

From this equation, a typical half-width of about 1–10 pm is obtained for most spectroscopic lines.

The first important line-broadening mechanism is *Doppler line broadening*. It results from the movement that emitting species make toward or away from the point of observation. The contribution to line broadening is

$$\Delta\nu_{\mathrm{D}} = \left[\frac{2\sqrt{(\ln 2)}}{c}\right]\nu_0\sqrt{\frac{2RT}{M}} \tag{15.35}$$

where c is the velocity of light, ν_0 is the frequency of the emission maximum, R is the gas constant, M is the atomic mass, and $\Delta\nu_{\mathrm{D}}$ is the observed Doppler line broadening, expressed as full width at half-maximum (FWHM). Equation (15.35) suggests that Doppler line broadening is strongly temperature dependent. It has therefore also often been termed *temperature broadening*. It may thus be used to determine the kinetic energy of the emitting atoms or ions. For example, Doppler broadening is about 0.8 pm for the Ca(I) emission at 422.6 nm at 300 K and reduced pressure, while it approaches 2 pm at 3000 K.

Pressure or *Lorentz broadening* is the second important factor for line broadening. It is a result of the interaction of the emitting species and other nonemitting particles. Its contribution to line broadening is

$$\Delta\nu_{\mathrm{L}} = \left(\frac{2}{\pi}\right)\sigma_{\mathrm{L}}^{2}N\sqrt{\left[2\pi RT\left(\frac{1}{M_1}+\frac{1}{M_2}\right)\right]} \tag{15.36}$$

where M_1 and M_2 are the atomic masses of the two interacting species. N is the concentration of the foreign atom species and σ_{L} is its cross-section. At low pressure, the contribution of pressure broadening is low: for example, for the Ca 422.6 nm line, only about 0.02 pm at 300 K and 0.9 kPa. However, with increasing pressure, this contribution becomes the dominant factor for line broadening.

Other factors contributing to line broadening are *isotopic effects* and *hyperfine structure* (due to the interaction between radiating and nonradiating atoms of the same species) and *Stark broadening* (which is due to the interaction with electric fields).

15.2.2.3 **Self-Absorption**

Self-absorption occurs when radiation emitted by the source is absorbed by atoms of the same species in the ground state. Since the probability of re-emission of an absorbed photon is always less than unity, self-absorption results in a reduction of the radiation produced. The intensity distribution of an emission line is $I_0P_{\mathrm{E}}(\nu)$, where I_0 stands for the intensity emitted at the line maximum, and $P_{\mathrm{E}}(\nu)$ the profile function. After passage through a layer of absorbing species with a number density n_{A} of absorbing species, the intensity distribution is

$$I(\nu) = I_0P_{\mathrm{E}}(\nu)\exp\left[\frac{-\rho P_{\mathrm{A}}(\nu)}{P_{\mathrm{A}}(\nu_0)}\right] \tag{15.37}$$

where ν_0 is the intensity in the line center, $P_{\mathrm{A}}(\nu)$ is the absorption profile function and $P_{\mathrm{A}}(\nu_0)$ its value at the line center, and ρ is an absorption parameter given by

$$\rho \sim BP_{\mathrm{A}}(\nu)n_{\mathrm{A}} \tag{15.38}$$

ρ increases with increasing Einstein coefficient for absorption and consequently is larger for transitions that are based on excitation from the ground state. It also becomes larger when the number density of species, n_{A}, increases in the source. Self-absorption is strongest in the center of the line where absorption reaches its maximum. Thus, flatter line profiles are observed in this case. When self-absorption is so pronounced that it leads to a minimum in the intensity profile and $\rho > 1$, this is called *self-reversal*. Self-reversal is seen only where the radiation source exhibits a strong temperature gradient and the number densities of the analyte are high in both the hotter and the cooler zones of the source.

15.2.2.4 **Ionization**

When the plasma is sufficiently energetic, atoms may be ionized. The degree of ionization depends on the temperature of the plasma and the ionization energy of the considered element. In particular, for easily ionizable species, ionic spectra also contribute to the emission spectra observed in a plasma to a great extent. The ionization of atoms a of a particular element into ions i with liberation of electrons e is an equilibrium reaction given by

$$n_a \rightleftarrows n_i + n_e \tag{15.39}$$

whose equilibrium constant $S_n(T)$ is the so-called Saha constant

$$S_n(T) = \frac{n_i n_e}{n_a} \tag{15.40}$$

As long as the degree of ionization α for the considered element is small, it can be expressed as follows:

$$\alpha = \frac{n_i}{n_{\text{total}}} = \frac{n_i}{n_i + n_a} \tag{15.41}$$

n_1 and n_2 are the concentrations of ions and atoms in the plasma, respectively, and can be expressed as fractions of the total element concentration.

$$n_a = (1-\alpha)n_{\text{total}} \quad \text{and} \quad n_i = \alpha n_{\text{total}} \tag{15.42}$$

This can be substituted into the Saha equation, giving

$$S_n(T) = \frac{\alpha}{1-\alpha} n_e \tag{15.43}$$

The Saha equation can also be expressed in partial pressures p as

$$S_p(T) = \frac{p_i p_e}{p_a} = \frac{\left[(2\pi m)^{\frac{3}{2}}(kT)^{\frac{5}{2}}\right]}{h^3\left(2\frac{Z_i}{Z_a}\right)\left[\exp\left(\frac{-E_i}{kT}\right)\right]} \tag{15.44}$$

The factor 2 is the statistical weight of the free electron (which has two possible orientations for its spin), k is the Boltzmann constant (1.38×10^{-23} J K^{-1}, m is the mass of an electron (9.11×10^{-28} g), and h is the Planck constant (6.63×10^{-34} J s). With the conversion to electron volts (1 eV $= 1.6 \times 10^{-19}$ J), the Saha equation reads

$$\log S_p = \frac{5}{2}\log\frac{T-5040}{T}V_i + \log\frac{Z_i}{Z_a} - 6.18 \tag{15.45}$$

where V_i is the ionization energy in electron volts.

The Saha equation is valid only when the plasma is in (at least local) thermal equilibrium. The temperature resulting from the Saha equation is then the ionization temperature of the observed species. Under these conditions, the degree of ionization can be calculated from the intensity of the atom and ion lines of the same element, I_{qp} and I_{qp}^{+}:

$$\log\left(\frac{\alpha}{1-\alpha}\right) = \log\left(\frac{I_{qp}^{+}}{I_{qp}}\right) - \log\left(\frac{g_q^{+}A_{qp}^{+}\nu_{qp}^{+}}{g_q A_{qp}\nu_{qp}}\right) + \frac{5040}{T}\,(V^{+} - V_q) + \log\left(\frac{Z_i}{Z_a}\right) \tag{15.46}$$

The temperature of the plasma must be precisely known and controlled for the calculation of the degree of ionization, as the partition functions Z_a and Z_i for the atom and ion species, respectively, are strongly temperature dependent. The accuracy of the values of gA determines the accuracy of the calculation of the degree of ionization. The line pairs Mg(II) 279.6 nm/Mg(I) 278.0 nm and Mg(II) 279.6 nm/Mg(I) 285.2 nm are very often used to calculate the degree of ionization of an element in a plasma. When the degree of ionization α is known, the electron pressure in the plasma can be determined. Starting from

$$\log\left(\frac{\alpha}{1-\alpha}\right) = \log\left(\frac{S_p(T)}{p_e}\right) \tag{15.47}$$

one can derive

$$\log p_e = -\log\left(\frac{\alpha}{1-\alpha}\right) + \log S_p(T) \tag{15.48}$$

This equation may be rephrased as

$$\log p_e = -\log\left(\frac{I_{qp}^{+}}{I_{qp}}\right) + \log\left(\frac{g_q^{+}A_{qp}^{+}\nu_{qp}^{+}}{g_q A_{qp} \nu_{qp}}\right) - \frac{5040}{T}(V_i + {V_q}^{+} - V_q) + \frac{5}{2}\log T - 6.18 \tag{15.49}$$

which indicates that the intensity ratio of the atom and ion lines of an element changes remarkably with the electron pressure. This is particularly true for elements with low ionization energy, such as the alkali metals. An important consequence of this is the occurrence of the so-called ionization interferences.

From the above, it can be concluded that there exists for each spectral line emitted by a radiation (plasma) source an optimum temperature at which its emission intensity reaches a maximum. This so-called standard temperature depends on the energy of ionization and excitation of this element, as well as on the electron pressure and temperature in the plasma. The standard temperature for many atom lines is around 4000 K, while the standard temperature of ionic lines is often around 10 000 K.

15.2.2.5 **Dissociation**

Although atomic spectroscopy requires the presence of free atoms, highly stable radicals or molecules are also present in a radiation source and contribute to the background emission. The atomic and ionic lines are then superimposed on the molecular bands. Common species encountered in plasmas are CN, NH, NO, OH, and N_2 or ${N_2}^+$, but refractory reaction products may also be observed (e.g., AlO^+, TiO^+, or YO^+). The dissociation of the molecular species within the plasma is an equilibrium reaction. It can be described by a formula similar to the Saha equation:

$$K_n = \left[\left(\frac{2\pi}{h^2}\right)\left(\frac{m_x m_y}{m_{xy}}\right)(kT)^{\frac{3}{2}}\right]\left(\frac{Z_x Z_y}{Z_{xy}}\right)\left[\exp\left(\frac{-E_d}{kT}\right)\right] \tag{15.50}$$

where K_n is the equilibrium constant and the indices x and y denote the species that are produced from the dissociation of xy.

$$K_n = \frac{n_x n_y}{n_{xy}}$$

If we take the example of a metal oxide in the plasma, the degree of dissociation can be calculated from the plasma temperature, the partial pressure of the reactant (oxygen, in this case), and the dissociation energy E_d.

15.2.2.6 Radiation Sources and Atom Reservoirs

In the discussion of the elementary steps of atomic spectroscopy, it is essential to distinguish between ''radiation sources'' and ''atom reservoirs.'' In the former, radiation is generated that is used for the spectroscopic measurement. The latter serve to produce free atoms (or ions) from the sample. The two devices may be separated, as is the case for atomic absorption (and also atomic fluorescence), or the atom reservoir may also be the radiation source, as for atomic emission.

The volatilization (vaporization) and dissociation of the sample usually require highly energetic conditions to be as complete as possible. This is essential to maximize sensitivity while minimizing matrix interferences at the same time. The effectiveness of volatilization, atomization, and excitation is dependent upon the supply of energy to the sample and is characterized by different spectroscopic temperatures. They represent an important diagnostic tool for the characterization of atomization conditions in the plasma:

Rotational temperature: This is important for all processes where molecules or radicals are involved. It can be determined from the intensity distribution from the rotational lines in rotational–vibrational spectra. In most cases, diatomic molecules or radicals such as OH and CN are used as thermometric probes.

Gas temperature: This depends on the kinetic energy of the atoms and ions in the plasma. It can be determined from the Doppler peak broadening. This is, however, not completely straightforward, as the contributions of Doppler and temperature line broadening have to be separated by mathematical deconvolution. Together with the rotational temperature, it is an indicator for the vaporization and atomization capability of a plasma.

Electron temperature: This is characteristic for the kinetic energy of the electrons. It is important for all excitation and ionization processes that are initiated by collisions with electrons. Electron temperatures are often determined from the intensity of the recombination continuum or from the energy distribution of the bremsstrahlung.

Excitation temperature: This characterizes the population of the excited levels of atoms or ions and is thus of fundamental importance for spectroscopic measurements. It can be determined from the intensity ratio of two lines of a given element in the same atomic or ionic state. Alternatively, it may be determined from a plot of the emission intensity at different lines over their excitation energies for the particular element at a defined state of ionization.

Ionization temperature: This describes the equilibrium between atoms, ions, and electrons in a plasma. When thermal equilibrium applies, the Saha equation can be used to calculate the ionization temperature from the intensity ratio of an ion and an atom line of the same element. Another possibility is to calculate the ionization temperature from the n_e value which

Table 15.1 Temperatures of different excitation sources and atom reservoirs used in atomic spectrometry.

Source	Temperature (K)				State
	Rotational, T_{rot}	Excitation, T_{ex}	Electron, T_e	Ion, T_i	
Arc (DC)	5 000	5 000	5 500	5 000	LTE
Spark	—	20 000	20 000	20 000	LTE
Inductively coupled plasma	4 800	5 000	6 000	6 000	~LTE
Microwave plasma	2 000	4 000	6 000	6 000	Non-LTE
Low-pressure discharge	600	20 000	30 000	30 000	Non-LTE

can be obtained from Stark broadening. In plasmas that are in thermal equilibrium, all the above temperatures are equal.

That means that

- the velocity distribution of all species in the plasma (molecules, atoms, ions, and electrons) can be described by the Maxwell equation;
- the population of the different energy levels follows the Boltzmann equation;
- the equilibrium between electrons, ions, and neutrals of the different species obeys the Saha equation.

Real plasmas provide, even in the best cases, just an approximation to LTE. However, their spatial inhomogeneity is very large, as far as the temperature and number density distributions of the different species are concerned. Consequently, the equilibria occur only within very small volume elements of the plasma. Table 15.1 gives an overview of the different temperatures observed in the most common excitation sources and reservoirs for atomic spectrometry.

15.3
Atomic Absorption Spectrometry (AAS)

15.3.1
Introduction

AAS is nowadays one of the most important instrumental techniques for quantitative analysis of metals (and some metalloids) in various types of samples and matrices. The history of AAS dates back to the discovery of dark lines in the continuous emission/spectrum of the Sun by Wollaston in 1802. The lines are caused by the absorption of the elements in the atmosphere of the sun. His work was taken up and further pursued by Fraunhofer in 1814. In 1860, Kirchhoff and Bunsen demonstrated that the yellow line emitted by sodium salts when introduced into a flame is identical with the so-called D-line in the emission spectrum of the

Sun [1]. However, it took nearly one century before this important discovery was transformed into a viable analytical technique. In 1955, Alan Walsh published the first paper on atomic absorption spectroscopy [4]. At the same time, and independently of Walsh, Alkemade and Wilatz published the results of their fundamental AAS experiments [5, 6]. But it was the vision of Walsh and his indefatigable efforts that eventually led to the general acceptance and commercialization of AAS instrumentation in the mid-1960s. Further instrumental achievements (such as the introduction of the graphite furnace and the hydride generation technique) in the second half of the 1960s further promoted the popularity and applicability of the technique [6b].

15.3.2
Instrumentation

The instrumental requirements of AAS will be discussed in the following section. In Figure 15.3, the essential components of an atomic absorption spectrometer are depicted schematically: a suitable radiation source, an atomizer, some optics and a monochromator, a detector, and suitable electronic signal processing [7, 8]. The individual components of an AAS instrument will be discussed in this order.

15.3.2.1 Radiation Sources

For absorption-based optical methods, one has to consider the line width of the excitation source in relation to that of the respective transition of the absorbing species.

The half-width of elemental lines is of the order of 0.002 nm when observed by emission spectroscopy with flame or electrothermal atomization. The broadening of the line can be due to a number of reasons, of which the most important and best understood are natural, pressure, resonance, and Doppler broadening. If a stable and sensitive detection is to be achieved, the line width of the excitation radiation must be narrower than the FWHM of the analyte line. Under these conditions, the entire radiant energy produced by the excitation source will be available for absorption by the analyte. The typical line sources used for atomic absorption are thus element-specific excitation sources such as the HCL or the EDL. More recent developments have demonstrated that even continuum sources can be used with appropriate instrumental designs.

15.3.2.1.1 **The Hollow-Cathode Lamp** Initially described in 1916 by Paschen, the HCL is probably the most versatile excitation source for AAS. A schematic of this excitation source is given in Figure 15.4. It consists of a Pyrex glass tube (“envelope”) in which the cathode and anode are located under an inert gas

Figure 15.3 Essential components of an atomic absorption spectrometer.

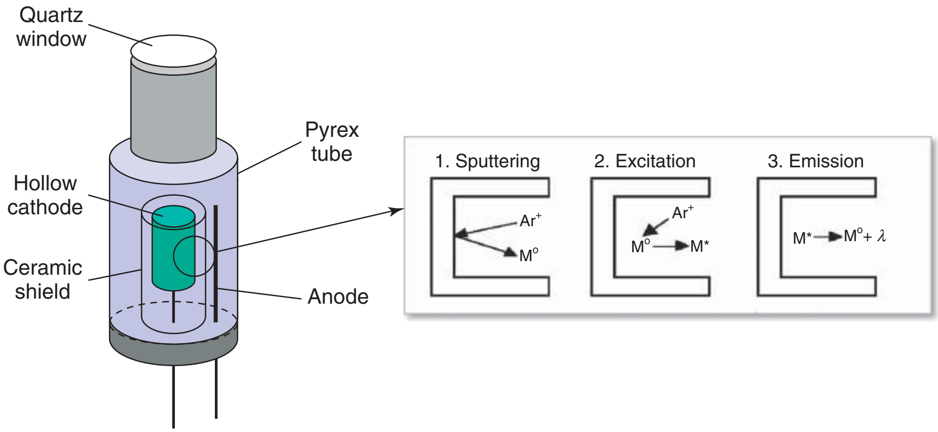

Figure 15.4 Schematic of a hollow cathode lamp (HCL). *Inset*: Signal formation mechanism in the HCL.

atmosphere (neon or argon; neon is typically preferred for its simpler spectral background, and preference is given to Ar only where spectral interferences by Ne emission lines are anticipated) at a pressure of typically 1–5 Torr. The hollow cathode is made from (or coated with) the respective pure element or the element alloyed with another suitable element. Alloying is used where the element is not available in an appropriate form, such as sodium, arsenic, and so on, to achieve a balanced output (Cd, Cr), or in the case of precious elements where significant cost savings can be made without compromising analytical performance. The anode is a strong nickel or tungsten wire. The anode often is coated with a getter material which assists in removing any impurities released from the cathode during the sputtering process from normal operation. The getter is also activated during lamp processing to collect any impurities remaining in the cathode material. This process deposits the impurities onto the glass bulb in such a form that they remain inert throughout the life of the lamp. It is this process that creates the dark colored ring on the wall of the envelope adjacent to the getter. The two electrodes are separated by a ceramic shield. At the front end of the HCL, a borosilicate glass (>400 nm), a special UV-transparent glass (240–400 nm), or a high-purity quartz glass window (>160 nm) is attached in order to achieve the optimum transmission of the key spectral lines of the cathode element.

The emission is generated by applying a voltage of typically 350–500 V across the electrodes, which leads to a current of 1–50 mA, resulting in an electrical discharge. Positive noble gas ions are accelerated toward the hollow cathode where their impact sputters atoms of the element to be determined from the hollow cathode. The sputtered metal ions are then excited through collisions with Ne or Ar ions in the gas phase. The metal ions return to the ground state by emitting radiation at characteristic wavelengths. The typical half-width of an atomic emission line produced by a HCL is approximately 0.2 pm, which fully complies with the requirements for an AAS line source discussed above.

The intensity of radiation produced by an HCL is proportional to the number of sputtered and excited atoms and will thus depend on the kinetic energy of the inert gas ions, which is controlled by the lamp current. Although the increase in lamp current produces a higher radiance and thus provides a higher sensitivity, there is, however, an upper limit for the HCL current for practical reasons (Figure 15.5): At high lamp currents, a large number of metal atoms are sputtered and brought into the gas phase. In this dense cloud of gas phase metal atoms, self-absorption reduces the intensity of the element-specific radiation, resulting in a reduction in sensitivity. Ideally, the sputtered metal atoms are redeposited on the hollow cathode upon radiative de-excitation. However, the metal atoms may also be transported and deposited on the glass walls of the HCL, thereby reducing the lifetime of the lamp. For this reason, the geometry of the cathode walls is optimized, and a protective shield is placed around the cathode.

In addition to single-element HCLs, multielement HCLs are also available and provide multielement excitation capabilities with one single HCL at a price that is comparable to a single-element HCL. More important than the cost advantage, however, is their ability to enable the simultaneous analysis of up to six elements without the need of changing the HCL for each element. Their principle of operation is the same as that of single-element lamps, with the cathode being made either from an alloy or from pressed powders of the respective elements (e.g., Al/Ca or Cr/Co/Cu/Fe/Mn/Mo). Although they represent a significant improvement for multielement AAS measurements (and make the exchange of HCLs obsolete when several elements are to be determined), they have some practical drawbacks. Their

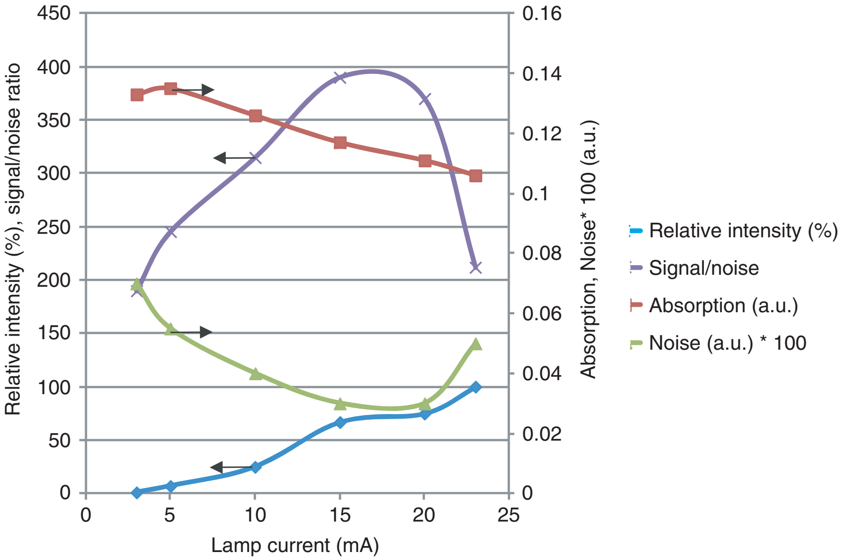

Figure 15.5 Relative intensity, noise, signal-to-noise ratio, and absorption for the determination of Cu (at 2 mg l^{-1}) by flame AAS as function of the lamp current.

lifetime is typically shorter than that of single-element HCLs, since the elements used for the production of the HCL have different volatilities. The element with the highest volatility will be preferentially sputtered and, with time, it will cover all other elements in the HCL, making them inaccessible to sputtering by accelerated gas ions. This will cause the sensitivity of the less volatile elements to diminish over time and will eventually shorten the effective lifetime of the HCL.

15.3.2.1.2 **The Boosted Hollow-Cathode Lamp** A very intense radiation source for AAS is the boosted HCL. It has been developed from the regular HCL and includes a second pair of electrodes between which a boost discharge is initiated, using the existing instrument lamp current supply. Via this discharge, the excitation of the sputtered atoms is increased significantly while self-absorption is minimized. As a result, the emission intensity is 5–15 times higher than for a standard HCL, which significantly improves the signal-to-noise ratio.

15.3.2.1.3 **The Electrodeless Discharge Lamp** The EDL is another atomic line source that allows one to produce a highly effective excitation source for elements that cannot be cast into hollow cathodes, such as mercury, arsenic, antimony, and some other elements.

The EDL is produced by filling a small quartz bulb with a few milligrams of the respective element under an inert gas atmosphere (usually argon) at reduced pressure and then sealing this tube. The quartz bulb is located at the center of a radio frequency (RF) coil (Figure 15.6). When an RF field, typically oscillating at 27.12 MHz, is applied to the coil, the argon atoms are ionized. The collision of free atoms of the particular element in the gas phase with the electrons produced by ionization of the argon leads to their excitation and subsequent radiative relaxation. While the EDL produces element-specific radiation of greater intensity than the HCL, its use is restricted to the more volatile elements. It also requires a separate power supply that provides the RF current.

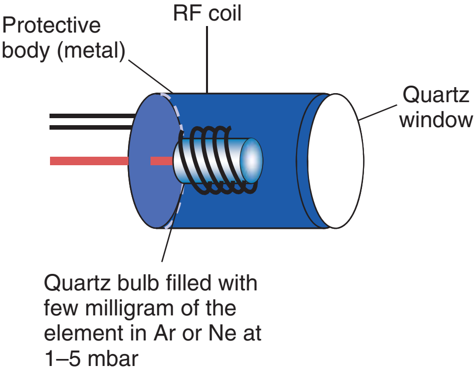

Figure 15.6 Scheme of an electrodeless discharge lamp.

15.3.2.1.4 **Continuum Sources** The disadvantage of having to change HCLs for each new element to be determined explains the interest in continuum light sources in AAS. However, as the line width of the absorbing species (0.0002 nm) is typically much smaller than the bandpass of common monochromators (0.1–0.2 nm), this approach is limited in practice [9]. This would mean that a large fraction of the light reaching the detector is not at the characteristic wavelength of the element. The small fraction of light that is actually absorbed by the atoms at their characteristic excitation wavelength would result in only a low analytical sensitivity. Echelle grating monochromators with their smaller spectral bandpass have, in part, overcome this shortcoming of AAS with continuum light sources, but still the sensitivity that can be reached is smaller than that with atomic line sources of narrow line widths.

Continuum sources that are currently used are the high-intensity xenon arc lamp and the deuterium lamp, the former being preferred owing to its higher brilliance. Although the presently realized continuum-source (CS) AA spectrometers are still operated sequentially for multielement detection, it may be anticipated that, with the use of suitable optics and multiarray detectors, this method will become a truly simultaneous multielement technique [10].

However, even as a single-element technique, CS-AAS provides a variety of advantages over conventional line source (LS) AAS. First, the atomic absorption can not only be measured at the center of the absorption line (with maximum sensitivity) but also at its wings (with reduced sensitivity). This leads to a greatly enhanced dynamic range of approximately 5–6 orders of magnitude in concentration or mass. This, together with very favorable detection limits as reported in recent literature, eliminates one of the classical disadvantages of AAS – its limited dynamic range.

Second, the setup shown in Figure 15.7 with a charge-coupled device (CCD) detector provides a lot of information about the spectral neighborhood around the analytical line, which eventually results in a much more reliable and accurate background correction, as essentially any pixel or set of pixels may be used for that purpose, depending on the nature of the background. In addition, as this wavelength-resolved absorbance is measured over time with each pixel, a three-dimensional absorbance pattern is obtained eventually for the background signal which is recorded simultaneously with the analytical signal – a unique property that not even Zeeman-effect background correction can provide which records the analyte and background absorbance sequential in time. In case of a structured background, background correction with a deuterium lamp is impossible, and presents a problem even for Zeeman-effect background correction. In the case of CS AAS, however, it is possible to eliminate the background almost completely by a least-squares background correction with the normalized spectra of the interfering species.

15.3.2.1.5 **Diode Laser Sources** Already in 1980, lasers had been suggested as excitation sources for AAS [11]. Tunable dye lasers can provide virtually any atomic line between 213 and 900 nm with a bandwidth corresponding to the natural line width of an atomic line and with a comparatively high intensity. However, they

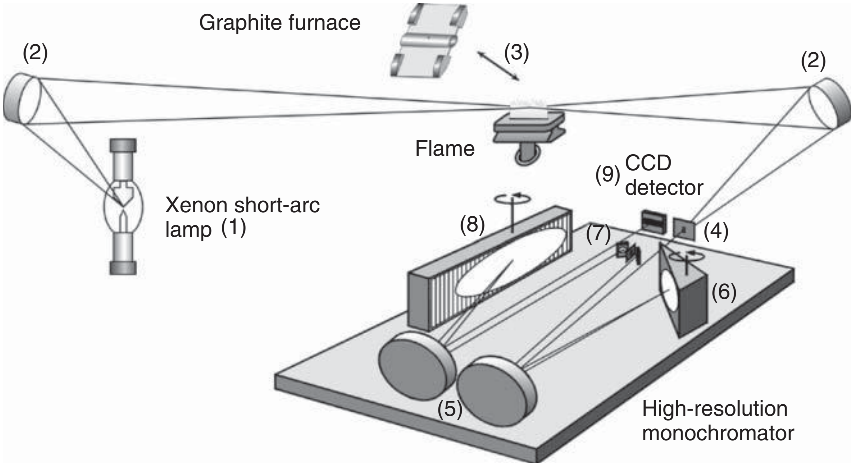

Figure 15.7 Experimental setup for CS AAS with double echelle monochromator. (1) Xenon short-arc lamp; (2) off-axis ellipsoid mirrors; (3) longitudinal Zeeman graphite furnace module (exchangeable with flame atomizer); (4) entrance slit; (5) off-axis parabolic mirrors; (6) Littrow prism; (7) deflection mirrors and intermediate slit; (8) echelle grating (75 grooves/mm, blaze 76°); and (9) linear CCD array detector. (Reprinted from Welz *et al*. [10b], with permission.)

have not found widespread acceptance for this application so far owing to their cost and complex operation compared to HCLs or EDLs. This situation seems to have changed with the advent of inexpensive, mass produced diode lasers (DLs) [12, 13].

DLs provide a radiant output that can be several orders of magnitude higher than that of common HCLs. Together with their excellent stability (both in terms of wavelength and intensity), this accounts for an improvement in signal-to-noise ratio, which brings about a 1–2 orders of magnitude improvement in the detection limit when compared with HCLs.

The typical line width of a commercial DL is approximately 2 orders of magnitude lower than that of atomic absorption lines in flames and furnaces. This allows one to expand the linear dynamic range of the method by tuning the DL to the wings of the absorption line where optically thin conditions prevail. Also, owing to the simplicity of DL emission (which basically consists of one single line), the requirements for the monochromator are much lower, allowing the construction of simpler instruments.

The possibility of modulating the emitted wavelength of DLs at gigahertz frequencies by the modulation of the diode current allows one to reduce the low-frequency (flicker) noise in the baseline, which again improves the detection limit. Emission wavelength modulation also provides a means of correcting for unspecific background absorption, thereby improving the selectivity of the technique.

DL AAS allows measurements that are almost shot-noise-limited with relatively high laser powers, leading to very low element detection limits (~1 ppt) if strong absorption lines are used. Although the wavelength range has been extended to the blue and near-UV spectral region with the introduction of new GaN-type laser diodes, the measurement of absorption lines down to 200 nm still needs frequency doubling of the laser radiation in optically nonlinear media which results in low radiation power and hence higher detection limits than theoretically possible. Further progress in the development of short wavelength laser diodes is needed, and is driven by the telecommunication and electronics industry.

The small line widths of DLs provide the opportunity of high-resolution spectroscopy, and thus the measurement of isotopes and isotope ratios. This allows the application of isotope dilution for improving the accuracy of elemental analysis, as known from mass spectrometry.

15.3.2.2 Atomizers

AAS requires that the species under investigation prevails in the gaseous and atomic state so that absorption of free atoms can be observed. The two most common methods for the production of atoms in the gas phase make use of thermal energy to vaporize and atomize the analyte. The sample transfer efficiency, that is, the amount of analyte that reaches the actual atomization zone, and the atomization efficiency that tells which fraction of the analyte is released in atomic form from its compounds, determine the overall efficiency. These two factors are important and directly related to the sensitivity that can be achieved with the particular method of atomization.

15.3.2.2.1 **Flame Atomization** In flame atomization, the sample solution is introduced into the flame with a specially designed nebulizer (Figure 15.8). The function of the nebulizer is to disrupt the continuous sample stream into a mist of fine droplets of typically 5–20 μm diameter which are swept into the mixing chamber. The aerosol is then mixed with the fuel gas and the oxidant gas before reaching the burner head. As a number of physical and chemical reactions, for example, vaporization, dissociation, reduction, or oxidation, may occur, it becomes evident that precise control of the operating conditions of flame atomization is required to obtain stable and sensitive signals. Optimization of flame atomic absorption measurements has thus the double role of maximizing the element's response and minimizing the undesired side reactions.

15.3.2.2.2 **Nebulizers** The most common type of nebulizer is the concentric tube nebulizer which consists of a capillary through which the liquid is introduced and an outer tube of larger diameter with a nozzle at its end. Through this outer tube, the nebulizer gas stream is directed at high pressure and achieves both transport of the liquid sample stream by aspiration and disruption of the continuous supply of sample. The advantages of this nebulizer type are its simple construction and the fact that it is self-aspirating. Other nebulizer types are in use, such as the cross-flow nebulizer where the high pressure gas flow is directed perpendicular to the capillary from which the liquid emerges. This type of nebulizer requires the liquid to be pumped through the capillary, which reduces the effect of viscosity on

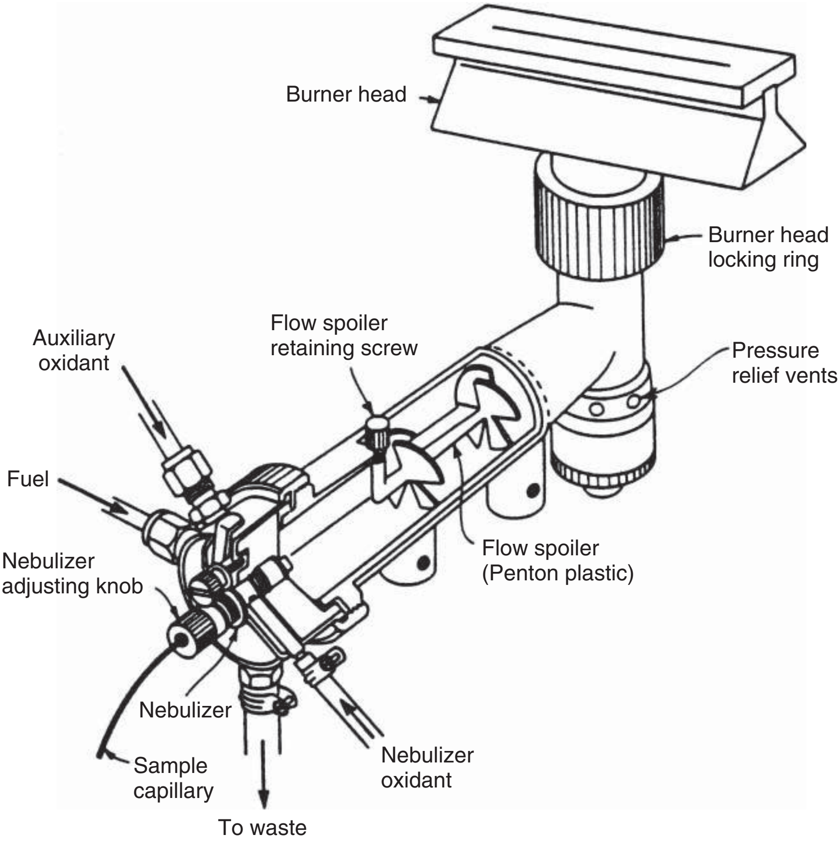

Figure 15.8 Design of a laminar flow burner. (Courtesy of the Perkin-Elmer Corporation, Norwalk, CT.)

sample introduction. The high-pressure gas is usually the oxidant, while the fuel gas is mixed subsequently with the sample aerosol.

15.3.2.2.3 **Burner Design** The aerosol is sprayed into the mixing chamber, which serves two functions. First, the fuel gas and additional oxidant gas are added (if required) and premixed to achieve optimum flame conditions. Second, droplets larger than about 20 μm in diameter are prevented from reaching the flame by arranging flow spoilers inside the mixing chamber. As a concentric tube nebulizer produces an aerosol of rather wide droplet size distribution, it is important to prevent droplets of larger diameter from being transported into the flame. Owing to the short residence time of the sample in the flame, large diameter droplets are not completely desolvated and atomized and thus increase the background noise of the flame. They are separated from the smaller diameter droplets by impacting on baffles and are drained to waste. Therefore, only less than 10% of the sample being converted to an aerosol actually reaches the burner head. High-efficiency nebulizers and flow-injection systems may introduce up to 30% of the aerosol into the flame, and high-pressure nebulizers even up to 50%.

The burner head is constructed in the form of a long, narrow slit (''laminar flow burner''). The long slit through which the flame expands (typically 10 or 5 cm) increases the absorption path length and thus also the sensitivity.

A point of critical importance in the AAS system is the optimization of fuel and oxidant gas flow ratios. Although fuel and oxidant gases are usually combined in approximately stoichiometric ratios, the determination of certain elements may require significantly different ratios.

Typical flame gas mixtures and resulting flame temperatures are given in Table 15.2. Early AAS work was carried out with natural gas/air and hydrogen/air flames and was focused mainly on those elements that, although easy to atomize, were difficult to excite because of the short excitation wavelengths, that is, Zn (213.8 nm), Cd (228.8 nm), Ni (232.0 nm), and Pb (283.3 nm). The use of hotter flames became necessary, however, as it was realized that a higher temperature is required for complete atomization (particularly for Al, Ti, or Si). While oxygen/natural gas or oxygen/acetylene mixtures can easily produce significantly higher flame temperatures, they require a particular burner head design that allows stable and safe operation even at the very high burning velocities of these gas mixtures.

The burning velocity is the velocity at which the flame expands in a premixed fuel/oxidant gas mixture. If the burning velocity is larger than the flow rate of the burner gas mixture, the flame propagates back into the burner, resulting in a flashback and potentially causing ignition of the explosive mixture in the mixing chamber. At higher flow rates, a point is reached where the flow velocity equals the burning gas velocity, so that a stable operation of the flame is achieved. If the flow velocity is further increased, the flame rises and eventually reaches a point where the flame is blown off the burner head. The extremely high burning velocities of oxygen/natural gas or oxygen/acetylene mixtures make their use in flame AAS very inconvenient and hazardous. A significant breakthrough was the introduction of the nitrous oxide/acetylene flame, which permits operation at reasonable burning velocities. However, the burner design has still to be modified

Table 15.2 Typical gas mixtures and flame properties for flame AAS.

Fuel	Oxidant	Flame temperature (°C)	Maximum burning velocity ($\mathrm{cm\,s^{-1}}$)	Burner slot (mm)
Natural gas	Air	1700–1900	39–43	100 × 1.5
Natural gas	Oxygen	2700–2800	370–390	—
Hydrogen	Air	2000–2100	300–440	—
Hydrogen	Oxygen	2550–2700	900–1400	100 × 1.5
Acetylene	Air	2100–2400	158–266	—
Acetylene	Oxygen	3050–3150	1100–2480	—
Acetylene	Nitrous oxide	2600–2800	285	50 × 0.5

for nitrous oxide/acetylene flames in contrast to air/acetylene or air/natural gas flames, that is, both the length and width of the burner head slit have to be of particular dimensions. This design provides a more efficient heat sink for the flame than with the larger dimension slit and thus reduces the risk of flashback.

Flames that operate in fuel-rich conditions are sometimes called *yellow flames*, while flames that are operated under fuel-lean conditions are often called *blue flames*. While the latter are oxidizing flames, the former provide reducing conditions which may be advantageous for the determination of certain elements. The atomization of an analyte is not homogenous throughout the flame, as the production of free atoms in the flame is governed by the variation in temperature in the different zones of the flame, as well as by the rate of diffusion of the flame gases that dilute the free atom population in the observation zone (Figure 15.9). For the highest sensitivity, the radiation from the light source must be directed through the zone of the flame that contains the highest fraction of free atoms. To meet this condition, the height and alignment of the burner head relative to the light path must be carefully optimized [13b].

15.3.2.2.4 **Electrothermal Atomization** In the late 1950s, L'vov made the first attempts to use a graphite furnace for the atomization of the sample in AAS [14]. It did, however, take until the early 1970s before the first graphite furnace (GF) or electrothermal (ET) atomizers were introduced to the market. Measurements by ET-AAS are discontinuous, and an analysis cycle comprises the following four steps: (i) the sample is introduced into the cold GF; (ii) the solvent is evaporated

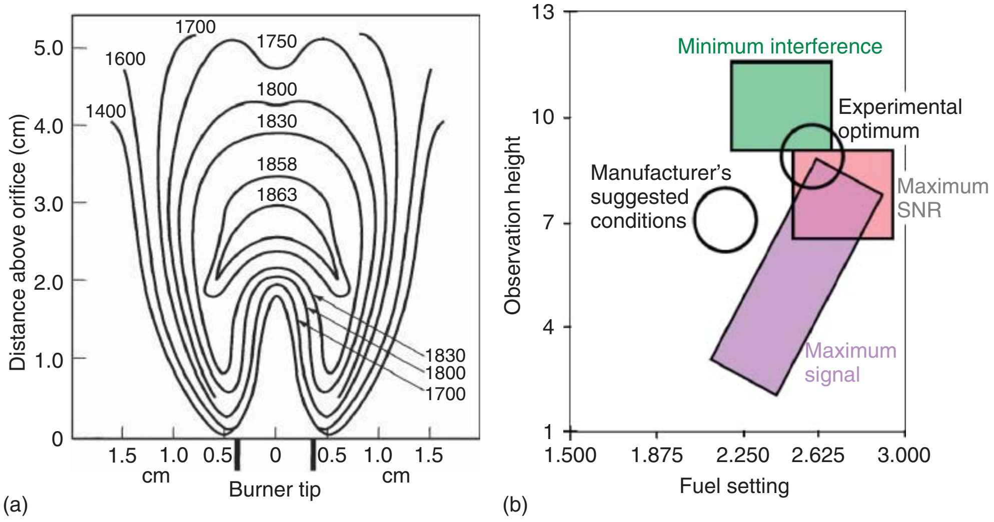

Figure 15.9 (a) Flame temperature as function of the observation height above the burner head for a natural gas/air flame. (Reprinted from Ebdon *et al.* [7], with permission.) at temperatures of around 100 °C; (iii) the sample is ashed and any volatile sample constituents are removed by keeping the sample for about 1 min at 450–900 °C before; and (iv) the temperature is rapidly increased to 2000–3000 °C to vaporize and atomize the sample in a very short interval (milliseconds to a few seconds). The entire cycle can be accomplished in about 1 min because of the fast heating rates achieved by direct electrical (resistive) heating of the GF at currents of up to 400 A and a voltage on the order of 8 V (Figure 15.10).

The GF (Figure 15.11a) comprises the following features. The cylindrical graphite tube is open at both ends and has, typically, a length of 18–28 nm and an internal diameter of 6–10 mm. At its center, it has a small hole through which the sample (typically 5–20 μl) is introduced automatically. At its ends, the graphite tube is tightly fitted into a pair of water-cooled graphite ring electrodes through which the heating current is provided. The entire furnace is purged with argon to exclude air from the graphite tube and to prevent its incineration at high temperatures. An additional argon gas stream is directed from both ends of the tube toward the center to purge vapors from the sample matrix generated during the vaporization and ashing step. Argon has excellent optical transparency in the UV region, which is important for the detection of elements at short wavelengths. Despite the use of an inert gas atmosphere, the graphite tubes are severely affected during the heating cycles and must routinely be replaced after about 100 analyses.

Although this technique offers a much improved sensitivity in comparison with flame AAS owing to the fact that the entire sample is atomized and that the concentration of free atoms is very high in the restricted volume of the graphite tube (about 2 ml), some disadvantages arise from the use of graphite tubes with the above-mentioned design. As the graphite tube is rapidly heated, it will be considerably hotter than the gas phase in the center of the tube. Thus analyte

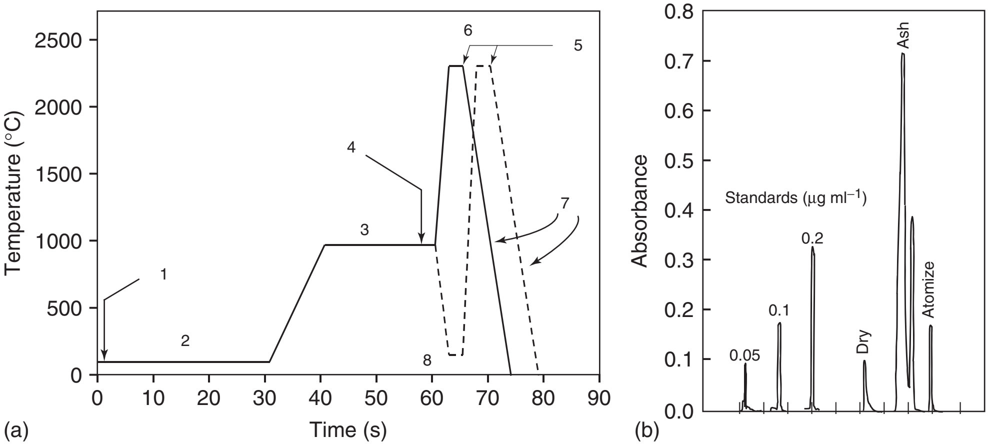

Figure 15.10 (a) Schematic temperature program of the graphite furnace: (1) Ar flow on; (2) drying; (3) ashing; (4) Ar flow off; (5) Ar flow on; (6) atomization step; (7) cooling period; and (8) cool-down procedure). (b) Typical signal output of a graphite furnace AAS measurement.

atoms are evaporated into a significantly cooler zone where they may recombine and further condense. This disadvantage has been alleviated by the introduction of the sample onto a small platform (L'vov platform) of graphite that is located in the center of the graphite tube (Figure 15.11b). The heating characteristics of the modified graphite tube remain essentially unaltered compared to those without a platform. However, since the platform has only a limited heat capacity, it will basically be heated by radiation from the tube walls. This will cause the temperature of the platform to lag somewhat behind the platform of the tube walls. The analyte will thus be volatilized with delay when compared to a graphite tube without platform, and it will also evaporate into an atmosphere that is significantly hotter than with wall atomization. In this way, the platform reduces interferences that arise from temporal non-isothermality. However, GFs of this design still have a remarkable spatial non-isothermality because of the water-cooled electrical contacts acting as effective heat sinks. The graphite tube has its highest temperature in the center and becomes cooler toward its ends. Elements of low volatility may therefore condense after initial volatilization or adsorb on cooler wall regions located away from the tube center. During a subsequent atomization sequence, revaporization of the analyte may occur and lead to memory effects since the ends of the tube initially also attain higher temperatures. For this reason, the transversely heated atomizer has been introduced which provides spatial isothermality through which condensation and memory effects are notably reduced (Figure 15.12). It has, furthermore, been observed that some of the sample matrix effects and the poor

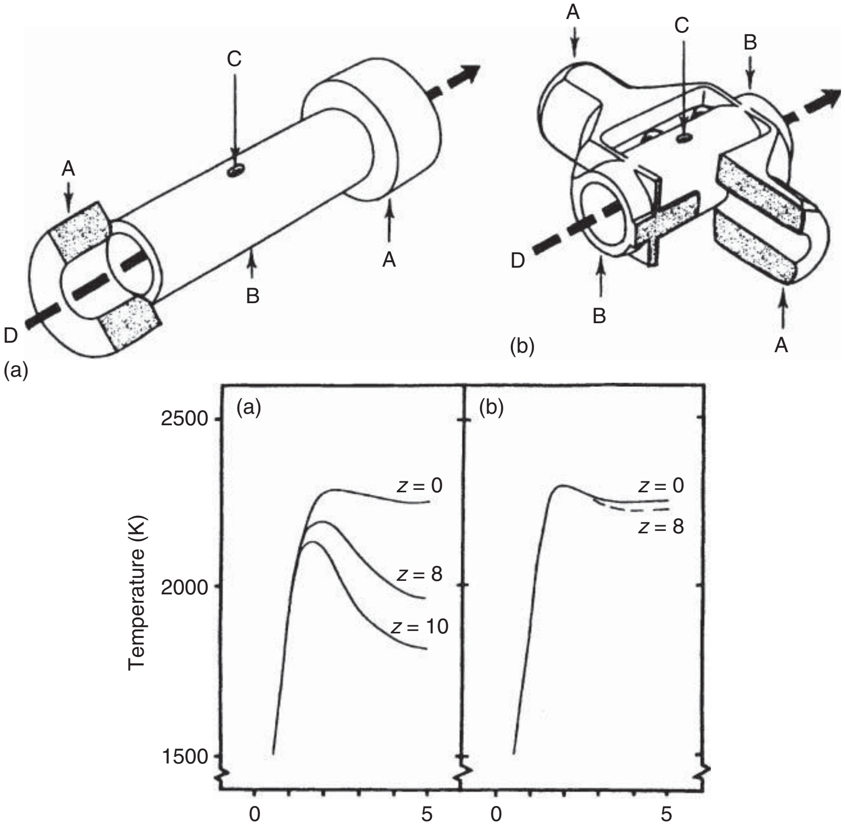

Figure 15.12 (a) End-heated and (b) side-heated electrothermal atomizer configuration and temperature profiles associated with these furnace designs. A, water-cooled electrical graphite contact cylinders; B, graphite tube; C, sample injection port; and D, light path of the spectrometer. The value of *z* denotes the distance from the center (in millimeters) at which the temperature profiles have been recorded for a graphite tube of 28 mm length.

reproducibility sometimes associated with GF atomization can be improved by reducing the natural porosity of the graphite tube. It appears that part of the analyte and matrix diffuse into the pores of the tube. This slows down the atomization process and causes smaller analyte signals or memory effects due to revaporization in a subsequent analysis cycle. To reduce the porosity, the graphite surfaces are covered with a thin layer of pyrolitic carbon through which the pores of the graphite tube are sealed.

15.3.2.2.5 **Vapor Generation Technique** The generation of gaseous analytes from the sample and their introduction into atomization cells for subsequent absorption spectrometric determination offer a number of advantages over the conventional sample introduction by pneumatic nebulization of the sample solution. These include the elimination of the nebulizer, the enhancement of the transport efficiency, which approaches 100%, and the presentation of a homogenous sample vapor to the atomizer. The most common and versatile techniques for the formation of volatile compounds are the hydride generation technique and the cold vapor technique.

Other techniques for the formation of volatile compounds, such as volatile chlorides or volatile organic complexes (e.g., β-diketonates or dithiocarbamates) have also been used, but rarely, and will thus not be discussed in the following.

The versatility and general acceptance of vapor formation techniques in AAS result from the various advantages that they offer:

- Separation of the analyte from the matrix is achieved, which improves the accuracy of the determination.
- Preconcentration of the analytes is easily implemented, which allows significant improvements in concentration detection limits.
- Different chemical species can be discriminated in some cases.
- The procedures are readily accessible to automation.

Only a few disadvantages are quoted for vapor generation techniques. These include the (chemical) interferences, notably in the presence of transition metals; a pronounced pH effect on the reaction, and its dependence on the oxidation state of the element, which, however, can also be advantageously used for speciation analysis; and finally gas-phase atomization interferences which may be caused by the presence of other volatile hydrides.

Vapor-generation techniques comprise the following three steps: (i) transformation of the analyte into a volatile form, (ii) its collection or preconcentration (if necessary) and transfer to the atomizer, and (iii) decomposition of the volatile compounds to liberate the free analyte atom (not necessary for mercury) with subsequent measurement of the atomic absorption signal.

15.3.2.2.6 **Hydride Generation Technique** A number of different reactions have been described for the formation of covalent volatile metal hydrides, which all have as a common denominator that they rely on the formation of atomic hydrogen as reducing agent [15]. For the generation of volatile hydrides of arsenic, antimony, and selenium (AsH_3, SbH_3, and H_2Se), the well-known reaction of Zn with concentrated hydrochloric acid may be employed [15b]:

$$\mathrm{Zn} + 2\mathrm{HCl} \rightarrow \mathrm{ZnCI}_2 + 2[\mathrm{H}]$$

$$\mathrm{E}^{m+} + k[\mathrm{H}] \rightarrow \mathrm{EH}_n + \mathrm{H}_2(\text{excess} \uparrow)$$

In the above equation, E represents the analyte element, and m may, but need not necessarily be, equal to n (e.g., when the analyte occurs in various oxidation states). Reduction by Zn/HCl requires that the analytes be present in their lower oxidation states prior to reaction. When this is not the case, the analytes must be reduced, for example, by $SnCl_2$ in an acidic medium. The formation of volatile hydrides (and of excess hydrogen) is then initiated by the addition of zinc metal.

This reaction is rather inconvenient, since it is slow, difficult to automate, and subject to high blank values due to the impurities of the zinc. Also its efficiency is limited as a consequence of incomplete reaction and the possibility of adsorption or entrapment in the zinc sludge of the volatile metal hydrides formed. Because of these disadvantages, the use of this procedure has nowadays been practically abandoned.

Instead, the far more effective sodium tetrahydroborate reagent is used, which reacts according to

$$NaBH_4 + 3H_2O + HCl \rightarrow H_3BO_3 + NaCl + 8[H]$$

$$E^{m+} + k[H] \rightarrow EH_n + H_2 \text{ (excess } \uparrow)$$

The higher reactivity of this reagent allows its use for the formation of volatile hydrides of antimony, arsenic, bismuth, germanium, lead, selenium, tellurium, and tin. This method is superior to the Zn/HCl method not only because of the wider range of elements that are accessible but also with respect to speed, efficiency of the reaction, and reduced contamination. The reaction is essentially completed within 10–30 s, and the reagent is typically added into the acidified samples as 0.1–10% (w/v) solution. These factors contribute to the ease of automation, which has been a key factor in the success of the hydride generation technique.

The preferred acid for this application is hydrochloric acid. HNO_3 and H_2SO_4 have also been used, although less frequently. The acid concentration is a parameter that has to be carefully optimized and may vary considerably, depending on the element and the matrix. It may range from as low as 0.1–0.2 $mol\,l^{-1}$ for tin and lead to up to 9 $mol\,l^{-1}$ for antimony, arsenic, and bismuth. Only two disadvantages have to be mentioned for the tetrahydroborate reduction. The reagent is not completely free from contaminants (particularly tin), which limits the achievable detection limits, and the generation of a large excess of hydrogen may be a significant hindrance, although this is usually not the case for atomic absorption unlike for other spectroscopic techniques.

Hydride generation-AAS may be carried out in batch systems (where the $NaBH_4$ may even be added as pellets) as well as in continuous generation systems where the sample and the reducing agent are pumped continuously into the reaction chamber, then further to a gas–liquid phase separator, and then into a flow injection (FI) system. In such a system, discrete amounts of the sample are injected into a flowing carrier stream which is merged with the reagent streams. Reaction takes place in a reaction coil, and the volatile hydrides are purged in a gas–liquid phase separator and carried to the atomization cell (Figure 15.13).

The most widely used atomizer for hydride generation is the heated quartz T-tube atomizer with a typical diameter of 10 mm and a length of 100–150 mm, making it compatible with the optical path of most AA spectrometers. The quartz tube is electrically heated to 700–1000 °C, which permits the optimization of the atomization temperature for each element. The quartz tube may either have open ends, or these ends may be sealed by removable quartz windows, and holes at the extreme ends of the quartz tube provide the gas flow outlets. This setup increases

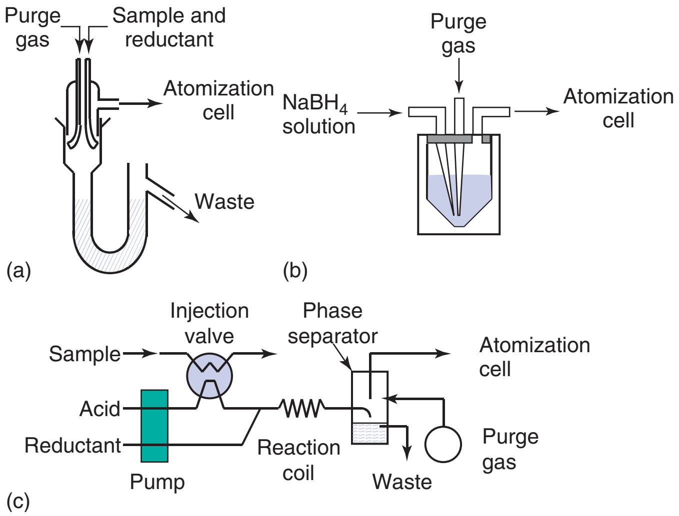

Figure 15.13 Hydride generation systems. (a) Batch generation. (b) Continuous generation. (c) Flow-injection generation.

the residence time of the atoms in the light path and thus improves sensitivity. With continued use, the performance of the quartz tube atomizer invariably deteriorates in terms of sensitivity and precision. This is attributed both to devitrification of the inner surface of the quartz tube to a less inert modification and to the contamination of the inner atomizer surface by deposition of small particles and droplets that were not efficiently removed by the gas–liquid phase separator.

The decomposition of hydrides to form free atoms is mainly due to the reaction with hydrogen radicals, but oxygen also plays an active role. The following reactions may take place within a quartz tube atomizer:

$$\mathrm{H}^{\bullet} + \mathrm{O}_2 \rightarrow \mathrm{OH}^{\bullet} + \mathrm{O}$$

$$\mathrm{O}^{\bullet} + \mathrm{H}_2 \rightarrow \mathrm{OH}^{\bullet} + \mathrm{H}^{\bullet}$$

$$\mathrm{OH}^{\bullet} + \mathrm{H}_2 \rightarrow \mathrm{H}_2\mathrm{O} + \mathrm{H}^{\bullet}$$

The concentration of the hydrogen radical in the atomizer tube is several orders of magnitude higher than that of the hydroxyl radical. Thus if a metal hydride is introduced into the quartz tube, it will undergo the following subsequent reactions, leaving finally the free atom in the gas phase:

$$\mathrm{EH}_x + \mathrm{H}^{\bullet} \rightarrow \mathrm{EH}^{\cdot}_{x-1} + \mathrm{H}_2$$

$$\mathrm{EH}^{\bullet} + \mathrm{H}^{\bullet} \rightarrow \mathrm{E} + \mathrm{H}_2$$

In addition to this process, thermal decomposition of the hydrides is also supposed to take place, but only if the oxygen supply to the atomizer is insufficient. Thermal decomposition is the dominant atomization process in the GF.

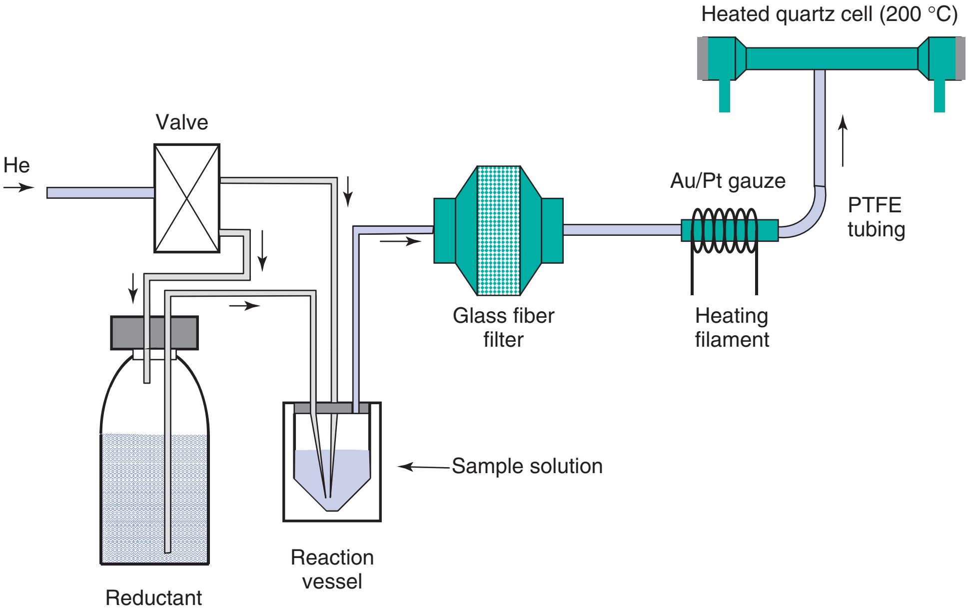

Figure 15.14 Scheme of a cold vapor generation system for mercury. (Redrawn from [16].)

15.3.2.2.7 **Cold Vapor Generation Technique** Mercury is the only metallic element that is liquid and sufficiently volatile at room temperature. These particular properties make this element uniquely suited for determination without an atomizer after reduction to the elemental state and transfer into the vapor phase and into the optical path of the absorption spectrometer [17]. As with hydride generation systems, the technique lends itself to both batch and flow-injection procedures which are becoming increasingly popular. A typical cold vapor generation system is depicted in Figure 15.14. For historical reasons, tin(II)chloride has been widely used as reducing reagent, but it is now being replaced by $NaBH_4$. Since the latter is a more powerful reducing reagent, particular precautions must be taken to avoid interferences that may have adverse effects on the preconcentration (amalgamation) trap which is normally used. Helium is preferred to purge elemental mercury from the sample solution. Either a chemical desiccant or a glass fiber filter is positioned between the reaction vessel and the amalgamation trap to prevent small water droplets from reaching the trap (which is more tolerant to water vapor). The material for the reaction vessels and all tubing must be selected with particular consideration to avoid permeation or adsorption of mercury. Quartz and fluorinated ethylene/propylene (FEP) are suitable materials showing only very little adsorption of mercury, while poly(tetrafluoroethylene) (PTFE) is said to be the most appropriate material for the transport of gaseous mercury.

Similar to hydride generation, the mercury vapor can be directly introduced into the absorption cell. However, because the vapor formation from the liquid phase is rather slow, requiring a period of typically 1–2 min, this would result in broad peaks of low intensity. Consequently, a trap is used to preconcentrate the generated Hg vapor and to improve the concentration detection limit for analysis in solution [16].

This is achieved by amalgamating mercury on a noble metal trap, from which it is subsequently thermally desorbed at 500–700 °C. In many instances, a gold–platinum gauze (90% Au, 10% Pt) is used for this purpose. It provides a high surface area, excellent thermal conductivity, ease of cleaning, and good physical stability. This results in excellent performance in terms of reproducibility and signal enhancement.

Since mercury is present already in the atomic state in the cold vapor technique, there is no need for an atomizer as such. The sample vapor is swept directly from the reduction cell or the amalgamation trap in the carrier gas stream to a 10-cm long T-shaped quartz tube that is moderately heated (to about 200 °C to prevent condensation of mercury). This quartz cell is located in the light path of a conventional AA spectrometer where the attenuation of a characteristic Hg line source is measured. Dedicated AA spectrometers (which, in this case, often have a continuum light source) may also be used with longer absorption cells (300 mm path length) to increase the sensitivity.

15.3.2.2.8 **Direct Introduction of Solid Samples** Both flame AAS and ET-AAS principally allow the direct introduction of solid samples. For flame AAS, cups may be used to introduce the solid sample, as suggested initially by Delves [18]. Alternatively, organic samples may be combusted and the vapors introduced directly into the flame. Although the direct introduction of solid powders into the GF had already been reported in the early 1980s [19], the analysis of sample slurries is preferable. Slurry sample introduction has been pioneered for flame AAS by Ebdon and Cave [20], who also demonstrated its applicability to GF-AAS. Solid sample introduction must, however, be carried out with particular attention. Since the amount of sample introduced is normally small – only a few milligrams is normally used – the sample homogeneity and the avoidance of potential sampling errors become important issues. For this reason, the use of larger furnaces, which may accept larger sample sizes, has been suggested. Calibration for solid sample analysis is generally difficult, since the nature and particle size of the solid affect analyte volatilization, transport, and, consequently, its response.

For the analysis of solid samples without prior digestion, the combination of cathodic sputtering with AAS has been proposed [21]. Jet-enhanced sputtering gives a high analyte number density, and the atom vapor cloud is introduced into the flame or ET atomizer. This approach is particularly feasible for the analysis of samples that are difficult to dissolve, such as refractory oxide-forming metals and alloys.

Laser ablation-AAS is also useful for insulating samples, where AA analysis is performed directly in the laser plume. Owing to the production of various particles in the measurement zone (solid particles, molecules, radicals) and the resulting background emission, appropriate techniques for the correction of spectral interferences must be used.

15.3.2.3 Optical Setup and Components of Atomic Absorption Instruments

Instruments for AAS can generally be divided into single- and double-beam designs. The sophistication and, consequently, the cost of the instruments span a very wide range.

The optical system of an AA spectrometer must provide a spectral resolution sufficient to separate the chosen analytical line from other lines that may interfere with it. Only in the case of some alkali metals, which have some few widely spaced resonance lines across the visible spectrum, may this be achieved by simple filter monochromators. For the determination of most elements, however, high-quality UV/vis monochromators are required that are capable of achieving a spectral bandwidth of the order of 0.1 nm. Such monochromators are nowadays incorporated in most commercial AA instruments. The optical components used (particularly, monochromators and detectors) are very similar to those used for emission spectroscopy and will be discussed in more detail later.

15.3.2.3.1 **Single-Beam Spectrophotometer** The typical design of a single-beam spectrophotometer is shown in Figure 15.15. It is constructed using an absolute minimum number of optical components with the evident advantage of high optical throughput and relatively low cost. The simplicity of this system is, however, at the price of limited signal stability, since any fluctuation in light source intensity will result in baseline variation.

15.3.2.3.2 **Double-Beam Spectrophotometer** The optical setup of a double-beam spectrophotometer is given in Figure 15.16. The beam from the light source is divided into two paths, one of which passes through the flame and the other is directed around the atomizer. These two light beams are subsequently recombined and modulated by a rotating (mirrored) chopper that alternately transmits the beams to the Czerny–Turner grating monochromator. The two signals are detected by a photomultiplier tube (PMT) and ratioed before further amplification and electronic signal processing. Double-beam spectrophotometers, being more complex and costly, offer the advantage of compensating any variations in light source intensity.

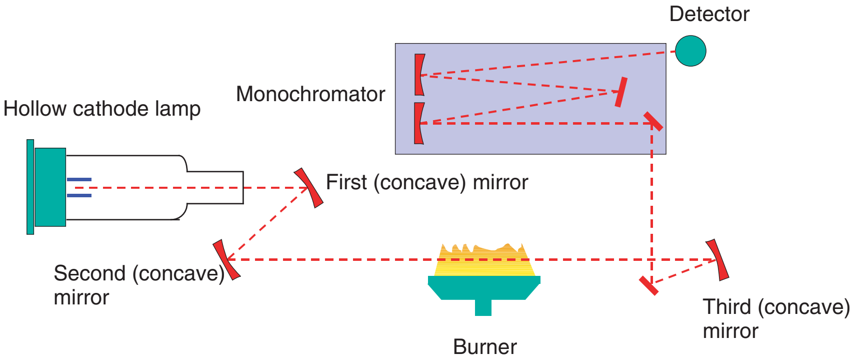

Figure 15.15 Optical system for a single-beam atomic absorption spectrophotometer.

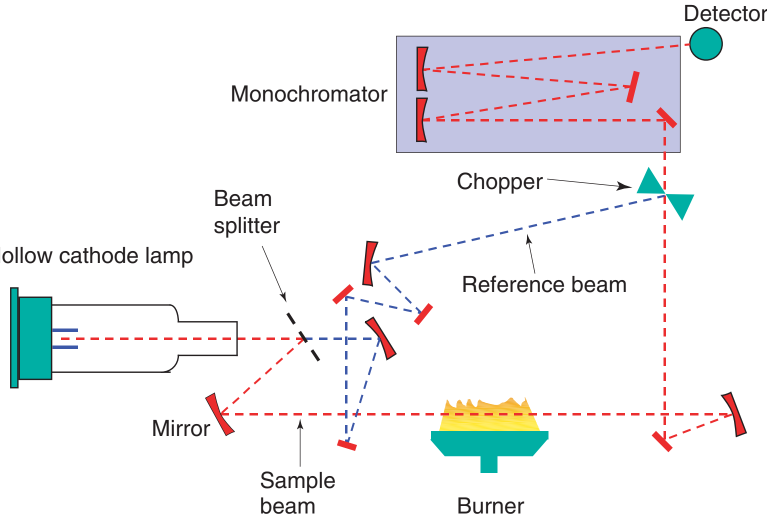

Figure 15.16 Optical system for a double-beam atomic absorption spectrophotometer.

However, radiant power loss through absorption and scattering effects in the flame is still not accounted for, since the reference beam bypasses the flame. Methods for the correction of these optical losses are discussed in the following section.

Detection is normally done with PMTs, or, for instruments that incorporate echelle-grating-based polychromators, with solid-state detectors consisting of a two-dimensional array of photodiodes.

15.3.3
Spectral Interferences

Two types of interference are encountered in atomic absorption spectroscopy: *Spectral interference* is the result of the absorption of an interfering species that either completely overlaps with the signal of interest or lies so close to this signal that it cannot be resolved by the monochromator. *Chemical interference* may be a consequence of the various chemical processes that occur during atomization and alter the absorption characteristics of the analyte.

Spectral interferences can, to a certain degree, be compensated or eliminated by suitable instrumental designs and analytical procedures.

15.3.3.1 Origin of Spectral Interference

As the emission lines of HCLs are very narrow, interference due to overlapping lines is rather unlikely. The separation between two spectral lines would have to be less than typically 0.01 nm for such an interference to occur. As an example, the vanadium absorption line at 308.211 nm interferes in the analysis of aluminum at

308.215 nm. A simple alternative is to carry out the measurement at a different (intense) aluminum absorption line, for example, at 309.270 nm.

Spectral interferences may also result from combustion products that exhibit broadband absorption or particulate matter, which causes scattering of the incident radiation. As both reduce the spectral radiance of the light source, they may erroneously lead to an overestimation of the absorbance and, consequently, the concentration. When the combustion or the particulate products arise from the fuel/oxidant mixture, they may be determined by measuring the absorbance while a blank is aspirated into the flame. The situation is more complicated if the absorption or scattering arises from a product associated with the sample or its matrix. For example, an elemental absorption line can be interfered by a molecular absorption line from reaction products of coexisting elements in the sample. In the case of Ba determination in the presence of Ca, the elemental absorption line at 553.6 nm can be overlapped by a broad $Ca(OH)^+$ absorption band in the range 548.0–558.0 nm. In many cases, such interference can be eliminated by replacing air by nitrous oxide as the oxidant. The resulting higher flame temperature leads to the decomposition of the $Ca(OH)^+$ and eliminates the absorption band.

In flame AA determination of elements such as Ti, Zr, and W, spectral interferences from the formation of refractory oxide particles with diameters greater than the wavelength of the light can increase the scattering. Interference due to scattering may also be observed when organic solvents are used. When these are combusted incompletely, carbonaceous particles may be generated and cause light scattering.

This interference is, however, not very frequently observed in flame AA, or they can easily be eliminated by the judicious choice and optimization of the analytical conditions. Alternatively, one may add the interfering substance (if this is known) in large excess to the sample. In that case, the interference due to the compound initially present in the sample will become insignificant in comparison to that of the compound added. Such a procedure is sometimes referred to as *spectral buffering*. While ET-AA was considered to be more susceptible than flame-AA to the interferences discussed above, this appears no longer true with the instrumental developments that have been realized over the past decades. Nowadays, GF-AA may be considered as being affected by interferences to a level not higher than observed with flame AA.

15.3.3.2 Methods for Correcting for Spectral Interferences

A number of methods have been developed for correcting spectral interference caused by matrix products. Perfect background correction can be achieved only when the background absorbance measurement corresponds exactly in space, time, and wavelength with the atomic absorbance measurement. Since this exact matching of all three parameters is impossible – at least with line source instruments – it is common to give priority to the equality in space and to make the difference in wavelength and/or time as small as possible. This is due to the fact that the background absorption can never be assumed to be completely constant over the considered (spectral or temporal) range.

In general, any type of background correction requires two measurements to be made, one of which is the measurement of the gross or total absorbance at the wavelength of the resonance line, A_{total}. Then, the background attenuation, $A_{\text{background}}$, is subtracted from the total absorbance to yield the absorbance of the analyte, A_{analyte}.

15.3.3.2.1 **Two-Line Background Correction**

The two-line correction method, which was proposed in the late 1970s [22], is based on measuring the absorption at a second, nonresonant line. This line should be close to the resonance line of the element that is measured but should not be absorbed by the analyte. If these conditions are met sufficiently well, it can be assumed that the attenuation at this second line is only due to the background absorption in the sample.

The reference line may, for example, be a neon or argon line from the gas in the HCL, or it may arise from an impurity in the hollow cathode material. Alternatively, another source of an element that is not present in the sample may be used for background measurement. The closer the reference line is to the analytical line, the better the background correction will be. In reality, this is not always easy to achieve. Particularly for short wavelengths of resonance absorption, the spectral distance of the two lines should not be more than 1 nm; otherwise, significant errors may arise from inadequate background correction since scattering is strongly dependent on the wavelength (and increases proportional to λ^{-4}).

15.3.3.2.2 **Continuum-Source Background Correction**

In a second, more widely used method for background correction, a deuterium lamp provides a source of continuous emission throughout the UV region. Deuterium lamps consist of an arc that is sustained in a deuterium atmosphere. They provide sufficient energy in the wavelength range between 190 and 330 nm, with an emission maximum near 250 nm. For longer wavelengths, a halogen lamp is used alternatively.

The radiations from the HCL and the deuterium lamp are directed alternately through a chopper to the (flame or GF) atomizer. The rotating chopper wheel allows the radiation of either source to pass alternately while the absorption is detected for one of the two beams (Figure 15.17). The absorbance of the deuterium lamp is then subtracted from that of the element-specific line source.

The continuous-source emission of the deuterium lamp is passed through a bandpass filter that has a transmission window of 0.2–1 nm. Since the half-width of an atomic absorption line is only about 2–5 pm, the attenuation of the comparatively wide spectral window of the continuous-emission source due to the specific absorption of the analyte will be negligible. It is thus possible to assume the attenuation of the continuous light source as being due only to the background absorption and scattering while the additional attenuation observed at the resonance wavelength is caused by element-specific absorption (Figure 15.18). In continuous-source background correction, it is assumed that the background is constant over the considered spectral range. If this is not the case, significant positive or negative correction errors may occur.

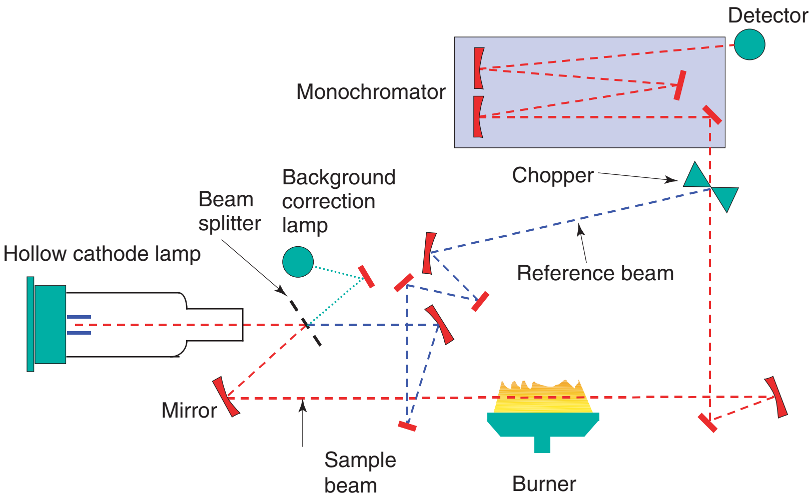

Figure 15.17 Schematic of a system used for continuous-source background correction. The chopper may be eliminated when each lamp is pulsed alternately.

Since the alteration between the two light sources is fast, continuum-source background correction can conveniently be used even with GF-AA instruments that produce fast transient signals. A few disadvantages have been reported for this type of background correction. These include the more complex (and thus more expensive) instrumental setup with two light sources, and the fact that, even if the two light sources are perfectly aligned, they will illuminate different sample volumes because of different light source geometries and also the differing intensity profiles across the beam.

However, continuum-source background correction is implemented in many commercial instruments and is particularly useful in combination with flame atomization or hydride generation.

15.3.3.2.3 **Zeeman Background Correction** In 1897, Zeeman observed a splitting of the electronic energy levels of a free atom that is introduced into a strong magnetic field (of 0.1–1 T). For each electronic transition, the Zeeman effect produces several absorption lines with a splitting in the order of 10 pm. The sum of the integrated absorbance of all lines equals the absorbance of the original line from which they derive. Different types of splitting exist, depending on the electronic state from which absorption occurs. In the simplest case (for singlet transitions), a single line is split into three components under the action of the magnetic field. The central (π) line is at the wavelength of the original line, while the other two (σ) lines are located symmetrically around this line. The absorbance of the π line is twice that of each σ line. With other transitions, the splitting pattern becomes more complex, which is often termed the *anomalous Zeeman effect* (in contrast to the "normal Zeeman effect" observed for the simpler systems). Zeeman patterns are observed in both absorption and emission.

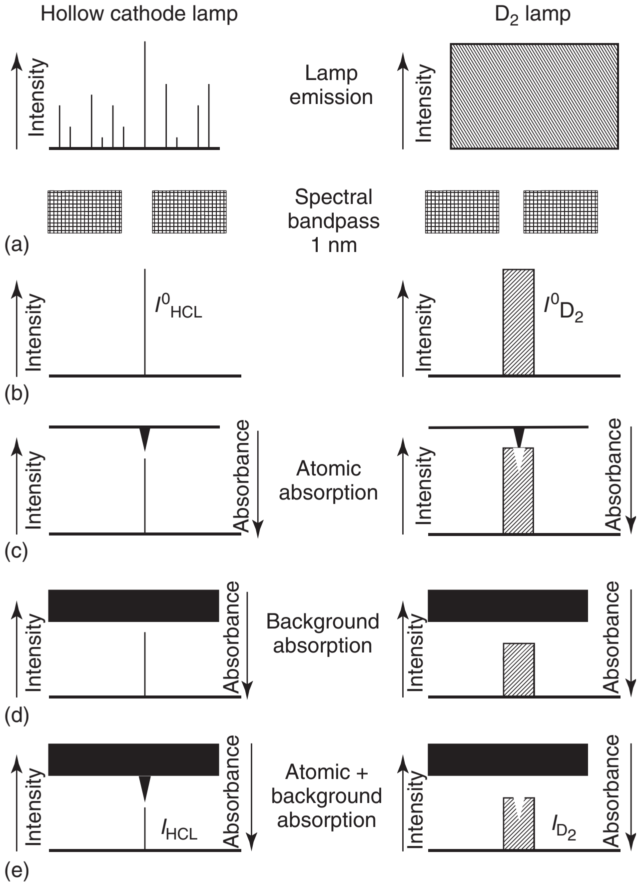

Figure 15.18 (a–e) Principle of background correction using a continuous source, for example, a deuterium lamp.

Use is made of the Zeeman effect for background correction, as the response of the two types of absorption peaks (π/σ) to polarized radiation is different: While the π peaks absorb only radiation that is polarized in a plane parallel to the external magnetic field, the σ peaks absorb only radiation that is polarized in a plane perpendicular to this field (Figure 15.19).

Generally the unshifted or only slightly shifted π components are used to measure the total absorbance of the analyte atoms and the background, while the shift of the σ components is used to measure the background absorbance. For background correction by the transverse Zeeman effect, a strong magnetic field is aligned perpendicular to the GF (Figure 15.19a). The element-specific absorption takes place only within the π component of the absorption line profile, while the σ components of the absorption line are shifted to different wavelengths λ_1 and λ_2. When a polarizer is inserted in the light path that rejects the π component, and the magnetic field is switched on and off at a sufficiently high frequency (e.g., at 50 Hz) by an alternating current, the gross absorbance and the background absorbance can be measured alternately. The net absorbance is obtained by subtracting the background absorbance from the gross absorbance. In this way, the background absorption is obtained at a single analyte wavelength λ_a, so that the background absorbance is measured correctly even for a structured background.

Alternatively, a permanent or DC magnet can be used in combination with a rotating polarizer. This allows alternate measurements with π- and σ-polarized radiation. The π-polarized radiation is absorbed by both the background and the element to be determined, providing the gross absorbance. In contrast, the σ-polarized radiation is absorbed by the background only, as these lines are shifted away from the resonance absorption wavelength λ_a. The net analyte absorbance again results from the difference of these two measurements (Figure 15.19b).

The longitudinal Zeeman effect for background correction employs a longitudinal magnetic field instead of transverse magnetic field. In this case (Figure 15.19c), the original atomic absorption line is split only into the two σ components which are circularly polarized. When the longitudinal magnetic field is modulated by application of an alternating current, then the gross absorbance is measured at zero field strength while the absorbance of the background is measured with the magnetic field. The advantage of the longitudinal Zeeman effect background

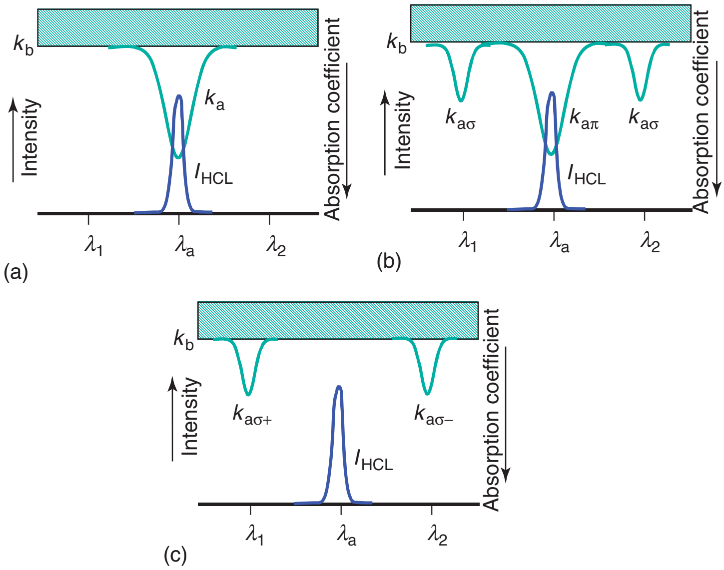

Figure 15.19 Principle of Zeeman background correction. The lower curve in each graph represents the emission of the hollow cathode lamp (I_{HCL}), while the upper line shows the absorption coefficient of the analyte (k_a) at wavelength in the presence of a background absorbance k_b. (a) Conventional AAS, no magnetic field applied; (b) in the presence of a transverse magnetic field; and (c) in the presence of a longitudinal magnetic field.

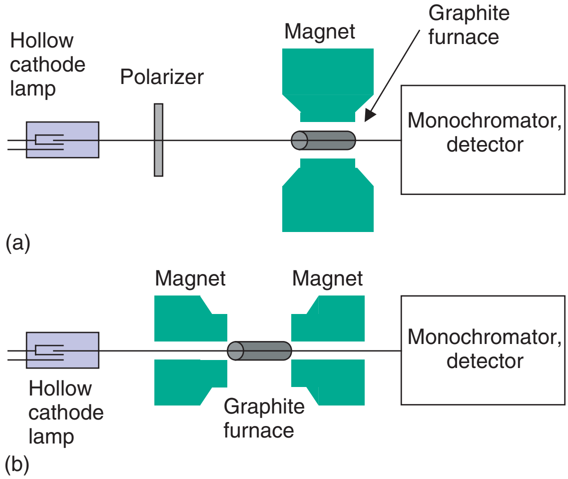

Figure 15.20 Schematic diagram of different Zeeman background correction systems for AAS: (a) Transverse magnetic field, that is, the magnetic field is perpendicular to the optical axis of the spectrometer. The rotating polarizer provides alternately p- and s-polarized radiation when the magnetic field is constant or transmits only p-polarized radiation if the magnetic field is modulated periodically by an AC current. (b) Instruments in which the longitudinal magnetic field is oriented parallel to the optical axis of the spectrometer do not require a polarizer.

correction is that no polarizer is required. For this reason, the full intensity of the HCL can be used in both measurement phases.

Principally, Zeeman background correction can be applied to either the source or the atomizer. When the magnetic field is located around the element-specific line source, its emission lines will be split into σ and π components. Depending on the polarizer orientation relative to the magnetic field, these will account for either only background absorption or the absorption of the analyte and background. For practical reasons, however, the arrangement is preferred where the GF is located in the magnetic field, since smaller magnets can be used. This is also the reason why Zeeman background correction is particularly popular with ET-AAS but hardly used with flame AAS, since the magnet would have to be large enough for the burner head to fit into its gap (Figure 15.20).

The use of the Zeeman effect for background correction in AAS was initially proposed in 1969 [23]. Six years later, the first commercial instruments became available [24]. Zeeman background correction is nowadays widely used in ET-AAS instruments. It is capable of reliably handling even highly nonspecific absorption. In particular, the more volatile elements Pb and Cd are preferably measured by ET-AAS with Zeeman background correction, since the relative volatility of the elements does not allow high temperatures to be used in the pyrolysis step to remove interferences.

Zeeman effect background correction is effective at any wavelength. There are, however, some disadvantages: A slight decrease in the sensitivity can be observed (about 20%), as well as a bending of the calibration curve (“rollover”).

15.3.3.2.4 **Pulsed-Lamp Background Correction**

A very simple method of background correction has been proposed by Smith and Hieftje [25] and is therefore known as the Smith–Hieftje method. It is based on the self-reversal behavior of the radiation emitted by HCLs when they are operated at high currents. This effect is seen when a large number of nonexcited atoms are brought into the vapor phase. These atoms absorb the characteristic radiation emitted by the excited species. At the same time, a significant broadening of the emission line is observed.

Altogether, this results in a broad emission line that has a minimum in intensity at its center, that is, exactly at the position of the atomic absorption line. Thus, at low lamp current, the sum of the specific and the nonspecific absorption is measured, while at high lamp currents effectively only the background emission is determined because of the intensity minimum at the wavelength of specific absorption and of the significantly broadened peak profile which is attenuated by the nonspecific absorption to the left and right of the characteristic absorption of the analyte. The difference between the two signals yields the background-corrected absorption of the analyte (Figure 15.21).

Background correction is thus achieved by modulating the lamp current to generate a longer pulse at low current (e.g., 9 ms at 5–10 mA), followed directly by a short pulse at high lamp current (e.g., 0.3 ms at 200–300 mA). As the atom cloud persists in the HCL for several milliseconds, a minimum pulse repetition time of typically 50 ms is required to allow the atom cloud to clear before the next measurement cycle is started.

Background correction by self-reversal is instrumentally very simple to implement and has consequently been used with flame and ET atomization and with hydride generation systems. It is particularly attractive since, like the Zeeman background correction, it does not require an additional radiation source. The efficiency of pulsed-lamp background correction depends on the degree of band broadening

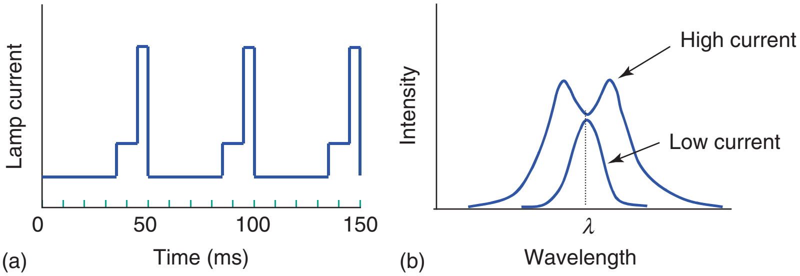

Figure 15.21 Background correction by source self-reversal. (a) Modulation of the lamp current that drives the hollow cathode lamp. (b) Resulting hollow cathode lamp emission line profiles generated at high and low current operation.

that can be achieved. This, however, differs from element to element and also varies strongly (increases) with the lamp current. At the same time, high lamp currents significantly reduce their lifetime. Thus, specially designed HCLs and lamp current modulation circuits must be used to achieve an acceptable compromise.

It is assumed that only the background absorption is measured at high lamp current (which is only a partially valid assumption); however, the broadening of the line profile is limited and self-reversal is not complete. Thus, radiation is still emitted at the center of the emission line and is absorbed by the analyte, and will subsequently be subtracted from the gross absorption of the analyte. This significantly reduces the sensitivity of the determination, with an average loss of sensitivity of about 45% being observed for the elements most commonly determined by AAS. Also, the efficiency of background correction becomes insufficient, particularly at high absorbance values ($A > 2$).

15.3.3.2.5 **Wavelength-Modulation Correction Methods** When a broadband, continuous emission source is used, background correction can easily be performed by measuring the background absorbance in the direct vicinity of the resonant absorption line. Where a constant spectral background absorption can be assumed, it is sufficient to measure the absorption at the position of the resonance line and at one point next to this wavelength. If the spectral background is sloping, two points on either side are required to interpolate the background at the position of the absorption line (cf. Figure 15.36 in Section 15.4.3.1). The analytical signal is then obtained as the difference of the gross absorption signal and the background absorption. It is evident that for a structured background this method would provide inadequate results, but as long as the wavelengths used as baseline points are close to the analytical line, the error is usually small. This method of background correction was first described by Snelleman in 1968 [26] and developed further by Zander *et al.* [27].

Its instrumental realization is achieved by a wavelength modulator, which is a vibrating mirror driven by an ac current and inserted in the light path between the atomizer and the monochromator. By the periodic movement of the wavelength modulator, a very narrow wavelength across the analytical resonance line is scanned, resulting in a modulated absorption signal as output. Phase-sensitive detection allows the discrimination of the background (DC) signal from the first harmonic AC component of the signal (due to specific absorption) and the calculation of the net absorption as the difference of the two signals.

Background correction by wavelength modulation is not widely used, but has already demonstrated to have considerable potential for simultaneous multielement AAS with continuum sources [10b]. Alternatively, high-resolution echelle gratings may be used that can detect both the elemental line and the background at the same time.

It becomes evident that there is no ideal method of background correction. Since each of the presented methods has its individual advantages and shortcomings, the choice of the most suitable technique depends on the instrumental design and particularly on the type of atomizer, as well as on the analyte and matrix.

15.3.4
Chemical Interferences

In addition to spectral interferences, chemical interferences are also significant in AA spectrometry. In many instances, however, they can be reduced by judicious optimization of the operating conditions. Chemical interferences are observed in AAS as a consequence of (i) the formation of compounds of low volatility, (ii) the influence on dissociation equilibria, and (iii) the ionization of the analytes.

15.3.4.1 Formation of Compounds of Low Volatility

This is perhaps the most common type of chemical interference. The presence of certain anions may cause refractory compounds to be formed with the analyte. As a consequence, its atomization is hindered and a decrease in response is observed. A well-known example is the suppression of the response of Ca with increasing concentrations of phosphate or sulfate. When the anion concentration in the flame is increased while keeping the calcium concentration constant, the absorbance decreases to about half its original value, which is attributed to the formation of hardly dissociated calcium phosphate or sulfate. At high anion concentrations, the analyte response again becomes independent of the anion concentration.

The co-occurrence of cations may also contribute to the formation of refractory compounds. The presence of aluminum has such an effect on the determination of magnesium. It is assumed that a refractory aluminum–magnesium oxide is formed, which reduces the sensitivity of the magnesium determination.

While an increase in atomizer temperatures (when possible) is an obvious way to reduce chemical interference, a second possibility is the use of matrix modifiers. An example of this is, for example, the addition of salts whose cations react preferentially with the interfering anion and thereby prevent their reaction with the analyte. The addition of Sr or La ions may, for instance, reduce the interference of phosphate in the analysis of calcium by forming a thermally stable compound with phosphate, with the effect that Ca will be released to form free atoms. An opposite approach is used when certain salts such as NH_4NO_3 are added to remove chloride salts by volatilization:

$$\mathrm{NaCl} + \mathrm{NH_4NO_3} \rightarrow \mathrm{NH_4Cl}\uparrow + \mathrm{NaNO_3}$$

In this case, NH_4Cl is removed during the ashing step and the residual $NaNO_3$ does not interfere during the atomization.

In a further approach, protective agents may be added to prevent the interfering substance from reacting with the analyte. Stable but volatile complexes or compounds are formed between the analyte and the protective agent. These protective agents are very often complexing agents, such as ethylenediaminetetraacetate (EDTA), ammonium pyrrolidone-dithiocarbamate (APDC), or 8-hydroxyquinoline.

15.3.4.2 Influence on Dissociation Equilibria

The influence of other elements present in the flame or GF on the dissociation equilibria of the analyte can be a significant cause of chemical interference. As the absorption requires that the analyte prevails in the atomic state, dissociation of its compounds must occur, following, for example, the equations

$$\mathrm{MO} \rightleftarrows \mathrm{M} + \mathrm{O}$$

$$\mathrm{M(OH)_2} \rightleftarrows \mathrm{M} + 2\mathrm{OH}$$

However, since the alkaline-earth metal oxides in particular are comparatively stable, molecular bands, arising from metal oxides or hydroxides, are frequently observed in the spectra of these elements. In contrast to this, the oxides of alkali metals are less stable, resulting in strong atomic lines.

A similar mechanism of interaction explains the increase in the response of vanadium in the presence of aluminum or titanium. This effect is observed more markedly in fuel-rich flames and depends critically on the concentration of oxygen-containing species (Ox), such as O and OH, in the flame. In the flame, the dissociation equilibria of the three metals

$$\mathrm{VOx} \rightleftarrows \mathrm{V} + \mathrm{Ox}$$

$$\mathrm{AlOx} \rightleftarrows \mathrm{Al} + \mathrm{Ox}$$

$$\mathrm{TiOx} \rightleftarrows \mathrm{Ti} + \mathrm{Ox}$$

coexist. The concentration of Ox is comparatively low in rich flames, so that the presence of Al or Ti in the flame shifts the dissociation equilibrium of the first equation to the right-hand side. The consequent increase in free metal concentration is accompanied by an increase in the absorption for vanadium. On the other hand, the concentration of Ox is high enough in lean combustion mixtures so that no significant shift is observed in the presence of Al or Ti. Thus, no particular shift of the dissociation equilibrium for vanadium is observed in flames with high oxidant concentration.

15.3.4.3 **Ionization in Flames**

Ionization in flames is a third mechanism that is largely responsible for chemical interference. In combustion mixtures that include air as oxidant, flame temperatures are usually not high enough to achieve a significant degree of ionization of the analyte. At the higher flame temperatures achievable with oxygen or nitrous oxide as oxidant, ionization is no longer negligible. Ionization can be treated as an equilibrium process according to the equation

$$\mathrm{A} \rightleftarrows \mathrm{A}^+ + \mathrm{e}^-$$

If we accept the treatment of ionization as an equilibrium process, it is evident that the degree of ionization will be affected by the presence of other ionizable species in the flame. As this interfering species B is also ionized to a certain degree in the flame, the degree of ionization of the analyte atom will be decreased, because of the law of mass action, by the electrons formed from B. The charge balance now requires consideration of the ionization of both species:

$$A \rightleftarrows A^+ + e^- \quad \text{with} \quad K_A = \frac{[A^+][e^-]}{[A]},$$

$$B \rightleftarrows B^+ + e^- \quad \text{with} \quad K_B = \frac{[B^+][e^-]}{[B]},$$

$$\text{and} \quad [e] = [A^+] + [B^+]$$

It can thus be concluded that, in the presence of an easily ionizable element B in the flame, the degree of ionization of the analyte A is reduced and thereby its absorption is increased. In all cases, it has to be borne in mind that at higher flame temperatures ionization is increased, which may counterbalance the increase in atomization. Thus, a hotter flame does not necessarily result in an improved sensitivity of AAS measurements.

The addition of an easily ionizable element at relatively high concentration as an *ionization buffer* allows the reduction of the effect of shifts in ionization equilibria. The ionization buffer (often an alkali metal salt such as potassium chloride) creates a high concentration of electrons in the flame, resulting in the suppression of the ionization of the analyte.

A generally useful and common approach to eliminate chemical interference in AAS is to use standard addition for quantitation. This will be described in more detail in the following section.

15.3.5
Data Treatment

15.3.5.1 Quantitative Analysis

Because of its principle and instrumental realization, AAS is a technique for quantitative analysis and is practically unsuitable for qualitative analysis. Quantitative response is governed by the law of Lambert and Beer, that is, the absorption A is proportional to the optical path length l, the absorption coefficient k at the observed wavelength, and the concentration c of the species (Equation 15.33).

In contrast to many other spectroscopic techniques, atomic absorption, however, often possesses only a very limited linear range. This deviation from linearity is the result of a combination of factors, including the finite width of the absorbing and the exciting lines, secondary lines within the pass band of the spectrometer, and stray light that reaches the detector. Also, spatial inhomogeneities of the excitation radiation and the atom cloud in the atomizer have been held responsible for these nonlinearities. The operating software of most spectrometers nowadays provides tools for curve-fitting nonlinear curves to optimize the useful dynamic range.

15.3.5.1.1 Quantitation by External Calibration The most common and straightforward method of calibration in AAS is the use of an external calibration with suitable standard solutions. It is based on the assumption that the standard solution matches the composition of the sample sufficiently well. This is an assumption that must always be examined with care, since, for example, samples of different viscosity may be aspirated at different rates in flame AAS, resulting in different sensitivities. Flame AAS normally produces step-function-like response curves as a result of the continuous introduction of sample or standard for a certain period (until a stable signal is reached). The height of this signal is evaluated. In ET-AAS, the transient signal is produced by subjecting the sample to a defined thermal cycle which produces a comparatively narrow signal of some few seconds (cf. Figure 15.12).

15.3.5.1.2 **Quantitation by the Standard Addition Technique** Matrix interferences result from the bulk physical properties of the sample, for example, viscosity, surface tension, and density. As these factors commonly affect nebulization efficiency, they will lead to a different response of standards and the sample, particularly with flame atomization. The most common way to overcome such matrix interferences is to employ the method of standard additions. This method, in fact, creates a calibration curve in the matrix by adding incremental sample amounts of a concentrated standard solution to the sample. As only small volumes of standard solutions are to be added, the additions do not alter the bulk properties of the sample significantly, and the matrix remains essentially the same. Since the technique is based on linear extrapolation, particular care has to be taken to ensure that one operates in the linear range of the calibration curve; otherwise significant errors may result. Also, proper background correction is essential. It should be emphasized that the standard addition method is only able to compensate for proportional systematic errors. Constant systematic errors can neither be uncovered nor corrected with this technique.

15.3.6
Hyphenated Techniques

The determination of the different forms (e.g., compounds or complexes) in which an element occurs (often referred to as the *speciation of an element* and *speciation analysis*, respectively) is in most cases performed by hyphenated techniques [28]. These are the combination of a high-performance separation technique such as gas or liquid chromatography (LC) or electrophoresis and an element- or compound-specific detector [29]. While the former provides the separation of the different elemental species present in the sample, the latter brings about selective and sensitive detection. In the case of AAS, only the hyphenation with gas or liquid chromatography has gained importance. The combination of AAS and electrophoresis has never proven successful, obviously due to the incompatibility of the extremely low flow rates of electrophoretic separations with the aspiration volumes of flame atomizers and the difficulties of interfacing the two techniques.

15.3.6.1 Gas Chromatography-Atomic Absorption Spectrometry

The combination of flame AAS and gas chromatography represents probably the first example of a hyphenated technique used for speciation analysis [30]. It is particularly favorable since the analytes arrive at the detector already in the gaseous state. Interfacing is straightforward, and in most cases a simple heated transfer line is used to direct the analytes to the atomizer. However, despite its apparent simplicity, the design of such a transfer line is critical since peak broadening due to dead volumes, cold spots, or lack of chemical inertness have to be avoided. In many cases, heated stainless steel capillaries or deactivated quartz capillaries inside a stainless steel tube of the shortest possible length are used, or the chromatographic column is directly interfaced to the premixing chamber of a flame atomizer. As the analytes are in the gaseous state, the transfer efficiency is in this case close to 100%. Capillary columns, as nowadays predominantly used in gas chromatography, are easier to interface than packed columns. They offer improved resolution, but the chromatographic peak width becomes much smaller, which poses higher demands on the speed of the data acquisition system. Also, capillary columns have a significantly smaller sample capacity than packed columns, which may result in less favorable relative detection limits.

The hyphenation of flame AAS and GC is easy to achieve, but it does not provide adequate sensitivity for most problems of environmental relevance. GF-AAS would provide trace-level sensitivity, but GF-AAS instruments are not designed for continuous operation. This prevents their use as online detectors for continuous chromatographic separation.

Hyphenated GC-AAS became successful by the introduction of quartz furnace-AAS(QF-AAS) with an electrothermally heated quartz T-tube furnace atomizer by Van Loon and Radziuk [31]. The system is designed for continuous operation, since the quartz tube can stand temperatures of up to about 1000 °C for an extended period, and combines the advantages of high sensitivity and low operation costs. QF-AAS appears to be an ideal detector for speciation analysis as long as the analytes are introduced in the vapor form. In most instances, the quartz furnace is operated at temperatures of 700–950 °C (Figure 15.22). For metal hydrides, atomization in the graphite furnace takes place according to the equations given already. Generally, the addition of O_2 and H_2 is required, which leads to the formation of $H^\bullet$ and $OH^\bullet$ radicals that initiate the atomization reaction.

For organometallic species, the decomposition of a molecule takes place via a series of electrophilic and nucleophilic reactions of the alkylated (or otherwise organically substituted) molecule with the hydroxyl and hydrogen radicals. For the example of an alkylated triorganotin compound, atomization can be described by the following reaction sequence:

$$R_3SnR' + HO^\bullet + H^\bullet \rightarrow R_3SnH + R'OH$$

$$R_3SnH + 2H^\bullet \rightarrow R_2SnH_2 + RH$$

$$R_2SnH_2 + 4H^\bullet \rightarrow Sn^0 + 2RH + 2H_2$$

The lifetime of the quartz tube atomizer is variable and can range up to several months. New tubes initially perform poorly and must be conditioned by several runs before achieving optimum sensitivity. Contamination of the quartz surface may result in significant signal suppression. As the electrothermal quartz furnace

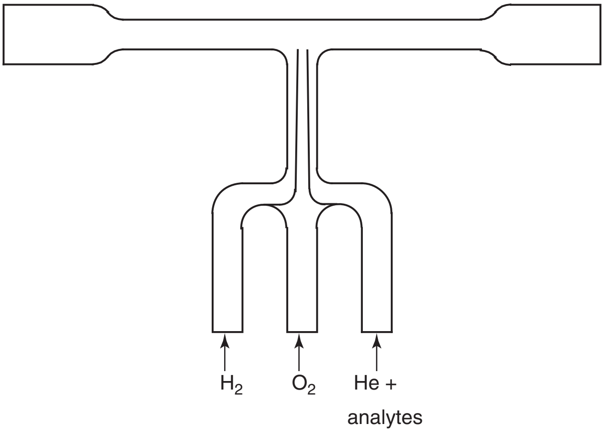

Figure 15.22 Design of a quartz T-tube atomizer (typical dimensions: length 20 cm, internal diameter 0.8 cm).

atomizer is comparatively robust and offers high overall efficiency and sensitivity at relatively low cost, it has found widespread application for the analysis of organometallic species of the elements Sn, Se, As, Sb, Pb, and Hg.

A simple, yet very efficient alternative to hyphenated GC-AAS is the use of a cryotrapping AAS system [32]. This technique combines an online aqueous derivatization of the ionic analytes, a preconcentration by cryofocussing, and chromatographic separation with detection by AAS. Details of the instrumental setup are presented in Figure 15.23. The analytes are derivatized *in situ* by $NaBH_4$ or $NaBEt_4$ and are purged to the cryotrap. Removal of the water vapor by a suitable dryer is required to avoid blocking of the trap at cryogenic temperatures. The cryotrap is a stainless steel U-tube (typically 300–450 mm long, 6 mm i.d.) that

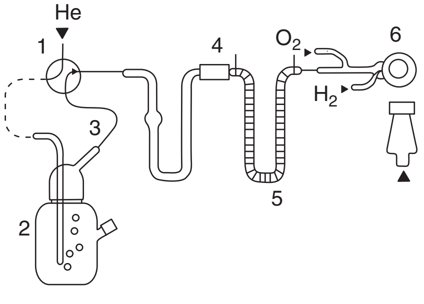

Figure 15.23 Schematic diagram of a hydride generation cryotrap-AAS HG/CT/AAS system for speciation analysis of organometallic compounds: (1) four-way valve; (2) hydride generator; (3) heated transfer lines; (4) moisture trap; (5) separation trap in liquid nitrogen; and (6) quartz furnace with inlets for hydrogen and oxygen gas. (Reproduced with permission from [33].)

is packed with a suitable adsorbent and immersed in liquid nitrogen and serves to trap the derivatized analytes. After removal of the liquid nitrogen, the trap eventually warms up or is actively heated by a Nichrome wire and the analytes are evaporated according to their volatility and transported with the carrier gas stream to the quartz furnace atomizer. Although the short packed column is only capable of achieving limited resolution (less than 1500 theoretical plates), this is often sufficient for speciation analysis of low molecular weight organametallic analytes such as organotin or organolead compounds. Because of the preconcentration effect that can be achieved by cryotrapping, detection limits in the low nanogram per liter range can be achieved for the analysis of samples of 100–500 ml volume.

15.3.6.2 **Liquid Chromatography-Atomic Absorption Spectrometry**

With its different modes of operation, high-performance liquid chromatography (HPLC) is the most suitable technique for the separation of less volatile, polar, or even ionic analytes. Depending on the column dimensions, HPLC separation provides a continuous eluent flow of typically few microliters up to 1 ml min^{-1} which can easily be introduced into the nebulizer of a flame AAS system. The interface design generally is a critical factor, since it may induce additional peak broadening which reduces both sensitivity and resolution [32b].

The column effluent is directly introduced into the mixing chamber of the flame atomizer. Since the transport efficiency of flame AAS is usually only 5–10%, this explains why the sensitivity of this type of coupling is limited, particularly in comparison with GC-AAS.

In part, this disadvantage can be overcome by using postcolumn derivatization for HPLC-flame AAS. The most versatile reaction is hydride generation, but aqueous phase ethylation has also been employed to form volatile derivatives *in situ* after liquid chromatographic separation. These are purged from the liquid phase in a nitrogen gas stream and carried into the flame atomizer. The advantage is that not only the analytes are converted to volatile forms and the transport efficiency is significantly increased thereby, but also a separation from the matrix is achieved. However, the application of this technique is obviously limited to hydride-forming elements or elements that can be alkylated by alkylborate reagents. Detection limits comparable to those of GF-AAS can be reached, for example, less than 1 ng absolute for Pb.

GF-AAS generally offers highly sensitive detection for small sample amounts; however, the sequential nature of the drying, ashing, and atomization steps makes it difficult to interface it to a continuous separation technique such as HPLC. As a simple solution, the autosampler of a commercial GF-AAS instrument may be modified in such a way that the effluent is passed through a PTFE flow-through cell from which the autosampler periodically injects a small aliquot (10–50 μl) into the furnace. Of course, this does not provide a continuous online signal, but the resulting discrete signals will allow one to reconstruct the chromatographic trace of the analytes.

Despite the better sensitivity of GF-AAS the coupling with HPLC has only found limited use, mainly due to the difficulties of coupling a continuous flow separation technique with the discrete nature of GF-AAS. Improvements may be expected by coupling HPLC and GF-AAS after online hydride generation as outlined for HPLC-flame AAS, but this technique has not been thoroughly investigated.

Although there may be niche applications where hyphenated techniques based on atomic absorption spectrometric detection are still used and provide valuable results, the use of these techniques is gradually declining. This is both due to the fact that the few existing instrumental platforms lack the continuing support of instrument manufacturers, and also that many of the applications where GC- or HPLC-AAS couplings were successful in the 1980s and 1990s have been taken over by GC and LC being coupled to either plasma emission spectroscopy or inductively coupled plasma mass spectrometry(ICP-MS), where ultratrace level sensitivity is required. These systems exist commercially, and allow integrated control of the separation and detection parameters, offering thus the convenience of use and excellent performance which as lacking in former AAS-based hyphenated systems.

15.3.6.3 **Conclusion and Future Directions**

Both flame AAS and GF-AAS can now be considered mature techniques. Flame AAS is very common, particularly in routine laboratories, as it is easy to use, inexpensive, and reliable. The technique is well understood, very little affected by interference, and provides satisfactory limits of detection. Where these are not sufficient, the use of GF-AAS is recommended. AAS is certainly the most widely employed method for elemental analysis in the routine laboratory.

Since AAS is classically a single-element technique, much effort has been spent in overcoming this disadvantage by the development of multielement spectrometers. While this is relatively easy to realize for the excitation sources by using multielement lamps which allow the analysis of up to six elements at least in a sequential mode, this is more difficult to achieve from the detection point of view, where a high-performance spectrometer must be used, consisting of an echelle spectrometer and a multichannel solid-state detector (Figure 15.24).

Such instruments have been available on the market, but have not been particularly successful. This is mainly due to the fact that these were GF instruments, which had to be operated under compromised conditions for the ashing and atomization steps for the simultaneously determined elements, but also due to the competition from emission spectrometers which by nature are more suitable for simultaneous multielement analysis.

Great interest has arisen in the direct introduction of solids in AAS. This technique has been introduced for GF-AAS [34] but has not yet been widely accepted because of the obvious difficulties in quantitative analysis. The introduction of solid suspensions (slurries) into the graphite furnace seems to be a further promising approach that has found better acceptance among users. After introduction of the sample slurry into the GF, it is subjected to a modified temperature program in the presence of modifiers as they are common for GF analysis of solutions. Thus, sample throughput is largely increased as there is no need for digestion of the sample material. It should be emphasized again that, since only very small sample amounts are analyzed, a problem arises for quantitative analysis from the

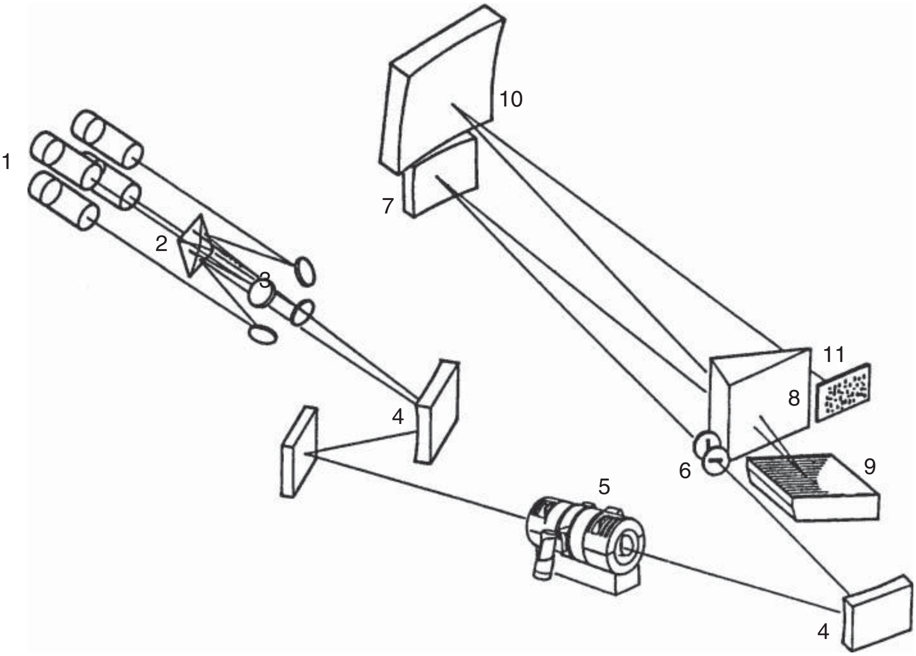

Figure 15.24 Scheme of a simultaneous graphite furnace AA spectrometer (SimAA 6100, Perkin Elmer Corp., Waltham, MA). inhomogeneity of the original sample. However, as there is no need for sample digestion or dissolution, the advantage of this technique is still convincing and it has consequently been applied to a great variety of sample types such as biological materials, polymers, as well as industrial and environmental samples.

15.4
Atomic Emission Spectrometry (AES)

15.4.1
Introduction

AES has considerable potential for qualitative and quantitative analysis because all elements can, upon excitation, emit radiation at characteristic wavelengths. Unfortunately, the conditions for excitation are so variable that until now no single source exists to excite all elements [35–39]. Historically, AES dates back to the pioneering work of Bunsen and Kirchhoff in the mid-1800s. However, it was not before 1920 that flame emission spectrometry was established as a quantitative method. Arc and spark discharges were developed for solid samples by 1940 and continue to be valuable tools for today's metallurgical analysis. With the increasing interest in plasma sources in the 1960s, a new era began with the ICP commercially introduced in the mid-1970s. Because of its commercial success and widespread use in research and routine analysis, the discussion in many sections will be devoted mostly to ICP-AES.

15.4.2
Instrumentation

15.4.2.1 Atomization Devices

An atomic emission source serves a twofold purpose: the atomization of analytes with high efficiency, and the supply of energy to excite all analytes of interest. In addition, it would be desirable for an ''ideal source'' to control the excitation energy in order to optimize the analytical conditions (see Figure 15.25). Atomization and excitation should occur in an inert atmosphere to minimize formation of interfering species and reduce background emission. The source should tolerate the introduction of solid, liquid, or gaseous samples, while organic solvents can be accepted as well as aqueous samples with a high salt or particulate load. Further, the ideal source should provide reproducible atomization and excitation conditions to facilitate a high precision for multielement analysis at reasonable cost and maintenance. Naturally, none of the atomizers described below fulfills all the criteria.

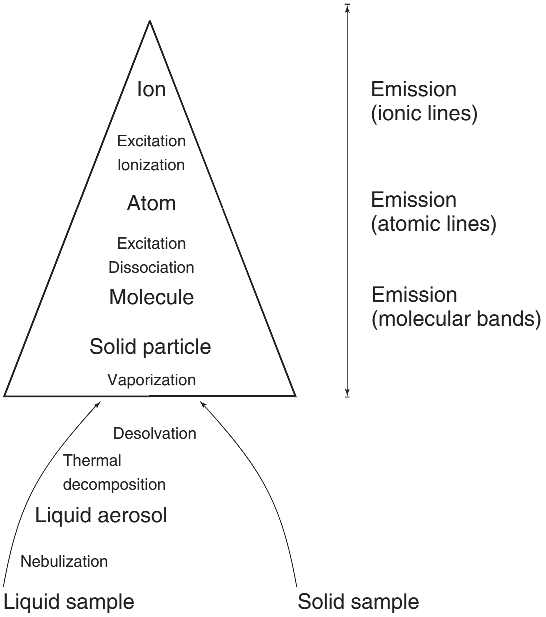

Figure 15.25 Main steps leading from a sample to atomic emission.

15.4.2.1.1 **Flame Atomizer** Historically, flames have been employed as the atomization source for various elements. Flames, as they are typically used for spectrochemical analysis, are characterized through a chemical reaction between a fuel, such as hydrogen, acetylene, or propane, and an oxidant, such as oxygen, air, or nitrous oxide. The burners are usually operated with premixed flames, in which fuel and oxidant are mixed before the combustion region. The sample is nebulized into the high-temperature region of the flame, where desolvation, volatilization, atomization, and excitation take place. The hotter flames, for example, acetylene–oxygen flames, generally produce a higher background emission, more ionization, and line-rich spectra of analytes and interferents. The background emission is typically reduced in cooler flames, for example, flames with hydrogen as fuel. However, problems can arise from nonvolatile matrix components. The fraction of excited atoms in a flame atomizer is rather low: less than 0.1% of all atoms are excited at temperatures around 2000 K and emit in the visible region between 500 and 700 nm; for elements emitting in the UV region, this fraction is even lower.

For multielement analysis, the significantly more energetic plasma sources are therefore by far superior to flames in most regards. Today, flames are used only for the determination of alkali metals, as these can be excited at low temperatures and give simple spectra free of interferences. The determination of these metals is especially important for the analysis of biological fluids, so that emission in acetylene–air flames is still routinely used in highly automated and simplified systems based on single or multiple interference filters and photomultiplier detection (see Figure 15.26). The systems often also include automatic addition of an internal standard and dilution [40].

15.4.2.1.2 **Inductively Coupled Plasma** Early types of plasmas that are the predecessors of the current ICP appeared in the early 1960s and were first reported independently by Fassel and Greenfield around 1964/1965 [41]. The ICP nowadays is probably the most common source in AES and has been widely used in routine elemental analysis since its commercial introduction in 1974. An ICP is formed

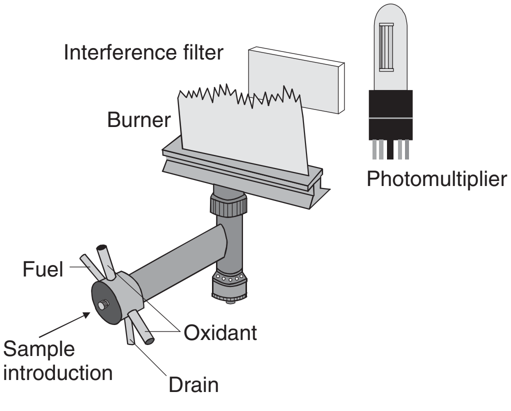

Figure 15.26 Schematic diagram of a simple flame photometer.

within the confines of three concentric quartz tubes, called a *torch*, through which a total flow of argon between 5 and 20 l min^{-1} is established. Figure 15.27 shows a schematic diagram of a torch with the outer tube, the intermediate tube, and the inner or carrier gas tube. A two- or three-turn water-cooled induction coil around the torch produces an intense oscillating magnetic field around the coil via an RF generator. These RF generators, producing 0.5–2 kW, are oscillators generating an alternating current at the desired frequency, typically at 27.12 or 40.68 MHz. In free-running oscillators, the frequency is fixed by the impedance of the components in the circuit itself. Alternatively, a piezoelectric crystal can stabilize the frequency through feedback. A higher frequency of oscillation leads to a lower excitation temperature and a lower electron density, which can result in a lower background emission and improved detection limit. With electrons and ions from a Tesla discharge, the ionization of the argon begins and a plasma is initiated in the toroidal region around the induction coil. The plasma is then sustained by inductive heating. The power delivered to the plasma will determine its temperature, with higher power resulting in higher excitation temperatures. Typical gas-kinetic temperatures in the ICP are about 5000–6000 K, while the excitation temperature is between 6500 and 7000 K and the electron temperature about 10 000 K. Because of the high temperatures inside the coil (about 5000 K), a vortex gas flow of about 10 l min^{-1} between the outer and the intermediate tube thermally isolates the outer tube and centers the plasma in a radial direction. The toroidal plasma core extends a few millimeters above the tube and emits a continuum which originates from ion–electron recombination and bremsstrahlung. On top of this continuum emission, atomic argon lines are superimposed. Between 10 and 30 mm above the core, the continuum background is reduced by several orders of magnitude so that the plasma is optically thin. The background in this second zone consists primarily of argon lines, OH bands, and some molecular bands. Because of the

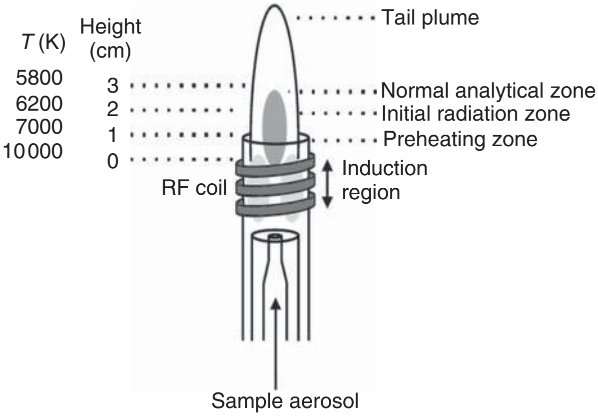

Figure 15.27 Schematic diagram of an inductively coupled plasma (ICP) assembly showing the three concentric tubes composing the torch, the RF coil, the different plasma regions, and the temperature as a function of height above the load coil. (Reprinted from Hou and Jones [42b], with permission.)

large temperature gradient, emission in this zone is observed from elements with a wide range of excitation energies. Above this zone, a flame tail is observed with temperatures similar to those of ordinary combustion flames, which can be used for easily excitable elements. Traditionally, the emission is viewed laterally through the plasma (side-on) and has the advantage of providing immediate venting of exhaust gases and heat to an overhead extraction system. Newer instruments also allow axial viewing, which permits a longer path length in the central channel and improved detection limits, by a factor of 4–10. For a long time, axial viewing had a poor reputation with regard to matrix effects, as the atomization zone within the coil and the recombination zone at the top of the plasma are also probed by the observation system. Recently, systems have appeared on the market that displace the cooler tail flame of the plasma away from the optical path either by a sampling cone or a directed gas flow. In this way, most of the original problems mentioned above can be solved.

The sample enters the plasma as an aerosol through the inner tube at a flow rate of about $1\,\mathrm{l\,min^{-1}}$ and has a residence time of about 2 ms in the plasma at temperatures between 4000 and 8000 K, after which it enters the observation zone above the core. The carrier flow shapes the plasma into the characteristic toroidal form. The intermediate gas flow is optional and can be employed, for example, for the analysis of samples in organic solvents to prevent soot deposition on the torch. The nebulizer or carrier gas flow affects not only the residence time in the plasma and the plasma conditions but also the size of the aerosols produced. With conventional nebulizers, the aerosol size increases at a low nebulizer gas flow, reducing the transport efficiency and decreasing the emission from all lines. However, lower flow rates also increase the residence time and the excitation temperature, enhancing the emission of ionic lines. For atomic lines, the excitation is improved by the increased residence time. On the other hand, the ionization rate is increased, resulting in a net decrease of atomic line emission.

The temperatures of an ICP are significantly higher than those in any combustion flame, and the atomization occurs in an inert gas atmosphere, which tends to enhance the lifetime of the free atoms by preventing oxide formation. As the temperature across the plasma is fairly uniform, self-absorption and self-reversal are not observed, thus permitting a considerable dynamic range (five orders of magnitude). Normally, the background intensities are rather low compared to other sources, which results in good detection limits in the parts-per-billion range.

15.4.2.1.3 **Direct Current Plasma** The direct current plasma (DCP) is an electrical discharge between two graphite anodes and a tungsten cathode, which are arranged in such a way that a tangentially flowing argon stream from the two anodes forms an inverted V-shaped plasma (see Figure 15.28). The cathode is located above the central apex into which the sample aerosol is directed. The plasma jet is built up by bringing the cathode and anodes into contact, resulting in ionization of the argon and development of a current (about 13–15 A). Although excitation temperatures of 6000 K can be reached, the sample volatilization is often not complete because of the relatively short residence times in the plasma. Spectra from a DCP generally have

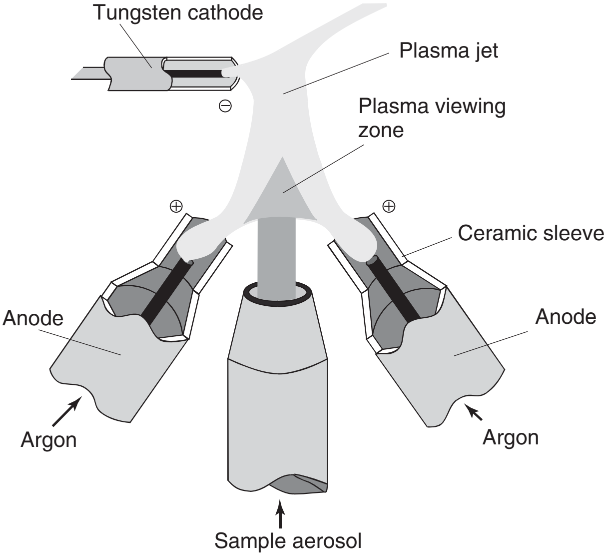

Figure 15.28 Schematic diagram of a direct current plasma (DCP).

fewer lines than those from an ICP and the lines are largely from atomic species. Problems arise from the small triangular region in which an optimal signal-to-background ratio can be achieved. The main advantage is the good stability and the ability to tolerate organic solvents as well as aqueous solutions and solutions with high solid contents. In addition, the power requirement is only 700 W and the argon consumption is, compared to the ICP, moderate, at around 7 l min^{-1}.

15.4.2.1.4 **Microwave Plasmas** Microwave plasmas can be differentiated into microwave-induced plasmas (MIPs) and capacitively coupled microwave plasmas (CMPs). In the case of MIPs, the plasma is usually generated in a flat, cylindrically shaped Beenakker-type cavity resonator (Figure 15.29) which is connected to a magnetron by coaxial or cavity waveguides. The power consumption is between 50 and 200 W at 2.45 GHz. A dielectric (quartz) capillary of 1–2 mm inner diameter is located at the center of the cavity in an axial direction. The plasma is formed within the capillary and ignited by a Tesla coil or an electrical spark. The sample is introduced into the capillary at a flow rate of 0.05–1 l min^{-1} with a carrier gas such as helium, nitrogen, or argon. The MIP is characterized by a high excitation temperature (4000–7000 K depending upon the carrier gas), which favors the atomic emission of nonmetals, but a low gas temperature (about 1000 K). Thus, there is little kinetic energy for dissociation of thermally stable compounds or high solvent loads, and the atomization efficiency is not much better than that of common flames. MIPs have been extensively used for detection of nonmetals in species separated by gas chromatography or supercritical fluid chromatography, as well as for the speciation analysis of organometallic compounds [43].

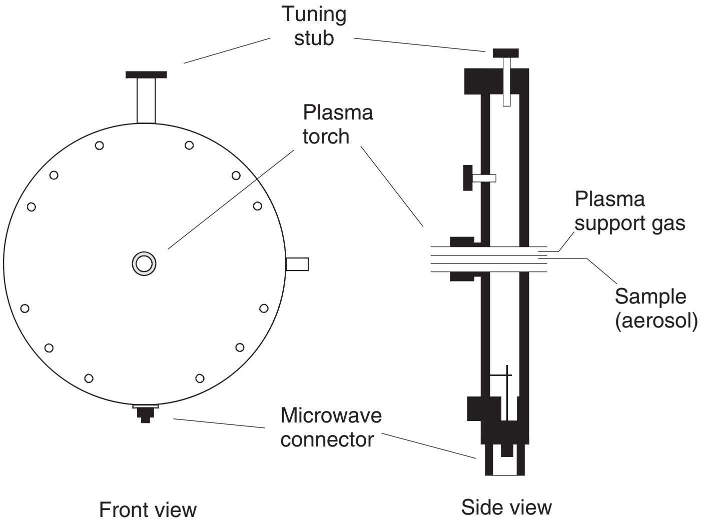

Figure 15.29 Schematic diagram of a Beenakker resonant cavity for microwave induced plasmas.

CMPs are operated at higher powers (0.5–3 kW) than MIPs, while the same frequency is used. A waveguide system transfers the energy into a plasma tube, where the plasma is ignited via a spark discharge. While excitation temperatures between 4900 and 8200 K, similar to MIPs, are achieved, gas temperatures between 4500 and 5700 K can be reached as a result of the higher power, so that CMPs are better suited for direct solution analysis.

15.4.2.1.5 **Arc and Spark Plasmas** Arc and spark discharges have been the workhorses for qualitative and quantitative emission spectrometry since the 1920s. Electrical discharges, classified into arcs and sparks, allow one to remove material from a sample surface and to excite it at the same time. Depending on the experimental conditions, the material is vaporized, eroded, or sputtered, usually in an argon atmosphere, for concurrent or subsequent excitation. The sample must be conductive, either naturally or through the addition of a conductive material such as powdered copper or graphite. Arcs are formed between a pair of metal or graphite electrodes a few millimeters apart. The DC arc, the most commonly used type, is ignited by a low-current spark and then sustained by thermal ionization. The kinetic temperature, typically between 4000 and 7000 K, depends upon the resistance between the electrodes and thus is a function of the atomization of material from the sample and the electrodes. Samples are generally introduced into the arc by evaporation from a cup-shaped electrode. Alternatively, liquid samples can be deposited on a graphite electrode and evaporated to dryness. The emission spectra contain mainly atomic lines and are interfered by those from the formation of CN radicals from the electrodes, even in an inert gas atmosphere. Because of the different rates of volatilization and excitation, the spectra of different species are time dependent, and long integration times are needed to record all species under study. On the other hand, selective volatilization can be used advantageously to enhance the signal-to-background ratio. The low-temperature outer regions of the arc contain high densities of ground-state species and are therefore prone to self-absorption and self-reversal. With the DC arc, about 70–80 elements can be excited; the analysis is mainly qualitative or semiquantitative because of the moderate precision of the arc.

Owing to their good precision (relative standard deviation (RSD) of the order of 1%), high-voltage spark source emission spectrometry is still popular for analysis of metallic samples down to concentrations of 1 ppm. For light elements, spark source AES easily outperforms X-ray fluorescence spectrometry. The high-voltage discharge is an intermittent discharge and lasts typically a few microseconds at a repetition rate of 100–1000 Hz. The sparking includes two phases. In the first phase, a low-energy discharge is produced by a primary circuit applying a potential difference of more than10 kV for a few microseconds across the electrodes to ionize the argon and create a conducting plasma. In the second phase, the main circuit of the spark generator discharges with an energy of 100–400 W at a moderate voltage of 300–500 V. In this phase, the sample is melted and evaporated at the impact point of the spark, while the different species are excited in the first phase in which excitation temperatures above 20 000 K can be reached for a short time. While in early spark systems the current waveform of the discharge was determined by the circuit resistance, inductance, and capacitance, today's systems allow excellent control of the waveform to improve detection limits and precision. Ionic spectra are more pronounced in a high-voltage spark source than in an arc. With a spark, electrode material is randomly sampled by many successive discharges on the surface, resulting in spatial averaging. To overcome changes in the surface, the integration is usually postponed for a prespark time of 1–2 min. Metallic samples for spark excitation are most often machined into the proper geometry to serve as electrodes.

15.4.2.1.6 **Laser Plasmas** Laser ablation (LA) AES is employed in two major fields of applications: bulk analysis with a spatial resolution between 100 and 1000 μm, and local microanalysis with a spatial resolution of 5–50 μm [42]. In the case of AES with the laser plasma, the technique is often denoted as laser-induced breakdown spectroscopy (LIBS) or laser-induced plasma spectroscopy (LIPS). For LIPS, an intense pulsed laser beam (typically a Nd:YAG or excimer laser) is focused on the sample of interest, resulting in evaporation, atomization, and partial ionization of the sample in an expanding plasma cloud. After a delay of some hundred nanoseconds to discriminate from the background, the elemental composition of the sample can be determined via the spectrally and temporally resolved detection of the characteristic atomic and ionic emissions. Because of the minimal sample preparation, the low cost for a single measurement, and the potential for extensive automation, LIPS is an attractive approach to environmental screening and monitoring and can be used to process solid, liquid, and gaseous samples. In addition, remote sensing is also possible either directly over a distance of some meters, or with fiber optics over a distance of 10–30 m. A microanalytical approach, either under atmospheric pressure or with Ar as buffer gas, has a considerable advantage compared to other beam techniques due to the higher sampling rate achievable with the laser. Quantitative determinations are often hampered by the lack of suitable matrix-matched standards or reference materials as well as by elemental fractionation.

15.4.2.1.7 **Reduced-Pressure Discharges** In addition to its widespread use as a light source for AAS, the hollow cathode discharge can also be used for AES. The sample is positioned in the hollow cathode and volatilized thermally and by cathode sputtering. The analyte vapor has a long residence time in the negative glow region of the plasma and is very efficiently excited, while the signal-to-background is very good because of the low electron densities. The time-consuming evacuation and gas-filling operation does not allow a fast throughput of samples, which makes the approach more suitable for solid samples, especially refractory materials.

Glow discharges with planar electrodes were introduced by Grimm in 1968 [44]. In this case, the glow discharge is confined to the sample, operating as cathode. The distance between the cathode and the anode block is below the mean free path of electrons so that the sample is volatilized by cathodic sputtering. Owing to the absence of thermal evaporation and separate atomization and excitation, matrix effects are low. Glow discharges are suitable for depth-profiling solid samples in the ppm range. Recently, glow-discharge emission spectrometry experienced a further impetus by the development of RF sources (see Figure 15.30), which allows direct analysis of nonconducting samples.

15.4.2.2 **Optical Setup and Detection**

In AES, the number of detectable elements is related to the wavelength coverage of the collimating and dispersive optical system. Alkali metal elements are usually observed above 500 nm, while elements such as Cl, Br, N, or As are detected in

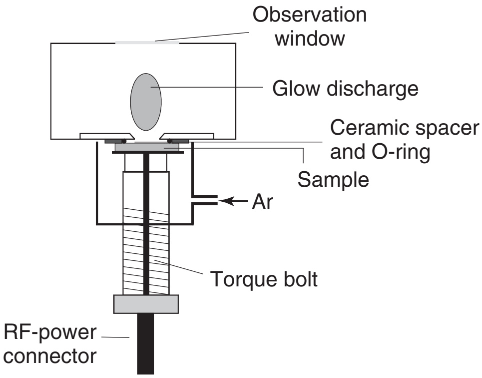

Figure 15.30 Schematic diagram of a discharge cell for RF glow-discharge atomic emission spectroscopy.

the vacuum ultraviolet (VUV) region between 130 and 190 nm. In addition, the selectivity is related to the spectral resolution of the system, which minimizes spectral interference from elements with line-rich spectra and the overall signal-to-background ratio. However, the high spectral resolution is accompanied by reduced light throughput, which can degrade the detection limits.

There are more than 50 000 documented spectral lines in ICP-AES, which makes a high-resolution spectrometer mandatory for analysis, especially when matrix effects have to be considered. The most versatile detection systems are characterized by large spectral coverage (120–770 nm) and high spectral resolution. The best spectral resolution achieved for the Ba(II) indicator line (see below) at 230.424 nm is currently below 5 pm. For high spectral resolution, all systems have to compensate for thermal and mechanical drifts by periodic spectral recalibration.

Design goals for an atomic emission spectrometer are (i) low spectral bandpass ($\lambda/\Delta\lambda > 40\,000$) and low stray light level, (ii) simultaneous measurement of the background and analyte line intensity, (iii) a detector with noise characteristics that are not the limiting noise sources, (iv) precise intensity reading <1% RSD at concentration levels 500 times the detection limit of the analyte under study, and (v) large dynamic range (6 orders of magnitude) of the detection system to record the emission intensity of major, minor, and trace constituents simultaneously.

15.4.2.2.1 **Sequential Instruments** Sequential systems are often based on a classical grating monochromator in a Czerny–Turner or comparable configuration with a holographic grating with 2400 to 3600 lines per millimeter. Scanning is performed by rotating the grating with a stepper motor, so that the different wavelengths are sequentially focused on the exit slit of the monochromator. PMTs are usually employed as detectors, though some instruments use dedicated photomultipliers for the UV and vis regions. In comparison with conventional linear-scanning monochromators, slew–scan monochromators provide significant savings in analysis time and sample consumption. Slew–scan systems can be programmed to scan slowly over or to stop momentarily at a wavelength region of interest, while the instrument moves rapidly between such regions.

To a certain extent, the linear dispersion and resolution can be improved by a finer ruled grating and a larger focal length. However, high resolution is more easily achieved with an echelle monochromator which utilizes diffraction orders greater than 80. The echelle grating provides high dispersion and a constant blaze at all wavelengths. The spectral coverage is much lower, so that a low-dispersion grating or a prism is needed as the order sorter or cross disperser (see Figure 15.31). Ambiguities in order overlap can be solved with a separate predispersion system, which also improves the overall optical throughput by removing the entrance slit height restrictions [45]. This results in a bandpass of the order of 0.007 nm at 200 nm with an accessible spectral range of 165–900 nm.

15.4.2.2.2 **Multichannel Instruments** In general, two types of multichannel instruments can be identified: polychromator instruments with several independent

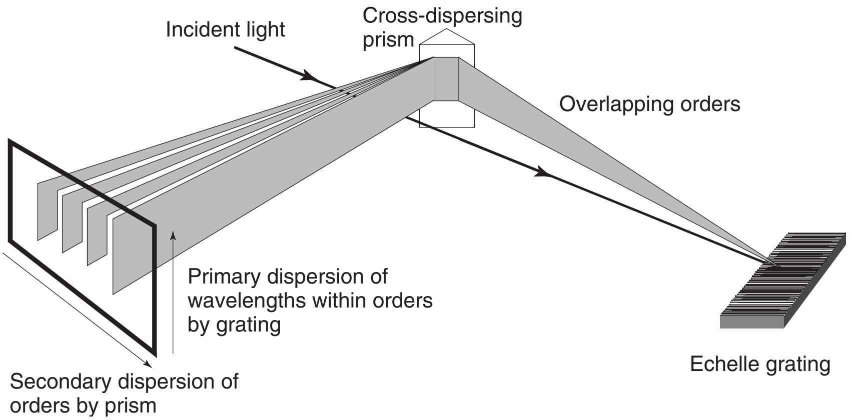

Figure 15.31 Principle of an echelle spectrograph.

detectors such as photomultipliers or small linear CCD arrays, and echelle spectrographs with solid-state array detectors such as CCDs or CIDs (charge-injection devices). Polychromators, such as the Rowland spectrometer in Figure 15.32, are based on a concave grating, which does both imaging and dispersion. This reduces the cost of optical components in the instrument, reduces alignment time, and also minimizes reflective and refractive losses. The spectral lines appear as astigmatically extended images of the entrance slit in a curved focal area. The entrance slit, the grating surface, and several exit slits with photomultipliers are arranged along the circumference of the Rowland circle. The circle diameter equals the radius of curvature of the grating. With holographic gratings with nonequidistant curved grooves, a nearly flat focal plane can be achieved for a defined spectral range. Then, an arrangement of small linear CCDs tangential to the circumference of the Rowland circle becomes possible, as employed in recent commercial systems. By moving the entrance slit tangentially to the Rowland circle, emission signals can be scanned and the background recorded. The dispersed light from the exit slits is directed with small mirrors to the corresponding photomultipliers (compare Figure 15.32), whose signals are processed by individual analog integrators. This allows very fast readout of the detectors, while the dynamic range and sensitivity for each line can be adjusted individually. Up to 60 elements can be determined simultaneously (with a 1-m Paschen–Runge spectrometer equipped with a 20-μm slit and a sampling time of 1 min), which makes polychromators the standard instrumentation for arc and spark analyzers.

In cases where no a priori information about the elemental composition is available, a more flexible approach is needed to cope with numerous emission lines and a potentially variable background. Echelle spectrographs (see Figure 15.31), based on an echelle grating and an order sorter, for example, a prism or second grating, disperse the spectrum in two dimensions in the focal plane [45]. With solid-state array detectors, a large spectral range can be addressed simultaneously with superior spectral resolution. Although CIDs have a poorer signal-to-noise

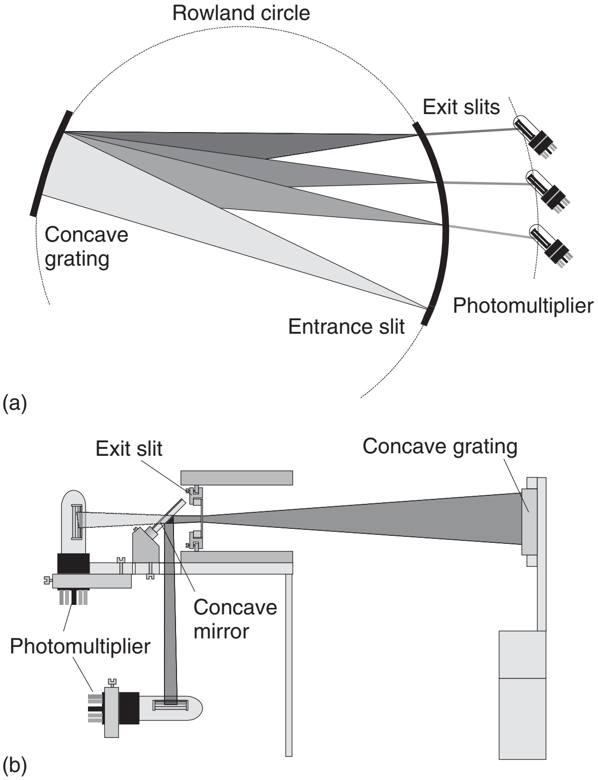

Figure 15.32 Schematic diagram of a polychromator based on a Paschen–Runge mount and photomultiplier detection. (a) General optical setup. (b) Side view and arrangement of the photomultipliers.

ratio compared to CCDs, their intermediate, that is, during an exposure, readout capability provides an improved dynamic range ($>10^5$).

Simultaneous detection permits in this way an increased sample throughput and a significant reduction in source flicker noise. Disadvantages of the two-dimensional dispersion are the reduced optical throughput and the fact that certain element combinations can be measured only in sequential groups because of different plasma conditions needed for their optimum determination. In addition, the dynamic range of the ICP-AES system itself (10^5–10^6) is larger than the dynamic range of today's CCDs (about 10^4), so that multiple exposures with different exposure times are needed for determination of trace, minor, and major components. This can also complicate the use of an internal standard if the elements under study are present in very different concentrations.

15.4.2.3 **Instrumentation for Solid Sample Introduction**

Although most samples are commonly presented as liquids for AES, direct solid sample analysis has the advantage that no major pretreatment or dissolution steps are required [46]. This minimizes dilution errors or contamination from reagents, and reduces the reagent and manpower cost per sample. In addition, improved detection limits may be obtained if microsamples or microanalyses are possible without any further dilution. However, the analyst has to ensure that the solid material sampled is representative of the bulk material. ICP-AES has generally a remarkable tolerance for total dissolved solids compared to ICP-MS or flame AAS so that, depending on the overall matrix, between 2 and 25% suspended solids can be coped with. Therefore, most of the solid sample introduction devices described below are dedicated for ICP-AES.

15.4.2.3.1 **Direct Insertion** The sample, ground into a powder, dried, and weighed, can be deposited on a probe made of graphite, tantalum, or tungsten and directly introduced into the plasma. An ICP torch can be modified, for example, by replacing the inner tube with a quartz tube which also guides the sample probe. The insertion process can be carried out in one or several defined steps by automatic positioning devices. Positioning the probe at successively closer positions to the plasma enables sample pretreatment and atomization steps, analogous to drying, ashing, and atomization in a graphite furnace. The signal is recorded as time-dependent intensity due to the differential volatilization of the sample. A typical precision of 7–15% is achieved because of the sample heterogeneity, irreproducible vaporization and sample insertion, or reactions of the sample with the probe material.

15.4.2.3.2 **Slurry Nebulization** Conventional pneumatic nebulizers are prone to serious losses and blockage if solids in the form of slurries are introduced. Usually, Babington-type nebulizers are employed, where the sample solution is pumped along a V-shaped groove and nebulized via a gas stream centered in this groove. Slurry nebulization is very suitable for small particles (particle diameter $<6\,\mu m$) and narrow size distributions. In this case, simple aqueous solutions can be used for calibration. The plasma conditions for slurries can differ considerably from solutions, and a separate optimization is needed. Apart from difficulties in the reproducible preparation of slurries, the inherent problem is the effect of particle size on evaporation and excitation. Slurry nebulization is especially interesting for fast monitoring studies, for example, geochemical and geological screening, or in the food industry [47].

15.4.2.3.3 **Electrothermal Vaporization** ET vaporization, analogous to the approach utilized in AAS, can be performed by resistive heating of sample devices such as boats, ribbons, rods, or tubes from graphite or a refractory element [48].

Usually, the vaporizer, exemplarily illustrated in Figure 15.33, can be sequenced through several heating stages, so that the solvent and matrix components can be temporally separated from each other and do not disturb the plasma conditions. The dry, highly dispersed aerosol produced under these conditions is swept into the plasma by an appropriate carrier gas stream. Because of the highly efficient sample vaporization and transport efficiency (30–80% compared to the typical 2% efficiency of a conventional cross-flow nebulizer), detection limits for aqueous

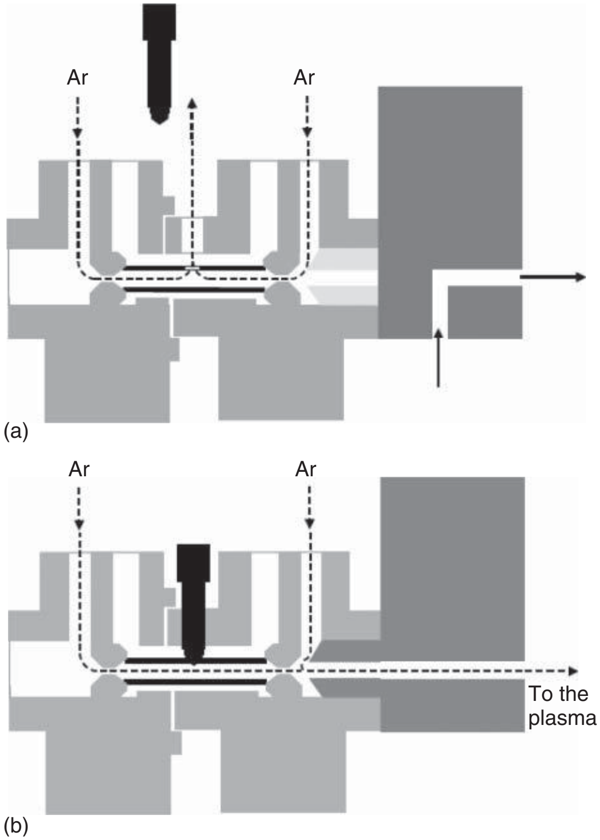

Figure 15.33 Layout of the modified graphite furnace for ETV operation during (a) the sample drying and ashing and (b) analyte vaporization. (Reprinted from Todolí and Mermet [48b] with permission.)

solutions are generally improved by a factor of 10–100. For solid samples, the maximum load is limited to 0.5 mg, with which absolute detection limits in the nanogram to picogram range can be achieved.

15.4.2.3.4 **Arc and Spark Ablation** Arc and spark ablation systems for sample introduction are similar to the respective atomization sources described above [49]. The DC arc equipped with metal or graphite electrodes is the most widely used form of the arc. Spark sources, as depicted in Figure 15.34, are frequently used for conducting samples because of their instantaneous high temperature whereas the arc temperature will increase during a measurement cycle, which can lead to fractionation effects.

15.4.2.3.5 **Laser Ablation** LA in combination with the ICP atomizer has become a powerful and flexible technique for solid sample introduction [49]. LA-AES

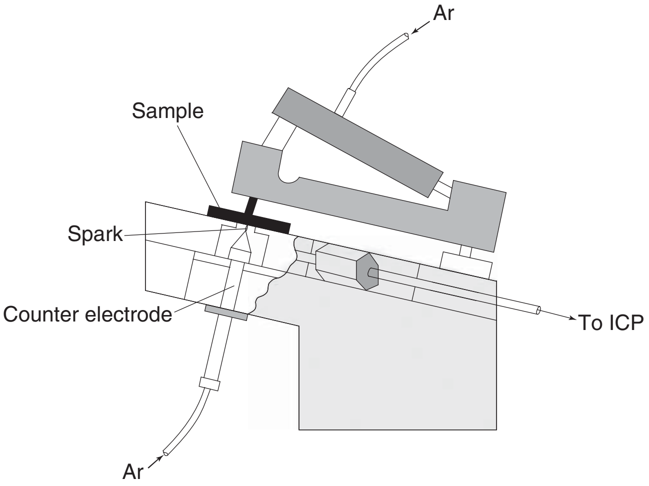

Figure 15.34 Spark chamber for solid sample introduction.

has found its niche primarily as a bulk sampling technique for the analysis of bulk solid materials with a large focal spot (500–1000 μm). It offers comparable detection capability to spark ablation/emission but is not dependent on the sample being conductive. The experimental setup, revealed in Figure 15.35, consists, in its simplest form, of a pulsed laser (excimer or Nd:YAG) with a defined pulse energy, some focusing optics, and a sample cell with a continuous Ar flow connected to the ICP torch with a simple plastic tube of 1–5 m length. For microanalysis, considerable efforts have been described in the literature to provide a homogeneous beam profile and suitable focusing optics for focal spots below 10 μm. Because of the superior sensitivity of ICP-MS, microanalysis with ICP-AES is usually limited to minor and main components. Calibration is typically based on solid reference standards, if possible with a suitable internal standard. Problems can arise from fractionation: that is, not all elements exhibit similar ablation and transport characteristics. The fractionation is related to the key parameters of a LA system, that is, laser wavelength, irradiance, and pulse width, and possibly transport phenomena or subsequent processes in the atomizer itself, and, of course, also depends on the sample itself. LA can be also used favorably in combination with other excitation sources such as microwave plasmas. The experimental setup is similar to that of LA-ICP-AES systems.

15.4.3
Matrix Effects and Interferences

In the early phase of ICP use, this technique was claimed to be free of matrix interference. Although the ICP was superior to earlier employed excitation sources and was less prone to interference than, for example, arc and sparks, matrix interference and spectral interference can still be observed.

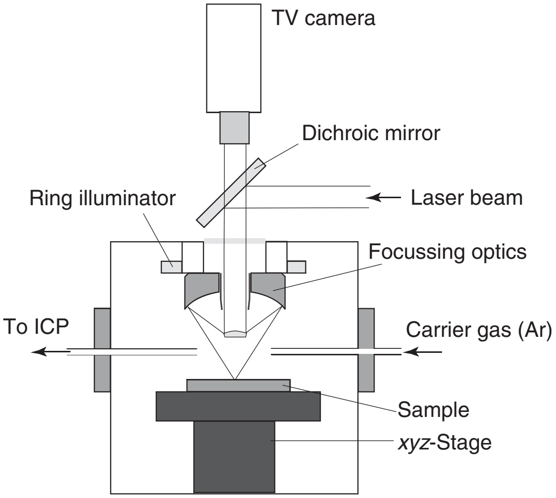

Figure 15.35 Laser ablation setup for solid sample introduction.

15.4.3.1 **Spectral Interferences**

Spectral interferences have been well studied and are probably best understood in AES. The usual remedy to alleviate a spectral interference is to either increase the spectral resolution of the spectrometer (which often is not possible with a given type of instrument) or to select an alternative emission line. Three types of spectral interference can be discriminated: (i) direct wavelength coincidence with another emission line, (ii) partial overlap of the line under study with an interfering line in close proximity, and (iii) a linear or nonlinear increase or decrease in background continuum (see Figure 15.36).

Interferences of types (i) and (ii) can occur not only from another element in the matrix but also from an argon line or molecular species such as OH or N_2. An example of a type (i) interference is the Zn(I) line at 213.856 nm overlapping with the Ni(I) line at 213.858 nm. As type (ii) can be eliminated only by improved spectral resolution, mathematical algorithms are used on a routine basis to solve this type. If the interference can be identified and quantified, then interelement correction factors can be inferred in a simple manner. First, a calibration for the analyte is constructed in the usual way, then different concentrations of the interfering element are studied, and the apparent analyte concentration is calculated at the emission line(s) of interest.

Type (iii) is easily solved by registering the background on either side of the line and modeling the background by an appropriate mathematical function. Provided that no fine structure is present, this approach should prove satisfactory. In general, the background emission decreases with wavelength, so most useful analytical lines are found in the UV region.

The selection of noninterfered lines is more critical for polychromator systems due to the limited number of channels. The major requirement is that the line is not spectrally interfered and provides sufficient sensitivity. However, for the

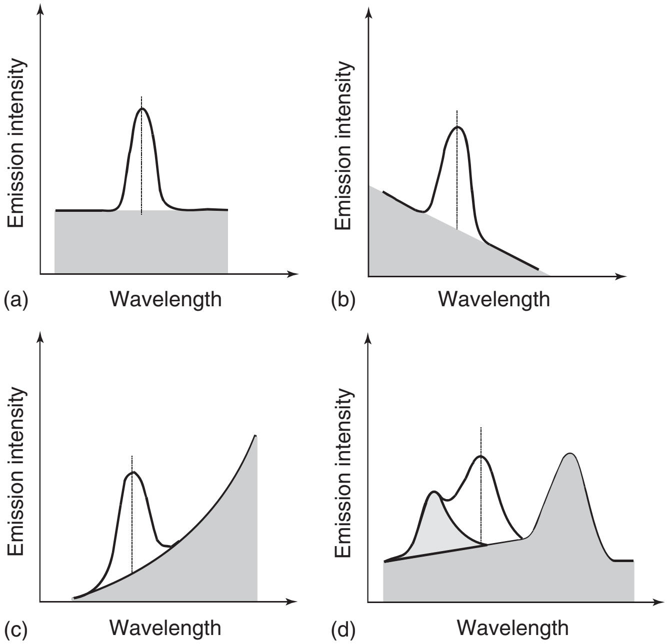

Figure 15.36 Typical spectral interferences and spectral background. (a) Flat background. (b) Sloped linear background. (c) Nonlinear background. (d) Structured background.

determination of minor and major components, less sensitive lines must also be included to allow for a better dynamic range.

15.4.3.2 Matrix Effects and Chemical Interferences

Matrix effects include nebulization interference, transfer and desolvation interference, chemical or ionization interference, and atomization and volatilization interference. Although the primary indication is a change in the emission intensity, it is often difficult to determine the origin of the interference.

As the spray chamber, through which samples are most commonly introduced into the ICP, can significantly affect the aerosol size distribution solely by its design, the trend is to use a direct-injection nebulizer (DIN). Matrix constituents, such as salts, organic compounds, or solvents altering the viscosity, surface tension, or solution density, can considerably change the quantity of the sample nebulized as a function of time. Interference by desolvation is due to the differences in volatility between the matrix and the analyte and is accompanied by a change in the analyte concentration in the aerosol during desolvation. Memory effects may be related to large tubing lengths or vessel surfaces used in the nebulization or desolvation system.

Mineral acids are widely used for sample preparation and solution storage and are therefore common matrices in AES. Depending on the nature and concentration of the acid, the atomic emission in ICP can be influenced. At low concentrations ($<1\%$ v/v), an increase in the analyte signal is observed, whereas higher acid concentrations lead to a decrease in net signal intensity. Possible explanations for this observation are a decrease in the sample uptake rate as a result of increased viscosity, a modified vapor pressure in the spray chamber, a change in the aerosol size distribution or transport efficiency, or a change in the ICP atomization and excitation conditions. Regarding the nature of the acid, it has been found that sulfuric and phosphoric acids result in an increased aerosol size due to the increased viscosity of the solution, while nitric, perchloric, and hydrochloric acids affect the excitation conditions in the plasma itself. Another well-known effect produced by acids is their influence on the duration of the nebulization period required to gain a steady-state signal.

Clogging of the injector tube by carbon or salt deposits is observed after prolonged spraying of organic samples, such as oils or organic solvents, or samples with a high salt content. Organic solvents, nebulized pneumatically, lead to a smaller aerosol size because of lower surface tension and viscosity. Hence, the solvent and analyte input in the plasma is increased and a signal enhancement may be observed. However, in some cases the solvent load may be too high, thus affecting the plasma stability and decreasing the excitation temperature and the electron density. Because of the high gas temperature of the ICP, long residence times, and inert gas atmosphere, chemical interference from the formation of thermally stable compounds or radicals is rarely observed for ICP sources, with low-power ICPs being the only exception. However, this interference is common in atomization sources with low gas temperatures, for example, the DCP, MIP, or flame.

Easily ionizable elements, such as alkali and alkaline-earth metal elements, can alter the emission intensity and may cause an enhancement or a depression. This problem is more serious with DCPs, MIPs, and CMPs, while less important with ICPs. Several mechanisms have been suggested to explain these changes, for example, lateral diffusion, changes in thermal conductivity, an altered volatilization rate, ambipolar diffusion or shifts in the ionization equilibrium, and the collisional processes.

15.4.4
Quantitative and Qualitative Analysis

Today, AES always makes use of relative quantitation, that is, unknown samples are quantitatively analyzed after calibration with samples of known composition. The most common approach to calibration is internal standardization. The underlying assumption, introduced by Gerlach in 1925, is that the ratio of the analyte mass to the mass of the internal standard, matching the analyte in its chemical properties, emission wavelength, energy of the line, and ionization potential, is constant, despite any fluctuations in the system. Internal standards thus compensate for instrumental fluctuations and improve the accuracy and precision of the determination.

Because many elements have several strong emission lines, AES can be regarded as a multivariate technique *per se*. Traditionally, for quantitative analysis in AES, a single strong spectral line is chosen, based upon the criteria of line sensitivity and freedom of spectral interferences. Many univariate attempts have been made to compensate spectral interferences by standard addition, matrix matching, or interelement correction factors. However, all univariate methods suffer from serious limitations in a complex and line-rich matrix.

On the other hand, atomic emission spectra are inherently well suited for multivariate analysis because of the fact that the intensity data can be easily recorded at multiple wavelengths. The only prerequisite is that the calibration set encompasses all likely constituents encountered in the real sample matrix. Calibration data are therefore acquired by a suitable experimental design. Not surprisingly, many of the present analytical schemes are based on multivariate calibration techniques such as multiple linear regression (MLR), principal components regression (PCR), and partial least-squares (PLS) regression, which have emerged as attractive alternatives.

Generally, AES systems are calibrated with multielement standard samples. In the case of sparks, arcs, glow discharges, and LA, solid samples are required, which are rarely available in large enough numbers to provide a satisfactory calibration. Hence, in solid sample analysis, secondary standards are usually prepared.

For conventional analysis by ICP or DCP, liquid standards are used, which are either easily prepared or commercially available. Interference problems are reduced to a minimum if the calibration solutions are matched to the samples with respect to their content of acids and easily ionizable elements (see above). Calibration curves obtained with sparks, arcs, and LA systems are usually curved, so that 8–15 calibration samples or more are needed to define a suitable calibration. In the case of liquid analysis by DCP and ICP, fewer calibration samples can be used because of the better linearity and dynamic range and absence of self-absorption effects. With the introduction of liquids, the spray chamber is the major source of flicker noise due to aerosol formation and transport. While shot noise can easily be compensated by longer integration times, the flicker noise is of multiplicative nature so that any element can be used as an internal standard provided that a true simultaneous measurement of the analyte and internal standard line intensity is possible.

To find optimal conditions for a given analysis, the principal parameters can be varied in a rational way. In the case of an ICP, to which the further discussion will be limited, this concerns the flow rate of aerosol carrier gas, the RF power input, the observation height above the induction coil, and the sample uptake rate. Numerous simple optimization schemes have been described in the literature, especially for ICP analysis. In addition, sophisticated and complex diagnostics have been suggested in the past to characterize the performance of ICP-AES systems, most of them requiring additional instrumentation. However, with commercial instruments, a simple approach based on several lines has been proposed by Mermet and others [50]. Table 15.3 gives an overview of the diagnostics that can be used to monitor the instrument performance. The spectral resolution is measured in the UV region where most analytical lines are found. Warm-up time and long-term stability are determined via the temporal behavior of three lines. Because of the all-solid-state RF generators, warm-up times are today usually about 15 min. The Mg(II)/Mg(I) ratio can be utilized to characterize the robustness of the plasma and the sensitivity of the method due to changes in the matrix. In the case

Table 15.3 Diagnostics to characterize ICP-AES performance.

Parameter	Diagnostics	Spectral line	Measurement
Selectivity	Resolution	Ba(II) 230.424	Line profile
Repeatability	RSD of signal	Mg(I) 285.213	RSD
Long-term stability	Warm-up time	Ar(I) 404.442 Ba(II) 455.403 Zn(II) 206.423	Intensity as function of time
	Stability	Ar(I) 404.442 Ba(II) 455.403 Zn(II) 206.423	RSD
Robustness	Mg(II)/Mg(I)	Mg(I) 285.213 Mg(II)280.270	Signal-to-background ratio
Limit of detection	Signal-to-background ratio RSD	Ni(II) 231.604 Background at 230 nm	Signal-to-background ratio RSD with optimized exposure time

Adapted from [50].

of a plasma, this corresponds to a constant excitation temperature and electron density as well as a similar spatial distribution of the species along the plasma axis. High RF power together with a low carrier gas flow, moderate solvent loading, and larger inner diameter of the injector usually results in robust conditions which are characterized by Mg(II)/Mg(I) ratios above 10, while, for example, a ratio of 4 indicates a high sensitivity to matrix effects. Lower power favors better signal-to-background ratio and improved detection limits.

For a long time, qualitative analysis was mainly carried out with DCP systems, while the sequential or direct reading ICP systems were too time and sample consuming for a general survey analysis. With the improved simultaneous observation of multiple emission lines via an echelle spectrometer, a general qualitative analysis of unknown samples becomes easily possible under robust plasma conditions.

15.4.5
Advantages and Limitations

15.4.5.1 Absolute and Relative Sensitivity

In the analysis of simple solutions with known composition, for ICP-AES, short-term precision between 0.2 and 3% RSD for analytes with concentrations 10 times the detection limits may be achieved, while over several hours a 5% RSD can be expected. This precision in combination with its robustness makes ICP-AES superior to ICP-MS for the determination of minor and major components. With ICP-AES, most elements (about 73) can be determined routinely at the $10\,\mu g\,l^{-1}$ level or better in solution with radial viewing. In favorable cases and for axial viewing, detection limits $<1\,\mu g\,l^{-1}$ can be achieved. For a single emission line, a linear range of 4 orders of magnitude may be easily attained and as many as 6 orders of magnitude can be observed in favorable cases. The linear range can be extended by multivariate calibration, as different emission lines with different sensitivities can be utilized for trace, minor, and major concentrations. While the speed of ICP-AES analysis will depend on whether simultaneous or sequential instruments are used for detection, generally this can vary between two and six samples per minute. Today, ICP-AES systems can be operated unattended overnight, because of the modern automated designs and safety inherent in the use of inert argon gas.

15.4.5.2 Hyphenated Techniques

Amongst the wide range of sample introduction methods available for AES, chromatographic methods are the most popular as they transform a complex mixture into a time-resolved separated analyte stream [43].

15.4.5.2.1 **Gas Chromatography and Atomic Emission Spectroscopy (GC-AES)** The combination of GS and plasma emission spectroscopy provides a specific and selective detection system for a large variety of analytes, for example, metallic elements, hydrogen, carbon, nitrogen, phosphorus, oxygen, sulfur, and the halogens. Compared to the Ar ICP, the hyphenation of a GC with normal-pressure helium MIP is extensively used, because of its superior performance in the determination of all elements that are particularly relevant in organic analysis (C, H, N, O, S, P, and halogens) and its significantly lower operation cost. In a first approximation, the emission intensity and mass response factor from an element in the plasma can be assumed to be independent of the structure of the parent compound. This is ideal for GC detection, since it significantly simplifies calibration. GC-MIP-AES is a universal, element-selective detector providing detection limits in the low picogram range. It is thus an ideal complement to GC-MS, particularly for screening purposes. The introduction of gaseous samples into a plasma offers several advantages over liquid introduction, as the transport efficiency approaches 100% in contrast to pneumatic nebulization where 95% of the sample is discarded. Sample introduction is achieved via a heated transfer line. In the case of hyphenated GC-ICP-AES, the carrier gas from the GC (normally He) is mixed with the Ar flow used to sustain the plasma and directly introduced into the plasma. The high sensitivity of ICP-AES detection, however, is partially offset by the large dilution of the GC effluent. Generally, the scope of analysis in GC-ICP-AES is limited, for example, to the determination of metal-organic species. These constitute a small group of compounds with similar chemical properties which are converted into volatile species, which, additionally, allows a substantial preconcentration and removal of interferents.

15.4.5.2.2 **Liquid Chromatography and Atomic Emission Spectroscopy (LC-AES)** LC is the most popular separation method for ionic, polar, nonpolar, and neutral compounds of intermediate to high molecular weight, low volatility, and low thermal stability. The LC effluent with a flow rate of up to 1 ml min^{-1} is connected directly to the nebulizer. The often-reported poor detection limits for LC-ICP-AES combinations are due to the ineffective conversion of the effluent into an aerosol.

This can be improved by utilizing an efficient nebulizer such as the DIN. While aqueous mobile phases are easily handled, organic phases are a greater challenge because of the increased spectral background and changes in the plasma characteristics. A simple solution is the use of a microbore LC with column diameters of ≤ 1 mm and, accordingly, lower mobile phase flow rates. Carbon deposition on the torch can be prevented with a cooled spray chamber or addition of 1–4% oxygen to the Ar plasma support gas. Microwave plasmas are difficult to use for LC detection. Because of the low plasma enthalpy, which is insufficient to desolvate and vaporize liquid aerosols effectively, they cannot tolerate the introduction of liquid phases at the usual LC flow rates. Again, the DIN or a thermospray interface can improve the coupling, but this adds significantly to the complexity of the system.

15.4.5.2.3 Capillary Electrophoresis and Atomic Emission Spectroscopy (CE-AES)

Capillary electrophoresis (CE) is a rapidly emerging tool for many routine clinical and pharmaceutical applications. Because of the high separation efficiency of the CE, this combination allows the speciation of elements even in rather complex matrices such as human serum. A challenge for this hyphenation is the interface compatible with the low flow rate of CE, which can be as little as a few nanoliters per minute, compared to a typical sample introduction rate of $1\,\mathrm{ml\,min^{-1}}$ into the ICP. Most interfaces reported in the literature contact the CE via a suitable Pt contact in a sheath buffer flow, which is mixed with the CE effluent, for example, in a polyether ether ketone (PEEK) tee. As the total flow is significantly increased by the make-up flow, a conventional nebulizer can be used for sample introduction.

15.4.5.2.4 Flow-Injection Analysis and Atomic Emission Spectroscopy (FIA-AES)

Flow-injection analysis (FIA) is a method in which small sample volumes, typically about 10–200 μl, are injected into a continuously flowing carrier stream. The corresponding transient signals can then be monitored each time a sample is introduced into the atomizer. The primary advantage of FIA as a means of sample introduction is that relatively high salt concentration in the sample can be tolerated, while viscosity effects and other interference are minimized. Further, FIA allows one to include several operations such as online dilution, standard addition, online preconcentration, and separation, which improve the sample throughput and ease of operation. For these reasons, many commercial ICP-AES systems can optionally be interfaced to highly automated FIA systems for unattended sample preparation and measurement.

15.5
Summary

Judging by a brief survey of the current literature, it can be concluded that the number of fundamental studies employing AAS is declining compared to those that use of ICP-AES and ICP-MS. At the same time, AAS continues to be one of

Table 15.4 Simplified comparison of ICP-AES, ICP-MS, flame AAS, and GF-AAS.

	ICP-AES	**ICP-MS**	**Flame AAS**	**GF-AAS**
Detection limits	Very good for most elements, ppb	Excellent for most elements, ppt	Very good for some elements, ppb	Excellent for some elements, ppt
Sample throughput	5–30 elements per min and sample	All elements per 2–6 min and sample	20 s per element and sample	5 min per element and sample
Linear dynamic range	10^5	10^5	10^3	10^2
Precision				
Short-term	0.2–3%	1–3%	0.1–1%	1–5%
Long-term	<5%	<5%	—	—
Acceptance of dissolved solids	2–25%	0.1–3%	0.5–3%	>20%
No. of elements detectable	>75	>73	>68	>50
Sample consumption	High	Low	Very high	Very low
Unattended operation	Yes	Yes	No	Yes
Operating cost	High	High	Low	Medium
Capital cost	High	Very high	Low	Medium/high

the workhorses of elemental analysis. This clearly indicates that AAS has become a mature analytical technique, both in instrumentation and analytical methodology, although some newer developments, such as continuous source-AAS, deserve particular mention and have the potential to even increase the analytical versatility of AAS. The differences in performance for different elements make AAS and ICP-AES not alternative but complementary analytical techniques. Table 15.4 illustrates this conclusion by a simplified comparison of the main analytical features of ICP-AES and ICP-MS, and flame AAS and GF-AAS, respectively. The operating cost for ICP-AES is still significantly higher than for AAS because of the considerable argon consumption during operation. Despite the generally very high performance of ICP-MS, which makes it a preferred analytical tool where available and where economically feasible, ICP-AES is a highly useful technique, as it offers excellent detection limits, particularly for those elements that are traditionally difficult to determine with ICP-MS due to interferences from elements such as Ca, Fe, and As.

In AES, flames, sparks, and MIPs will have their niche for dedicated applications, but ICP stays the most versatile plasma for multielement determination. The advances in instrumentation and the analytical methodology make quantitative analysis with ICP-AES rather straightforward once the matrix is understood and background correction and spectral overlap correction protocols are implemented. Modern spectrometer software automatically provides aids to overcome spectral and chemical interference as well as multivariate calibration methods. In this way, ICP-AES has matured in robustness and automation to the point where high-throughput analysis can be performed on a routine basis.

Inductively Coupled Plasma Spectrometry

José Alfons Clement Broekaert

16.1
The Inductively Coupled Plasma (ICP)

16.1.1
Historical Development

Atomic spectrometry is one of the oldest principles of instrumental analysis and goes back to the work of Kirchhoff and Bunsen, published in 1860 [1], who used flames both as radiation source for flame atomic emission spectrometry and as atom reservoir for atomic absorption spectrometry. Owing to the many developments in the sources, the spectrometers and the detectors, innovation in atomic spectrometry is still going on and analytical atomic spectrometry with flames and plasmas is one of the prominent methodologies in instrumental chemical analysis at present (for a treatment, see Ref. [2]). The flame remained of interest up to now but is only useful for the determination of easily ionized elements such as Na and the other alkali elements. Also, after the experiments with hot flames through the use of alternative burning gases, they could not be successfully used for the determination of further elements. Through experiments with electrical discharges in gases at the beginning of the twentieth century, their potential was also recognized for chemical analysis. DC arcs became famous for the direct analysis of solids, including both metals and alloys and electrically nonconducting materials in the powder form after mixing with an electrically conductive powder. DC arcs especially became popular for survey analysis in a wide field of applications such as geological samples analysis, soils analysis, plant residue elemental analyses and so on. In the same way, electrical sparks were recognized as a powerful tool for metal analysis and till date remained the main method for the production and product control in the metal industry. In view of their operation at low pressure, glow discharges were known as *narrow line sources* and became a main component of atomic absorption spectrometers as primary sources. However, since the 1960s it was found that sources of different geometry are also useful for the analysis of solids, which are then used as the cathode of the discharge and volatilized mainly by cathodic sputtering (for a discussion, see Ref. [3]). As this process progresses

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

layer by layer, it can be used for in-depth analysis as it is currently used in the metals industry. By the use of RF sources, not only electrically conductive solids but also electrically insulator materials can be analyzed. Plasmas at atmospheric pressure, with the volume and the time and spatial stability of a chemical flame, were recognized as powerful sources for the atomic spectrometric analysis of liquid samples or solids after bringing them into solutions. Indeed, as a result of their higher temperatures and their inert gas atmosphere in contrast to flames, they enabled the determination of practically all elements with high sensitivity instead of the alkali elements only. Microwave discharges, as described by Margoshes and Scribner [4], and dc plasma jets, as the one described, for example, by Rieman [5], were discharges between electrodes; the latter suffered from erosion and regularly had to be replaced. Also, the spectral lines of the electrode material occurred in the spectrum. Therefore, the inductively coupled plasma (ICP), as it was described by Greenfield *et al.* [6] and Wendt and Fassel [7] in 1964, first was an electrodeless discharge in argon at atmospheric pressure. As a result of the so-called toroidal structure of the plasma, a wet aerosol could be introduced with high efficiency (Figure 16.1). As a rule, it is operated in argon at reasonably high gas flows of $10-20\,\mathrm{l\,min^{-1}}$ and a power of above 1 kW. This results in a plasma with a diameter of 15–20 mm and a length of some 6–7 cm. It is very stable and robust and its stability is only limited by the constancy of the gas flows and of the power line. Intensive research on the ICP started in many prominent groups and dealt with the optimization of the torch, together with the selection of the working frequencies in a range of 20–100 MHz. Further work on sample introduction devices started and continues up to these days. For liquid samples, pneumatic nebulization is the most common way. Different types of nebulizers were conceived, developed, and used for a wide diversity of applications. Ultrasonic nebulization was improved to a maturity for specific applications such as the analysis of drinking water. The generation of volatile species by suitable chemical reactions such as hydride generation enables it to obtain highest sample introduction efficiencies. This is also the case with electrothermal vaporization (ETV), where experience from atomic absorption work can be used very well. For direct solids analysis, spark and laser ablation were intensively investigated. Further work dealt with spectral interferences and figures of merit when the ICP was used as radiation source for atomic emission spectrometry. Currently, inductively coupled plasma optical emission spectrometry (ICP-OES) can be found together with atomic absorption spectrometry in almost every large analytical laboratory and is used in routine for element determinations in a wide variety of samples. In 1980, the use of an ICP as an ion source for elemental mass spectrometry was first described by Houk *et al.* [8] and was soon made commercially available. It is currently the most powerful tool for multielement determinations of trace and ultratrace elements in solutions. Here, the use of different types of mass spectrometers helps to cope with spectral interferences or transient signals, and in different ways they are useful for high-precision isotope determinations. Inductively coupled plasma mass spectrometry (ICP-MS) is also of use for elemental detection in combination with

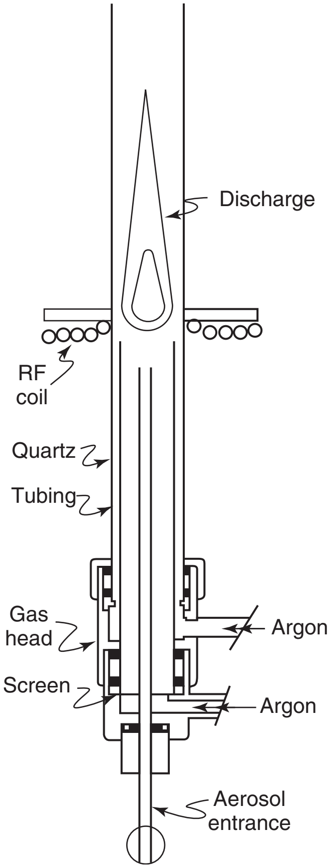

Figure 16.1 Plasma torch for ICP spectrometry. (Reproduced with permission from Ref. [7].)

chromatography and is very important for speciation in environmental and life sciences.

16.1.2
Excitation and Ionization Processes

The ICP in the form it first was described by Wendt and Fassel [7] is operated in a quartz torch consisting of three concentric tubes, of which the dimensions and form hardly have changed since the 1960s. Normally, the ICP is operated with argon in a torch with an external diameter of about 25 mm. There are three gas flows, namely, an external gas flow of 10–20 l min^{-1}, an intermediate gas flow, and the aerosol gas flow of about 1 l min^{-1}. The intermediate gas flow of 0.5–1 l min^{-1} must be used, namely, when analyzing organic solutions or when solutions with high salt contents are analyzed. However, in the original paper of Greenfield *et al.* [6] a larger torch was used and the outer gas flow could also be nitrogen, oxygen, or even air. Then, the power required is on the order of at least 2 instead of 1 kW. The plasma is powered by a high-frequency current delivered to the gas flow through a 1.5 turn coil, which is water cooled. Through a Tesla spark, some argon atoms are ionized and the charged species take up energy in the high-frequency field. A plasma is formed by ionization of additional gas atoms through the reactions:

$$\begin{aligned}\mathrm{Ar} + \mathrm{e} \rightarrow\ & \mathrm{Ar}^{+} + 2\mathrm{e}\ \text{(ionization energy : 15.7 eV) (electron impact)}\\ & \mathrm{Ar}^{*} + \mathrm{e}\\ & \mathrm{Ar}^{m} + \mathrm{e}\ \text{(metastable levels at 11.7 eV)}\end{aligned} \tag{16.1}$$

Indeed, the electrons can gain so much energy that they can ionize the omnipresent argon atoms and through this process the electron number density becomes so high that a high-temperature plasma is formed. In other cases, only excited argon atoms are formed, where electrons are promoted to higher energy levels. A special case is the population of the so-called metastable levels. As they are triplet states, they cannot decay directly by the emission of radiation and a transfer to lower energy states that are singlet states, because transitions between states with different multiplicities are forbidden. These metastable states can only decay by collisions and they have a considerable number density in analytical ICPs.

Because radiation is emitted by the decay of the excited states, a further important process is

$$\mathrm{Ar} + h\nu \rightarrow \mathrm{Ar}^{+} + \mathrm{e}\ \text{and}\ \mathrm{Ar}^{+} + h\nu \rightarrow \mathrm{Ar}^{2+} + \mathrm{e}\ \text{(radiation trapping)} \tag{16.2}$$

When analyte atoms (M) are brought into the ICP, they are excited through a number of processes, and during the decay of the excited species, element-specific radiation is emitted by the ICP. For the analyte excitation, the following processes may be important:

$$\mathrm{M} + \mathrm{e} \rightarrow \mathrm{M}^{*}, \mathrm{M}^{+*} + \mathrm{e}\ \text{(electron impact)} \tag{16.3}$$

$$\mathrm{M}^{+} + \mathrm{e} \rightarrow \mathrm{M} + h\nu \quad \text{(radiative recombination)} \tag{16.4}$$

$$\mathrm{Ar} + \mathrm{M} \rightarrow \mathrm{Ar} + \mathrm{M}^{*}\text{(collisions of the first kind)} \tag{16.5}$$

$$\mathrm{Ar}^{+} + \mathrm{M} \rightarrow \mathrm{Ar} + \mathrm{M}^{+*}\text{(charge transfer)} \tag{16.6}$$

$$\mathrm{Ar}^{m} + \mathrm{M} \rightarrow \mathrm{Ar} + \mathrm{M}^{+*} + \mathrm{e}\ \text{(Penning effect)} \tag{16.7}$$

The latter effect is especially interesting for ion lines, when the sum of the ionization energy of the element considered and the excitation energy of the respective line is near to the energy of the argon metastable levels (11.7 eV).

The high concentration of metastable argon species in the plasma even has been proposed in early studies on excitation mechanisms in the ICP to be responsible for the relatively high insensibility of the plasma to the injection of easily ionized elements. Indeed, changes in the ionization of analyte species as a consequence of introducing different concentrations of easily ionized elements such as Na, and so on, into the ICP are low, because of overionization as a result of the easy ionization of metastable argon [9]. Furthermore, the Penning effect may also explain the predominance of ion lines for a number of elements in ICP-OES. However, detailed spatially resolved measurements and probing of the excited species by laser-based techniques are still under investigation to draw up a more complete image of the relevant excitation and ionization processes in the different zones of the ICP at different working conditions (see, e.g., the recent work in the groups of Hieftje (see, e.g., Ref. [10]) and Farnsworth (see, e.g., Ref. [11])).

16.1.3
Diagnostics of the ICP

Plasmas contain not only molecules, radicals, and atoms but also ions and free electrons; all of these result from the coupling of energy with matter in the gaseous state. The species mentioned can be present in their ground states or in excited states; radiation can be emitted or absorbed when transitions from one to another state occur. The wavelength of the radiation can be obtained from Planck's law, whereas the intensities of the discrete lines depend on the number densities of the species and the states involved.

16.1.3.1 Excitation Temperatures

The transfer of energy for the different species in the ICP results from the nonradiative and radiative processes taking place. Nonradiative processes involve collisions and radiative processes involve emission, absorption, and fluorescence of radiation. The efficiency of collision processes is described by their cross section $\sigma(v)$, reflecting the loss in impulse that a particle with a mass m and velocity v undergoes when it collides with a particle with mass M. Apart from the cross section, however, the velocity distribution for a given species is important for describing the energy transfer in a plasma. In the absence of strong fields, as in the case of ICP, a Maxwell distribution can be assumed and the velocity distribution can be described by

$$\frac{\mathrm{d}n}{n} = \frac{2}{(\sqrt{\pi})} \cdot \sqrt{u'} \cdot \mathrm{e}^{u'} \cdot \mathrm{d}u' \tag{16.8}$$

with $u' = E / k{\cdot}T$, where E is the mean energy of the particles and T is the absolute temperature. For a plasma in a closed system and which is in so-called thermal equilibrium, that is, when each process is in equilibrium with its inverse process, the population of the excited levels for every type of particle is given by Boltzmann's law:

$$\frac{n_\mathrm{q}}{n_0} = \frac{g_\mathrm{q}}{g_0} \cdot \exp\left(\frac{-E_\mathrm{q}}{kT}\right) \tag{16.9}$$

where n_q is the number density of particles in the excited state, n_0 is the number density of particles in the ground state, g_q and g_0 are the statistical weights of the corresponding levels, E_q is the excitation energy of the state q, k is Boltzmann's constant (1.38×10^{-16} erg K), and T is the absolute temperature. In Eq. (16.9), a relationship is formulated between the temperature and the atom number density in a single excited state and in the ground state, respectively. The Boltzmann equation can be better formulated as a function of the total number of particles n

distributed over all states in the notations of Ref. [12] as

$$\frac{n_\mathrm{q}}{n} = \frac{\left[g_\mathrm{q} \cdot \exp\left(\frac{-E_\mathrm{q}}{kT}\right)\right]}{\left\{\Sigma_\mathrm{m} \cdot g_\mathrm{m} \cdot \exp\left[\frac{-E_\mathrm{m}}{(kT)}\right]\right\}} \tag{16.10}$$

where $n = \Sigma_\mathrm{m} n_\mathrm{m}$. The sum $Z_\mathrm{m} = \Sigma_\mathrm{m} \cdot g_\mathrm{m} \cdot \exp[-E_\mathrm{m} / (kT)]$ is the partition function. This is a function of the temperature and the coefficients of this function for a large number of neutral and ionized species are listed in the literature (see, e.g., Ref. [13]). When E_q is expressed in eV, Eq. (16.10) can be expressed as

$$\log n_\mathrm{q} = \log n + \log n_\mathrm{q} - \left[\frac{(5040)}{T}\right] \cdot V_\mathrm{q} - \log Z \tag{16.11}$$

Excited states are prone to decay, which may occur by collisions with surrounding particles or by emission of electromagnetic radiation. When this involves the levels q and p being involved, the number of spontaneous transitions per unit of time is given by

$$\frac{-\mathrm{d}n_\mathrm{q}}{\mathrm{d}t} = A_\mathrm{qp} \cdot n_\mathrm{q} \tag{16.12}$$

where A_qp is the Einstein coefficient for spontaneous emission (in s^{-1}). The intensity for the emitted spectral line (I_qp) is given by

$$I_\mathrm{qp} = A_\mathrm{qp} \cdot n_\mathrm{q} \cdot h \cdot \nu_\mathrm{qp} \tag{16.13}$$

After substitution of n_q for atomic species, according to Eq. (16.10):

$$I_\mathrm{qp} = A_\mathrm{qp} \cdot h \cdot \nu_\mathrm{qp} \cdot n \cdot \left(\frac{g_\mathrm{q}}{Z}\right) \cdot \exp\left[\frac{-E_\mathrm{q}}{(kT)}\right] \tag{16.14}$$

The excitation temperature T can be determined from the intensity ratio for two lines (a and b) of the same ionization stage of an element as

$$T = \frac{[5040(V_\mathrm{a} - V_\mathrm{b})]}{\left\{\log\left[\frac{(gA)_\mathrm{a}}{(gA)_\mathrm{b}}\right] - \log\left(\frac{\lambda_\mathrm{a}}{\lambda_\mathrm{b}}\right) - \log\left(\frac{I_\mathrm{a}}{I_\mathrm{b}}\right)\right\}} \tag{16.15}$$

For this purpose, often the line pair Zn 307.206/Zn 307.59 is used.

The excitation temperature can also be determined from the slope of the plot $\ln[I_\mathrm{qp} / (g_\mathrm{q} \cdot A_\mathrm{qp} \cdot \nu_\mathrm{qp})]$ or $\ln[I_\mathrm{qp} \cdot \lambda/(gA_\mathrm{qp})]$ versus E_q, which is equal to $-1/(k \cdot T)$ as

$$\ln\left[\frac{I_\mathrm{qp}}{\left(g_\mathrm{q} \cdot A_\mathrm{qp} \cdot \nu_\mathrm{qp}\right)}\right] = \ln\left(\frac{h \cdot n}{Z}\right) - \left[\frac{E_\mathrm{q}}{(k \cdot T)}\right] \tag{16.16}$$

For this purpose, often the iron lines Fe I 381.58, Fe I 383.04, Fe I 382.44, and Fe I 382.58 nm are used, of which the transition probabilities are well known.

After calculating the radial intensities from the laterally observed intensities at different distances away from the plasma center (through the application of Abel inversion – see Ref. [14]) – radially resolved temperature distributions can be calculated for the ICP. As shown by the results in Figure 16.2, for the ICP, temperatures close to 5000 K are obtained.

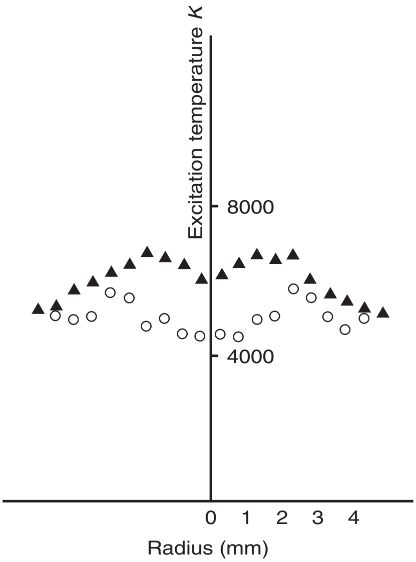

Figure 16.2 Radial distributions of excitation temperatures in ICP measured with Fe I lines. ○: with 4 mg $Na_2B_4O_7$ per ml and ▲: without $Na_2B_4O_7$; iron concentration: 100 µg ml^{-1}. (Reproduced with permission from Ref. [15].)

16.1.3.2 **Gas Temperatures**

Also, from the widths of the spectral lines, temperatures can be determined. The physical width of a spectral line results from several broadening mechanisms [16]:

The natural broadening of a spectral line is due to the finite lifetime τ of an excited state. The corresponding halfwidth in terms of the frequency is given by

$$\Delta\nu_N = \frac{1}{(2\pi\tau)} \tag{16.17}$$

For lines corresponding to transitions that are allowed according to the selection rules, lifetimes are on the order of 10^{-8} s and, accordingly, for most spectral lines this results in a natural broadening with a halfwidth on the order of 10^{-2} pm.

The Doppler linewidth results from the movement of the emitting atoms and their velocity component in the viewing direction. The respective halfwidth is given by

$$\Delta\nu_D = \left[\frac{2\cdot\sqrt{(\ln 2)}}{c}\right]\cdot\nu_0\cdot\sqrt{\left[\frac{(2\cdot R\cdot T)}{M}\right]} \tag{16.18}$$

where c is the velocity of light, ν_D is the frequency of the line maximum, R is the gas constant, and M is the atomic mass. The Doppler broadening thus strongly depends on the temperature and is often denoted as temperature broadening and reflects the kinetic energy of the radiating species (atoms, ions, or molecules). The relevant temperature is denoted as the gas temperature or Doppler temperature and the measurement of the Doppler width thus allows the determination of the gas temperature in a high-temperature plasma. In the case of the ICP, gas temperatures are on the order of 4000–5000 K.

Apart from natural and Doppler broadening, the pressure broadening and, for a number of lines, the Stark effect contribute to the line broadening.

16.1.3.3 **Ionization**

In the ICP, atoms are also ionized. The ionization of atoms (a) of an element j into ions (i) is an equilibrium:

$$n_{\mathrm{aj}} \rightleftarrows n_{\mathrm{ij}} + n_{\mathrm{e}} \tag{16.19}$$

The equilibrium constant $S_{\mathrm{nj}}(T)$ is known as the *Saha constant* and is given by

$$S_{\mathrm{nj}}(T) = \frac{(n_{\mathrm{ij}} \cdot n_{\mathrm{e}})}{n_{\mathrm{aj}}} \tag{16.20}$$

The degree of ionization α_{j} for an element is given by

$$\alpha_{\mathrm{j}} = \frac{n_{\mathrm{ij}}}{(n_{\mathrm{aj}} + n_{\mathrm{ij}})} \tag{16.21}$$

where n_{aj} and n_{ij} are the concentrations of the atoms (a) and the ions (i); these can be expressed as a function of the total number of atoms n_{j} by

$$n_{\mathrm{aj}} = (1 - \alpha_{\mathrm{j}}) \cdot n_{\mathrm{j}} \,\text{and}\, n_{\mathrm{ij}} = \alpha_{\mathrm{j}} \cdot n_{\mathrm{j}} \tag{16.22}$$

Accordingly, using the notations given in Ref. [9], the intensity of an atom line can be written as

$$I_{\mathrm{qp}} = \frac{A_{\mathrm{qp}} \cdot h \cdot \nu_{\mathrm{qp}} \cdot g_{\mathrm{q}}}{Z_{\mathrm{aj}}} \cdot (1 - \alpha_{\mathrm{j}}) \cdot n_{\mathrm{j}} \cdot \exp\left[\frac{-E_{\mathrm{q}}}{(kT)}\right] \tag{16.23}$$

while the intensity of an ion line is given by

$$I^{+}_{\mathrm{qp}} = \frac{A^{+}_{\mathrm{qp}} \cdot h \cdot \nu^{+}_{\mathrm{qp}} \cdot g^{+}_{\mathrm{qp}}}{Z_{\mathrm{ij}}} \cdot \alpha_{\mathrm{j}} \cdot n_{\mathrm{j}} \cdot \exp\left[\frac{-E^{+}_{\mathrm{q}}}{(kT)}\right] \tag{16.24}$$

These expressions for the intensities contain three factors that depend on the temperature, namely, the degree of ionization, the Boltzmann factors, and the partition functions. In particular, α_{j} can be written as a function of the electron number density and the Saha function as

$$\left[\frac{\alpha_{\mathrm{j}}}{\left(1 - \alpha_{\mathrm{j}}\right)}\right] \cdot n_{\mathrm{e}} = S_{\mathrm{nj}}(T) \tag{16.25}$$

However, the latter is also given by the well-known Saha equation. With the aid of wave mechanics and through differentiation of the Boltzmann equation, the Saha function in terms of the partial pressures can also be expressed as

$$S_{\mathrm{pj}}(T) = \frac{(p_{\mathrm{ij}} \cdot p_{\mathrm{e}})}{(p_{\mathrm{aj}})} = \frac{\left[(2\pi m)^{\frac{3}{2}} \cdot (kT)^{\frac{5}{2}}\right]}{h^3} \cdot \frac{2Z_{\mathrm{ij}}}{Z_{\mathrm{aj}}} \cdot \left\{\exp\left[\frac{-E_{\mathrm{ij}}}{(kT)}\right]\right\} \tag{16.26}$$

The factor of 2 is the statistical weight of the free electron (which can have two spin orientations).

This leads to the expression:

$$\frac{(p_{\mathrm{ij}} \cdot p_{\mathrm{e}})}{p_{\mathrm{aj}}} = S_{\mathrm{pj}}(T) = 6.58 \times 10^{-7} \times T^{\frac{3}{2}} \times \frac{Z_{\mathrm{ij}}}{Z_{\mathrm{aj}}} \times \left[\exp_{10}\left(-5040\frac{V_{\mathrm{ij}}}{T}\right)\right] \tag{16.27}$$

or in the logarithmic form:

$$\log S_{\mathrm{pj}} = \frac{5}{2}\log T - \frac{5040}{T} \cdot V_{\mathrm{ij}} + \log\frac{(Z_{\mathrm{ij}})}{(Z_{\mathrm{aj}})} - 6.18 \tag{16.28}$$

where V_{ij} is the ionization energy (eV).

The Saha equation is only valid for a plasma that is in local thermal equilibrium, that is, in which the balance of all energy processes is matched except for the radiative processes. Then the degree of ionization in a plasma can be determined from the intensity relationship between an atom and an ion line of the same element as

$$\log\left[\frac{\left(\alpha_{\mathrm{j}}\right)}{(1-\alpha_{\mathrm{j}})}\right] = \log\left(\frac{I^{+}_{\mathrm{qp}}}{I_{\mathrm{qp}}}\right) - \log\left[\frac{\left(g^{+}_{\mathrm{q}} \cdot A^{+}_{\mathrm{qp}} \cdot \nu^{+}_{\mathrm{qp}}\right)}{(g_{\mathrm{q}} \cdot A_{\mathrm{qp}} \cdot \nu_{\mathrm{qp}})}\right] + \left(\frac{5040}{T}\right)(V^{+} - V_{\mathrm{q}}) + \log\left(\frac{Z_{\mathrm{ij}}}{Z_{\mathrm{aj}}}\right) \tag{16.29}$$

In the case of the ICP, the line pair Mg II 279.6 nm/Mg I 278.0 nm has been used for the determination of the degree of ionization of elements and, depending on the ionization energies, values ranging from 10^{-5} to some percent have been found. Once α_{j} is known, the electron pressure can also be determined. Indeed, from

$$\log\left[\frac{\alpha_{\mathrm{j}}}{\left(1-\alpha_{\mathrm{j}}\right)}\right] = \log\left[\frac{S_{\mathrm{pj}}\,(T)}{p_{\mathrm{e}}}\right] \tag{16.30}$$

one can calculate that:

$$\log p_{\mathrm{e}} = -\log\left(\frac{I^{+}_{\mathrm{qp}}}{I_{\mathrm{qp}}}\right) + \log\left[\frac{\left(g^{+}_{\mathrm{q}} \cdot\ A^{+}_{\mathrm{qp}} \cdot \nu^{+}_{\mathrm{qp}}\right)}{(g_{\mathrm{q}} \cdot A_{\mathrm{qp}} \cdot \nu_{\mathrm{qp}})}\right] - \left(\frac{5040}{T}\right)(V_{\mathrm{ij}} + V^{+}_{\mathrm{q}} - V_{\mathrm{q}}) + \frac{5}{2}(\log T) - 6.18 \tag{16.31}$$

where:

$$\log n_{\mathrm{e}} = \log p_{\mathrm{e}} - \log T - \log k \tag{16.32}$$

In this manner, for the ICP, electron number densities of $n_{\mathrm{e}} = 10^{14}\,\mathrm{cm}^{-3}$ are found.

Independent of the fact that local thermal equilibrium is obtained, the electron number densities also can be determined from Stark broadening of the H_{β} line or of a suitable argon line. This contribution to broadening is a result of the electrical field of the quasi-static ions on one side and the mobile electrons on the other. As described in Ref. [17], it can be written as

$$d\lambda = 2[1 + 1.75\alpha(1 - 0.75\varsigma)]\omega \tag{16.33}$$

where ς is the ratio of the distance between the ions (ς_{m}) and the Debye path length (ς_{D}), ω is the broadening due to the interaction of the electrons ($\approx n_{\mathrm{e}}$), and α is the contribution of the interaction with the quasi-static ions ($\approx n_{\mathrm{e}}^{\frac{1}{4}}$).

$$\varsigma_{\mathrm{m}} = \left(4\pi \times \frac{n_{\mathrm{e}}}{3}\right)^{-\frac{1}{3}} \tag{16.34}$$

$$\varsigma_{\mathrm{D}} = \left[\frac{(k \times T)}{(4\pi \times \mathrm{e}^2 \times n_{\mathrm{e}})}\right]^{\frac{1}{2}} \tag{16.35}$$

$d\lambda$ can thus be calculated as a function of n_{e}. Accordingly, from the widths of the Ar I 549.59 or the Ar I 565.07 nm lines, which are mainly due to Stark broadening, n_{e} can be determined directly and this independent of the existence of LTE. For the ICP, values of 10^{16} cm^{-3} were obtained in this way. This shows that deviations of local thermal equilibrium exist.

16.1.3.4 Norm Temperatures

From Eqs. (16.23) and (16.24), which give the intensity from an atom and ion line, and from the Saha equation (16.28), it can be understood that for each spectral line emitted by a plasma source there is a temperature at which its intensity is maximum. This is the so-called norm temperature (T_{n}). In a first approximation [18], it can be written as

$$T_{\mathrm{n}} = \frac{(0.95V_{\mathrm{ij}} \times 10^3)}{\left[1 - 0.33\cdot\alpha + 0.37 \cdot \log\left(\frac{V_{\mathrm{ij}}}{10}\right) - 0.14 \log P_{\mathrm{e}}{}^*\right]} \tag{16.36}$$

where V_{ij} is the ionization energy, $\alpha = V_{\mathrm{a}}/V_{\mathrm{ij}}$ with V_{a} the excitation energy. $P_{\mathrm{e}}{}^*$ is the electron pressure (atm; 1 atm $\approx$ 101 kPa) and is a function of T and n_{e}:

$$P_{\mathrm{e}}{}^* = 1.263 \times 10^{-12} n_{\mathrm{e}} \times T \tag{16.37}$$

In cases where we have to consider the norm temperature for a line of an element that is only present as an impurity, as it is the case in an ICP formed in a noble gas, the dilution in the plasma (a) also has to be considered. For a system with more components, $P_{\mathrm{e}}{}^*$ is given by

$$P_{\mathrm{e}}{}^* = \left[\frac{(2i+1)}{(2i+3)}\right] \cdot \left(\frac{g_i}{g_{i+1}}\right) \cdot \left[\frac{4a}{(1+a)^2}\right] \cdot P \tag{16.38}$$

where g_i and g_{i+1} are the statistical weights of the ions with charge i and $i+1$, respectively. Accordingly, as a result of the dilution, the change in T_{n} after a dilution of the plasma by a factor of a will be given by

$$\frac{\Delta T_{\mathrm{n}}}{T_{\mathrm{n}}} = 0.14 \log\left[\frac{4a}{(1+a)^2}\right] < 1 \tag{16.39}$$

At a dilution of 0.1, the change in norm temperature will thus be −7.2%. In the ICP, the analyte dilution, however, is very high. It is on the order of 10^8, when 1 ml min^{-1} of a 1–10 μg ml^{-1} solution for an element with a mass of 40 is nebulized with an efficiency of 1% into an argon flow of 10 l min^{-1}. In the ICP, the norm temperatures for lanthanum atom lines such as La I 418.7 nm (with $V_{ij} = 6.61$ eV and $V_a = 2.96$ eV) will thus change from about 5000 K for a pure lanthanum plasma to 2830 K as a result of the large dilution. For atom lines of elements with relatively low ionization energies, the change in the norm temperatures as a result of the analyte dilution is high, but it is much less for ion lines. For the La II 412.3 nm line (second ionization energy: 11.43 eV and V_a: 3.82 eV), T_n is 9040 K. From the norm temperatures it becomes clear whether atom or ion lines will be optimally excited in a plasma of a given temperature, electron pressure, and gas composition. The norm temperatures further give important indications for line selection in a source of a given temperature. Atom lines often have their norm temperatures below 4000 K, especially at high analyte dilution, whereas those of ion lines often reach 10 000 K. The two types of lines are also often denoted as ''soft'' and ''hard'' lines, respectively. The fact that ion lines are predominant in the case of the ICP also is related to the overionization in the plasma, as these lines often have norm temperatures that are considerably higher than the temperatures in analytical ICPs.

16.1.3.5 **Dissociation**

The dissociation of molecular plasma gases (such as nitrogen and air in the case of the ICP) or analyte molecules that are brought into the plasma is an equilibrium reaction. Accordingly, thermally stable radicals, in particular, or molecules are often present in the ICP. They emit molecular bands that occur along with the atomic and ionic line spectra in the ICP emission spectrum. Radicals and molecules may also give rise to the formation of cluster ions, the signals of which will be present in the mass spectra in the case of ICP-MS. The main species stemming from the plasma gases are CN, NH, NO, OH, and N_2 (or ${N_2}^+$). From the analytes, predominantly thermally stable oxides remain (e.g., AlO^+, TiO^+, YO^+, etc.). A thorough treatment of molecular spectra is available in many classical textbooks (see, e.g., Refs. [19, 20]).

Molecules or radicals have different electronic energy levels ($^1\Sigma$, $^2\Sigma$, $^2\Pi$, ...), which have a vibrational fine structure ($\nu = 0, 1, 2, 3, \ldots$), and the latter again have a rotational hyperfine structure ($j = 0, 1, 2, 3, \ldots$). The total energy of a state is then given by

$$E_i = E_{el} + E_{vibr} + E_{rot} \tag{16.40}$$

E_{el} is on the order of 1–10 eV, the energy difference between two vibrational levels of the same electronic state is on the order of 0.25 eV, and for the case of two rotational levels of a vibrational band, the energy level is on the order of only 0.005 eV. A rotational line is emitted via a transition between two rotational levels. When the rotational levels considered belong to the same electronic level, the wavelength of the radiation emitted will be in the infrared region. When they belong to different electronic levels, the wavelength will be in the UV or in the visible region. Transitions are characterized by the three quantum numbers of the states involved, namely, n', ν', j' and n'', ν'', j''. All lines that originate from transitions between rotational levels belonging to different vibrational levels or two electronic states form a band: $n', \nu' \rightarrow n'', \nu''$. For these band spectra the selection rule is $\Delta j = j' - j'' = \pm 1, 0$. Transitions for which $j'' = j' + 1$ then give rise to the P-branch, $j'' = j' - 1$ to the R-branch and $j' = j''$ to the Q-branch of the band. The line corresponding to $j' = j'' = 0$ is the zero line of the band. When $\nu' = \nu'' = 0$, it is also the zero line of the system. The difference between the wave number of a rotational line (cm^{-1}) and the wave number of the zero line in the case of the P- and the R-branches is a function of the rotational quantum number j and the rotational constant B_ν, for which:

$$\frac{E_j}{(h \cdot c)} = B_\nu \cdot j(j+1) \tag{16.41}$$

The functional relationship is quadratic and is known as the *Fortrat parabola*.

For the CN radical and the N_2^+ molecular ion, the transitions give rise to band emission between 370 and 400 nm. For the violet system of the CN band, there is no Q-branch and the lowest j in the R-branch is $j = 1$.

Molecular and radical band spectra thus consist of electronic series, which in turn consist of many vibrational bands. They again consist of rotational lines, many of which are often only partially resolved. As in the case of atomic spectral lines, the intensity of a rotational line can be written as

$$I_{\mathrm{nm}} = N_{\mathrm{m}} \cdot A_{\mathrm{nm}} \cdot h \cdot \nu_{\mathrm{nm}} \cdot \frac{1}{(2\pi)} \tag{16.42}$$

where N_{nm} is the population of the excited level and ν_{nm} is the frequency of the emitted radiation. The transition probability for dipole radiation is

$$A_{\mathrm{nm}} = \frac{(64 \cdot \pi^4 \cdot \nu_{\mathrm{nm}}^3)}{(3k)} \times \frac{1}{g_{\mathrm{m}}} \times \Sigma |R_{\mathrm{nimk}}|^2 \tag{16.43}$$

The indices i and k refer to degenerated levels of the upper (m) and the lower state (n), R_{nimk} is a matrix element of the electrical dipole moment and g_{m} is the statistical weight of the upper state. N_{m} is given by the Boltzmann equation:

$$N_{\mathrm{m}} = N \cdot \frac{(g_{\mathrm{m}})}{Z(T)} \cdot \exp\left(\frac{-E_{\mathrm{r}}}{kT}\right) \tag{16.44}$$

where E_{r} is the rotational energy of the excited electronic and vibrational level and is given by

$$E_{\mathrm{r}} = h \cdot c \cdot B_{\nu'} \cdot J' \cdot (J' + 1) \tag{16.45}$$

$B_{\nu'}$ is the rotational constant and J' is the rotational quantum number of the upper state (m). For a ${}^2\Sigma_{\mathrm{g}} - {}^2\Sigma_{\mathrm{u}}$ transition, the term $\Sigma |R_{\mathrm{nimk}}|^2 = J' + J'' + 1$, where J' and J'' are the rotational quantum numbers of the upper and the lower states, respectively. Accordingly,

$$I_{\mathrm{nm}} = \frac{(16 \cdot \pi^3 \cdot c \cdot N \cdot \nu_{\mathrm{nm}}^4)}{[3Z(T)]} \cdot (J' + J'' + 1) \cdot \exp[-h \cdot c \cdot B_{\nu'} \cdot J'(J' + 1)] \tag{16.46}$$

or

$$\ln\left[\frac{I_{\mathrm{nm}}}{(J'+J''+1)}\right]=\ln\frac{[16\cdot\pi^3\cdot c\cdot N\cdot\nu_{\mathrm{nm}}^4]}{[3Z(T)]}-\left[\frac{h\ \cdot\ c\ \cdot\ B_{\nu'}\cdot\ J'\left(J'+1\right)}{(kT)}\right] \tag{16.47}$$

From a plot of $\ln[I_{\mathrm{nm}}/(J'+J''+1)]$ versus $J'(J'+1)$ for a series of rotational lines, a so-called rotational temperature can be determined. It characterizes the kinetic energy of the molecules and radicals responsible for emission of the band spectra. It is also a good approximation of the temperature, reflecting the kinetic energy of the neutrals and ions in a plasma. In the case of an ICP, rotational temperatures were measured with $N_2{}^+$, CN, and O_2 as thermometer species and radially resolved values published (see, e.g., Refs. [21, 22]). The values are at the 4000–5000 K level, being a bit lower than the excitation temperatures (5000–6000 K) commonly stated. This argues for the existence of deviations from local thermal equilibrium in an ICP.

The rotational temperatures are of the same level as the gas temperatures derived from the Doppler broadening of spectral lines.

As spectral lines of molecular bands may interfere with atomic spectral lines in ICP-OES or molecular fragments give rise to signals in mass spectrometry, which can also interfere with the signals from the ionized analyte atoms, it is important to consider the dissociation of molecular species in the ICP. The dissociation of gas-related species and molecule fragments is a function of the temperature and the plasma composition of the ICP. This dependence can be described by a dissociation equation, which is similar to the Saha equation:

$$K_{\mathrm{n}}=\left[\left(\frac{2\pi}{h^2}\right)\cdot\left(\frac{M_{\mathrm{X}}\cdot M_{\mathrm{Y}}}{M_{\mathrm{XY}}}\right)\cdot(k\cdot T)\right]^{\frac{3}{2}}\cdot\ (Z_{\mathrm{X}}\cdot\ Z_{\mathrm{Y}})\ \cdot\left[\exp\left(\frac{-E_{\mathrm{d}}}{(kT)}\right)\right] \tag{16.48}$$

where:

$$K_{\mathrm{n}}=\frac{(n_{\mathrm{X}}\cdot n_{\mathrm{Y}})}{n_{\mathrm{XY}}} \tag{16.49}$$

Z represents the partition functions for the different atomic and molecular species, M_{X}, M_{Y}, and M_{XY} are the respective masses, and E_{d} is the dissociation energy. This can be rewritten as

$$\begin{aligned}\log K_{\mathrm{n}}&=20.432+\frac{3}{2}\log\left(\frac{M_{\mathrm{X}}\cdot M_{\mathrm{Y}}}{M_{\mathrm{XY}}}\right)+\log\left(\frac{Z_{\mathrm{X}}\cdot Z_{\mathrm{Y}}}{Z_{\mathrm{XY}}}\right)-\log g+\frac{1}{2}\log T\\&\quad+\log B+\log\left(1-10^{-0.625\frac{\omega}{T}}\right)-\left(\frac{5040}{T}\right)\times V_{\mathrm{d}}\end{aligned} \tag{16.50}$$

For most diatomic molecules, the constants B and ω (cm^{-1}) have been listed in tables (see, e.g., [19]). V_{d} is then given in electron volts and for a diatomic molecule:

$$Z=\left[\frac{kT}{(h\cdot c\cdot B)}\right]\times\left[\frac{g\times\exp\left(-\frac{E_d}{(k\cdot T)}\right)}{\left\{1-\exp\left\{\frac{h\cdot c\cdot\omega}{(kT)}\right\}\right\}}\right] \tag{16.51}$$

Thus, for a metal oxide (XY), from $n_{\mathrm{XY}}/n_{\mathrm{X}} = n_{\mathrm{Y}}/K_{\mathrm{n}}$ the ratio of the number densities for the metal oxide and the metal atoms (n_{X}) as well as the degree of dissociation can be calculated when the plasma temperature, the partial pressure of oxygen in the plasma (p_{Y}), and the dissociation constant are known. This allows it to inform on the occurrence of band spectra and on the signal intensities for cluster ions in optical emission and mass spectra, respectively, in the case of the ICP.

16.2
Inductively Coupled Plasma Optical Emission Spectrometry

ICP-OES is a prominent method for multielement determinations of trace, minor, and major constituents in a wide variety of samples. Both its instrumentation, its optimization, and figures of merit as well as its application possibilities in different fields of chemical analysis are treated in this chapter.

16.2.1
Instrumentation

16.2.1.1 The Inductively Coupled Plasma

The energy of a high-frequency generator (in the frequency range of around 6–100 MHz) is transferred to a gas flow at atmospheric pressure (mostly argon) in a quartz tube system with the aid of a working coil. The electrons take up energy and collide with atoms, by which a plasma with a temperature of up to 6000 K is formed. At a suitable gas flow, geometry of the torch, and frequency, a ring-shaped toroidal plasma is formed, where the sample aerosol passes centrally through the hot plasma. The burner consists of three concentric quartz tubes. The aerosol is led with its carrier gas through the central tube. Between the outer and the intermediate tube a gas flow is introduced tangentially. It takes up the high-frequency energy and also prevents the torch from melting.

A torch of the type according to Fassel has a diameter of about 18 mm and it can be operated at 0.6–2 kW and with 10–20 l min^{-1} of argon. An intermediate argon flow (about 1 l min^{-1}) is useful when analyzing solutions of high salt content or organic solutions, so as to prevent salt or carbon deposition, respectively. In so-called low-consumption torches, the gas consumption could be brought down to about 6 l min^{-1} through the use of a special gas inlet or by reduction of the torch dimensions (see, e.g., Ref. [23]). It has been reported that ICPs in quasi-static operations can even be operated at powers of down to some 100 W and with an argon consumption as low as 1 l min^{-1} [24]. However, such plasmas are no longer robust sources that are capable of taking up wet aerosols of any aqueous sample solution with a sufficiently high sampling rate. Greenfield used a larger torch (outer diameter of up to 25 mm), in which an ICP can be operated at higher power and where argon, oxygen, or even air can be used for the outer gas flow (up to 40 l min^{-1}) [6].

ICP generators are R–L–C circuits producing a high-frequency current at high power. The stability of the power and the constancy of the gas flows are both essential in order to obtain the highest analytical precision. ICP generators with frequencies ranging from 27 to 100 MHz have been used and in general 27.12 and 40 MHz generators are now available. As a result of detailed investigations by Mermet and Michaud-Poussel, only slight differences in the performance in terms of detection limits and matrix interferences have been measured (see, e.g., Ref. [25]).

The ICP can be viewed side-on as well as end-on for atomic emission spectrometry. While in the beginning side-on observation only was used, end-on observation was later found to have a number of advantages: (i) the optical pathway is longer, which may remove detector noise limitations, especially when working at low UV and VUV wavelengths and (ii) it is easy to realize a system that is transparent at VUV wavelengths, enabling determinations to be made of elements such as the halogens, phosphorus, and sulfur, as well as of many metals with lines free of spectral interferences and with high line-to-background intensity ratios [26]. Therefore, limitations with respect to the linear dynamic range and higher easily ionized element interferences as a consequence of the larger influence of geometry changes of the plasma may occur [27].

16.2.1.2 **Sample Introduction**

In ICP spectrometry, the sample must be introduced into the source as a fine aerosol. The aerosol should enter the hot plasma zones with a low injection velocity so as to realize residence times in the millisecond range that are required for an efficient atomization and excitation. Therefore, the carrier-gas flow should not exceed $1–2\,\mathrm{l\,min^{-1}}$.

For solutions, sample introduction into the ICP in the rule makes use of *pneumatic nebulization*. The pneumatic nebulization of liquids is based on the viscous drag forces of a gas flow passing over a liquid surface and entraining parts of the liquid, by which small independent droplets are produced. This may occur when the liquid is forced through a capillary tube, and at the exit the gas then concentrically flows around the tube or perpendicularly with respect to the liquid stream. A fritted disk can also be used, which is continuously wetted and through which the gas flows.

Nebulizers are mounted in a nebulization chamber, which has the function of separating off the larger particles and leading them into the waste. Impact surfaces are often provided, so as to fractionate the aerosol droplets further, by which the efficiency of the aerosol production increases. In plasma spectrometry, a nebulization chamber according to Scott *et al*. [28] often is used. A cooling of the spray chamber may decrease the water vapor loading of the aerosol, which may increase the elemental signals and prevent cluster ion formation in ICP-MS (see later). The spray chamber needs some time to fill up with the aerosol produced and some tailing of the signals is seen, resulting from a removal of the sample aerosol by the new incoming gas and aerosol. These build-up and wash-out times limit the speed of analysis and lead to a flattening of transient signals, when a vapor

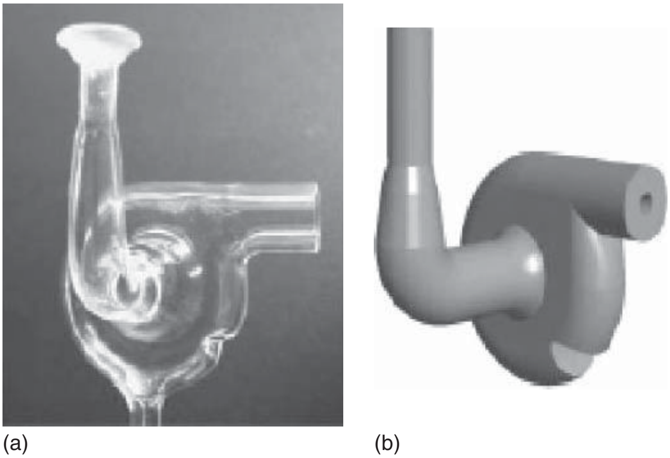

Figure 16.3 Photograph of a spray chamber according to Wu and Hieftje [29] (a) and a computer-generated 3D design (b). (Reproduced with permission from Ref. [30].)

cloud passes through the spray chamber, as is the case in flow injection analysis. In order to minimize these dead times, small spray chambers with short build-up and rinsing times have been constructed by decreasing their volume and optimizing their form with respect to ideal aerosol droplet fractionation and very efficient surface renewal. This resulted, for example, in the cyclone chamber described by Wu and Hieftje (Figure 16.3) [29]. They showed that with this spray chamber the wash-out times were very short without sacrificing analytical precision or power of detection.

In the pneumatic nebulizers used in ICP atomic spectrometry, the liquid flow is usually on the order of 1 to a few milliliters per minute and the full efficiency of the nebulizer (a small percentage) can actually be realized at gas flows below $2\,\mathrm{l\,min^{-1}}$. Even at lower gas flows, droplet diameters as low as about $10\,\mu\mathrm{m}$ and injection velocities below about $10\,\mathrm{m\,s^{-1}}$ can be obtained. Pneumatic nebulization in ICP spectrometry can be realized with concentric nebulizers, so-called cross-flow nebulizers, Babington nebulizers, and fritted-disc nebulizers (Figure 16.4). Concentric nebulizers consist of a narrow capillary through which the liquid is aspirated by the suction of gas flowing through a wider tube surrounding the capillary. At the tip of the capillary, small droplets are segmented from the liquid and with the gas form an aerosol. This type of nebulizer is known since the work of Gouy in the nineteenth century [31]. In ICP atomic spectrometry, the use of a concentric glass nebulizer (Meinhard Ass.) is typical. This nebulizer uses a gas flow of $1{-}2\,\mathrm{l\,min^{-1}}$ and is self-aspirating. The sample uptake rate is $1{-}2\,\mathrm{ml\,min^{-1}}$ and the aerosol efficiency is 2–5%. The gas pressure required is 2–7 bar and special types made of quartz also enable the analysis of dilute HF-containing solutions. Interesting developments are high-efficiency concentric nebulizers operated at very high pressures (tens of bars) [32] and microconcentric nebulizers [33], the latter allowing liquid flows in the sub-microliters per minute range as required

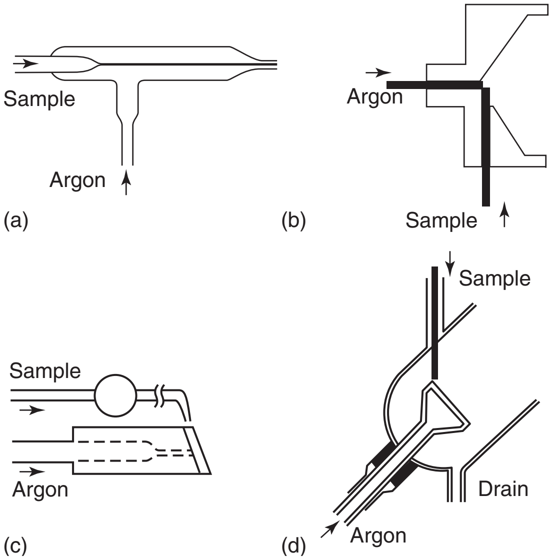

Figure 16.4 Types of pneumatic nebulizers: (a) concentric glass nebulizer, (b) cross-flow nebulizer, (c) Babington nebulizer, and (d) fritted-disc nebulizer. (Reproduced with permission from Ref. [36].)

in the coupling of liquid chromatography to ICP atomic spectrometry. Cross-flow nebulizers using glass or plastic nozzles are less sensitive to alkaline contents with respect to their stability but need to be fed with the aid of a peristaltic pump. Further, their characteristics are similar to those of concentric nebulizers. In the case of Babington nebulizers, the sample solution is pumped through a wide tube into a groove, where the film running off is nebulized by a gas flow entering perpendicular to the film of liquid. As the sample solution does not need to pass through a narrow capillary, solutions containing high salt concentrations and also slurries can be analyzed without the risk of clogging. This nebulizer, first described by Babington in 1973 [34], was later extensively used by Ebdon and Cave (see, e.g., Ref. [35]) especially for slurry nebulization.

Later on, direct injection nebulizers were designed, which allow it to work without a spray chamber. In this way, sample losses are low as are the dead times. This can only be achieved when the aerosol droplets are fine enough to avoid sample deposition or incomplete evaporation in the source. It ideally can be realized in the case of a high-efficiency nebulizer (DIHEN, direct injection high-efficiency nebulizer), as studied in Montaser's group [37] and is very useful when coupling liquid chromatography to ICP atomic spectrometry.

Further devices used for pneumatic nebulization make use of the expansion of liquid jets or impact nebulization.

In the optimization of pneumatic nebulizers, working conditions that give optimum droplet size and efficiency must be selected and where the droplets are brought with the highest possible residence time in the ICP. The so-called Sauter diameter d_0, that is, the diameter for which the volume-to-surface ratio equals that of the complete aerosol is approximated by the Nukuyama–Tanasawa equation (see Ref. [38]):

$$d_0 = \frac{C}{\nu_G} \cdot \left(\frac{\sigma}{\rho}\right)^{0.5} + C'\left\{\frac{\eta}{\left[(\sigma \cdot \rho)^{0.5}\right]}\right\}^{C''} \cdot \left[1000 \cdot \left(\frac{Q_L}{Q_G}\right)\right]^{C''} \tag{16.52}$$

where ν_G is the gas velocity, Q_G the gas flow, Q_L the liquid flow, η the viscosity, ρ the density, σ the surface density of the liquid, and C, C', C'', and C'' are constants. When the nebulizer gas flow increases, d_0 becomes smaller (through ν_G and Q_G) and the sample introduction efficiency will increase; as a result, the signals also increase. However, the higher gas flows through the ICP then cool the plasma and decrease the residence times of the droplets, and accordingly the atomization, excitation, and ionization also will decrease. These facts will counteract any increase in the signals as a result of the improved sampling. Accordingly, the highest signal intensity and thus the lowest detection limits will be achieved at a compromise gas flow. The physical properties of the liquid (σ, η, and ρ) also influence d_0, the efficiency and the analytical signals. Differences in the physical properties of the liquid samples to be analyzed thus lead to so-called nebulization effects and especially η has a large influence. It influences d_0 through the second term in Eq. (16.52). However, in the case of free sample aspiration, it also influences d_0 through Q_L, which is given by the Poiseuille law as

$$Q_L = \left[\frac{(\pi \cdot R_L^4)}{8 \cdot \eta \cdot l}\right] \cdot \Delta P \tag{16.53}$$

R_L is the radius and l the length of the capillary, ΔP is the pressure difference and is given by

$$\Delta P = \Delta P_U - g \cdot h \cdot \rho - f(\sigma) \tag{16.54}$$

where ΔP_U is the difference between the pressure inside and outside the nebulizer, h is the height, and $f(\sigma)$ a correction factor. In order to minimize the nebulization effects, one can utilize forced feeding with a peristaltic pump, the result of which is that Q_L is no longer a function of η. One also can operate the nebulizer at a high gas flow, by which Eq. (16.52) reduces to

$$d_0 = \frac{C}{\nu_G} \cdot \left(\frac{\sigma}{\rho}\right)^{0.5} \tag{16.55}$$

when Q_G/Q_L becomes >5000. However, the gas flow may then cool the source down through which incomplete atomization or signal depressions or enhancements may lead to even stronger interferences. Droplet sizes of most pneumatic nebulizers are at the 10 μm level and can be determined by measurements with cascade impactors or by stray light measurements. They are lower in the case of organic solutions than with aqueous solutions. As a lot of vapor can also accompany the aerosol droplets, desolvation of the sample aerosol may be required. This can be done by condensation of the vapor in a cooler or by diffusion through membranes such as

Nafion, which only can be permeated by the vapor and not by the droplets. Larger droplets, which represent a large fraction of the sample, may make the plasma unstable because of sudden evaporation effects. They have to be eliminated by the spray chamber and go into the waste as discussed earlier.

As an alternative to pneumatic nebulizers, *ultrasonic nebulizers* have been introduced in ICP atomic spectrometry for work with liquids. In these devices, the interaction of sufficiently energetic acoustic waves of a suitable frequency with the surface of a liquid leads to the formation of geysers by which an aerosol is produced. The diameter of the aerosol droplets produced depends on the frequency and on the physical properties of the liquid sample. In the case of water, for instance, aerosol droplets formed at a frequency of 1 MHz are about 4 μm in diameter. A system where the liquid flows over a transducer crystal was made commercially available. Because of the small droplet size, the aerosol production efficiency is high. As the accordingly high amount of liquid brought into the ICP cools the plasma more intensively, aerosol drying has to be applied. Then the power of detection is higher than with pneumatic nebulization. The approach, however, can only be used for samples with low salt loading such as drinking water, where the memory effects are high and the precision low.

Volatile species generation is a powerful approach for the determination of all elements that easily form volatile compounds as a result of chemical reactions. This has since long been applied for the determination of elements such as As, Se, Sb, Te, Bi, Sn, and so on, by atomic absorption spectrometry. Indeed, by *in situ* generation of the hydrides of these elements (AsH_3, etc.) from the sample solutions, the sampling efficiency can be increased from a small percentage in the case of pneumatic nebulization to virtually 100%.

Hydride generation can be performed efficiently by reduction with nascent hydrogen, as produced chemically by the reaction of acids with a solution of $NaBH_4$ in a flow cell. Also, electrolysis of acid solutions can be used for the production of nascent hydrogen. Here, the hydrogen is produced at the cathode and the oxygen at an anode separated from the cathode by a Nafion membrane, which prevents the mixing of both gases. Generally, the detection limits in ICP-OES for the elements mentioned in the case of flow-cell hydride generation can be improved by a factor of about 50 as compared to those of pneumatic nebulization (see, e.g., Ref. [39]). One can trap the hydrides and separate them from the excess of hydrogen produced by the use of a cooling trap with liquid nitrogen or by trapping the hydrides in a heated graphite furnace in which the hydrides are thermally decomposed (at about 700 K) and deposited as metals, which in turn can be volatilized at a temperature of >1500 K. In these cases, the power of detection of hydride generation, as a result of the preenrichment and the possibility of sweeping the collected analytes within a small time into the ICP, can be accordingly increased.

The accuracy in the case of hydride generation is limited by the fact that in different oxidation states the hydride generation species are formed with different efficiency, which in turn may be useful for speciation. Also, organometals in most cases first have to be mineralized to form the hydrides and heavy metals may influence the hydride generation efficiency as well. The latter interference can be prevented by complexing the interferents.

A similar volatilization reaction is possible in the case of Hg, where both under the use of a reducing agent such as $SnCl_2$ as well as through the use of $NaBH_4$ solutions, the volatile mercury metal can be formed with a high efficiency. Presently, research efforts are being made to expand the volatile species generation principle when using sodium tetraborate solutions to many more metals, and in the case of Cd, Au, and so on, this seems to be well possible [40].

Electrothermal evaporation of dry solution or suspension residues and transport of the released analyte with a carrier gas enable it to bring sample analytes with high efficiency into an ICP. As, here again, sample introduction efficiencies of theoretically up to 100% can be obtained, this is a technique with a high absolute power of detection, which is useful both for the analysis of small amounts of samples as well as for the determination of low concentrations. In the case of powders, the approach allows direct solids analysis after the preparation of slurries. Also, trace-matrix separations limiting the spectral interferences can be achieved by applying selective volatilization of the elements to be determined from the samples. For refractory powders, the approach seems to be very useful for the determination of volatile elements or of elements after converting them into volatile species by a suitable thermochemical reaction. Here, the principle of halogenation was found very useful as shown, for example, by a direct analyses of Al_2O_3 powders (see, e.g., Ref. [41]). The use of thermochemical reagents was found to be not only useful for volatile compound formation, but by radiotracer experiments it also could be shown that it may result in a considerable increase of the aerosol transport efficiency as a result of improved nucleation [42].

An extremely high absolute power of detection in ICP-OES can be obtained when *inserting the sample directly in the ICP*, as first shown by Salin and Horlick [43]. Here, detection limits of down to the sub-picogram level can be realized. The approach, however, was never made commercially available.

For direct solid analysis as in the case of compact solid samples, *ablation with both electrical discharges* and with *lasers* is important.

When applying a discharge between the electrically conductive sample and a counter electrode, material is ablated from the sample through local melting and evaporation of the material from the burning spot as well as by mechanical impact of atoms, ions, and clusters, for example, from ablated material or condensed droplets returning to the burning area. In the case of arc ablation, the heating of the sample and its local evaporation are predominant. In general, low burning voltages (below 100 V in argon) and high currents (up to several tens of ampere dc or ac) are used; for steel, copper base alloys, and so on, a material ablation of several milligrams per minute can be realized, which guarantees detection limits being in the same range as when the samples are dissolved and the solutions analyzed by ICP-OES using pneumatic nebulization. Owing to the evaporation process, selective volatilization of compounds with different thermal volatilities, such as Cu and Zn in the case of brass, may cause matrix effects. With spark ablation using medium-voltage sparks (burning voltages between 400 and 600 V) at medium frequencies (50 to several hundreds of Hertz), the cathodic sputtering may play a more pronounced role by which selective volatilization is lower. The ablation rates and detection limits are in the same range as with arcs. In both cases, burning spots of 6–8 mm are used, by which local analysis with lateral resolution is not possible.

Laser ablation enables to obtain much narrower burning spots at the sample surface (some micrometers) and accordingly is suitable for local analysis as well as for bulk analyses, where sample inhomogeneities, however, may become problematic. Laser ablation further has the advantage of being useful both for electrically conductive materials and isolators, such as glasses and ceramic samples. Several types of lasers have been used. While the first work was done with infrared solid-state lasers, now Nd-YAG-lasers are mostly used and instead of their basic wavelength of 105.4 nm one now uses frequency multiplexing to the UV range (also below 250 nm). In the case of laser ablation, craters produced at the sample surface with UV lasers and at atmospheric pressure have diameters of about 10 μm. They are determined by the diffraction of the laser radiation, heat conduction of the sample, the focal length of the focusing lens used, and the laser plasma effects. Because of the increase in the absorption of radiation toward shorter wavelengths but also because of the decrease in the diffraction limitations of the burning spots with smaller wavelengths, the use of UV lasers greatly increased the possibilities of laser ablation. While in the past lasers with pulses at best in the nanosecond range were exclusively used, one now gets access to lasers with pulses in the femtosecond range. It was found that not only the definition of the burning spot but also the level of selective volatilization in the latter case can be improved considerably (for an elaborate discussion, see Ref. [44]). Definitive answers here, however, have not yet been obtained. Also, modeling work now is done with the aim of further clearing the way of optimization and the finally achievable figures of merit, if possible, with these lasers. The concentration detection limits of laser ablation combined with ICP-OES are similar to those of arc and spark ablation, as are the matrix effects. A special procedure makes use of a rotation of the burning spot over the sample surface. Herewith an area of up to 8 mm in diameter can be covered, by which bulk information becomes less dependent on sample inhomogeneities. Applications of laser ablation combined with ICP-OES are in the field of studies on inclusions in geological samples, analyses of glasses and ceramics, forensic analysis of textiles, the analysis of aerosols, the investigation of welding, and so on.

16.2.1.3 **Spectrometers**

Spectrometers in optical atomic emission spectrometry are required to produce the spectrum. Dispersive spectrometers consist of an entrance collimator, a dispersive element, and an exit collimator, where a radiation detector is provided. With the entrance collimator, a quasi-parallel beam is produced from the radiation coming from the ICP through the entrance aperture. It essentially consists of a slit, with a slit width $s_{e,}$ and a collimating mirror with a focal length f_k and a width W. The exit collimator images the monochromated radiation, leaving the dispersive element on the exit focal plane. In the case of an exit window, in which one spectral area after another can be isolated by turning the dispersive element, we have a monochromator. In a polychromator, the dispersive element is fixed and different lines can be simultaneously measured at different locations in the focal plane. This is often done on a curved surface with a radius of curvature R (Rowland circle). Currently, a detector with two-dimensional resolution such as a charge-coupled device (CCD) is mostly used, with which a part of the spectrum over a certain wavelength range as well as the intensities of the signals, eventually at several locations in the ICP, can be recorded simultaneously. Virtually the only dispersive elements now used are diffraction gratings. Prisms are used only as predispersers. Distinction can be made between plane and concave gratings, of which the latter have imaging qualities. For a reflection grating, as a result of interference, a parallel beam of white radiation, inciding at an angle φ_1 with the grating normal, is dispersed and at an angle φ_2 radiation of wavelength λ is diffracted according to the Bragg equation:

$$\sin\varphi_1 + \sin\varphi_2 = m \cdot \frac{\lambda}{a} \tag{16.56}$$

where m is the order and a is the grating constant. It is the inverse of the number of grooves per millimeter. The theoretical resolving power R_0 equals the total number of grooves on the grating. The angular dispersion can be obtained by differentiation of Eq. (16.56) with respect to λ:

$$\frac{\mathrm{d}\varphi_2}{\mathrm{d}\lambda} = \frac{m}{(a\cos\varphi_2)} \tag{16.57}$$

The angular dispersion and the theoretical resolving power R_0 are related as $\mathrm{d}\varphi_2/\mathrm{d}\lambda = R_0/D_S{}'$, where $D_S{}'$ is the width of the monochromatic beam where it exits the dispersive element. The reciprocal linear dispersion is given by

$$\frac{\mathrm{d}x}{\mathrm{d}\lambda} = \left(\frac{\mathrm{d}x}{\mathrm{d}\varphi_2}\right)\left(\frac{\mathrm{d}\varphi_2}{\mathrm{d}\lambda}\right) = \left(\frac{f_k}{\cos\theta'}\right)\left[\frac{m}{(a\cdot\cos\varphi_2)}\right] \tag{16.58}$$

Here, θ' is the angle between the plane of the detector and the direction of the sorting beam.

With a plane grating, several mountings (Figure 16.5) can be used. In the Czerny–Turner mounting, two spherical mirrors with slightly different focal lengths are positioned at slightly different angles. In this way, spherical aberration can be adequately corrected for. This mounting is used for scanning ICP spectrometers with highly dispersive gratings (more than 1800 lines mm^{-1}). With the Ebert monochromator, there is only one mirror serving as the entrance and the exit collimator. Accordingly, aberrations such as coma occur.

Apart from gratings used at low orders, so-called Echelle gratings are also used in ICP spectrometers. Their groove density is low (up to 100/mm) but, therefore, order numbers of up to 70 can be used [45]. Here, the orders overlap and must be separated by using a second dispersive element (e.g., a prism) either with its axis parallel to that of the Echelle grating or in the so-called crossed-dispersion mode. In the latter case, the spectrum occurs as a number of dots with a height equaling

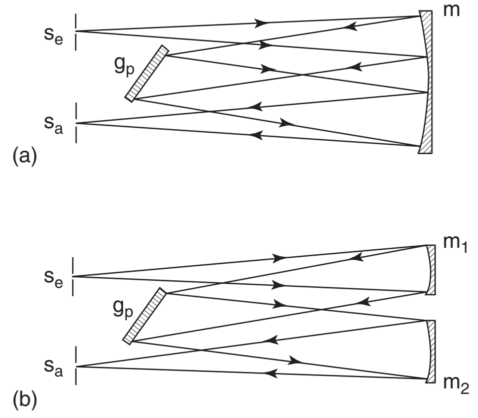

Figure 16.5 Ebert (a) and Czerny–Turner (b) mountings for monochromators. m: mirrors; s_e: entrance slit; s_a: exit slit, g_p: plane diffraction grating. (Reprinted with permission from Ref. [2].)

that of the entrance slit. The optical conductance is given by

$$\Phi = \frac{(B_\lambda \cdot t \cdot s \cdot h \cdot W \cdot H \cdot \cos \text{ß})}{f^2} \tag{16.59}$$

Here, B_λ is the spectral radiance, t the transmittance of the optics, W the width, and H is the height of the grating. Echelle spectrometers often use an Ebert mounting and allow a high spectral resolution to be obtained at low focal length (f). Therefore, they are thermally very stable. A two-dimensionally resolving array detector technology with high spatial resolution and sensitivity as well as high signal-to-noise ratios is now available. These detectors are much used in commercially available ICP-OES spectrometers. They allow large spectral regions to be collected on one detector of limited dimensions (e.g., 1 in. × 1 in.). The practical resolution then is finally limited by the pixel dimensions (e.g., 1000 pixels in one direction). In modern ICP spectrometers, a separate spectrometer is often built in to zoom into remote spectral areas, as required, for instance, for the alkali lines (Figure 16.6).

Mountings with a concave grating are also used. Here, the radius of the grating determines the so-called Rowland circle. In the direction of dispersion, the spectral lines are focused on the Rowland circle and are monochromatic images of the entrance slit. The Paschen–Runge mounting is most often used in simultaneous polychromators. Here, the grating, the entrance slit, and all detection elements are fixed on the Rowland circle. As the price of individual CCDs has come down, the whole relevant Rowland circle can be covered with CCDs. This allows more information as with classical polychromators, where, at the locations of the spectral lines, exit slits were provided and a photomultiplier was placed behind each individual exit slit. Indeed, by using CCDs information at any wavelength is accessible, whereas with photomultipliers one is limited to a number of lines (mostly below 30) and for background acquisition a scanning of the entrance slit has to be applied, which results in sequential measurements of line and background

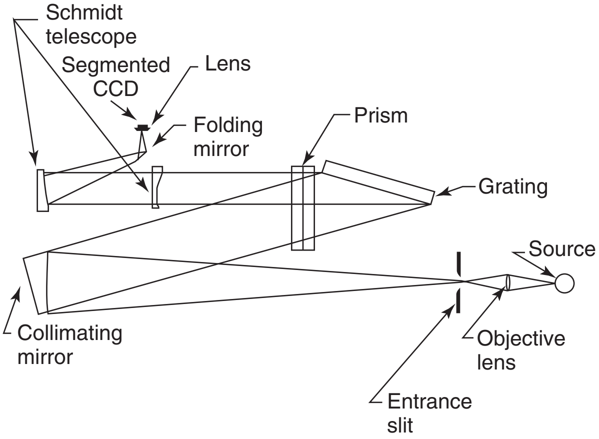

Figure 16.6 Echelle mounting in optical setup for CCD-ICP-OES (Optima) (Perkin Elmer Inc.).

intensities. The CCDs are positioned below and above the plane of the exiting radiation and mirrors placed at 45° are provided, by which a coverage of the whole spectrum, without missing any wavelength areas, becomes possible and a fully simultaneous spectrometer with data acquisition possibilities for analytical lines and background measurements at any wavelength can be realized (Figure 16.7). With such an instrument, the capacity of a photographically recording spectrograph for obtaining simultaneous information is now available for atomic spectrometry with the ease, precision, and time resolution of a photoelectrical system. However, some limitations in spectral resolution as a result of the minimum dimensions of

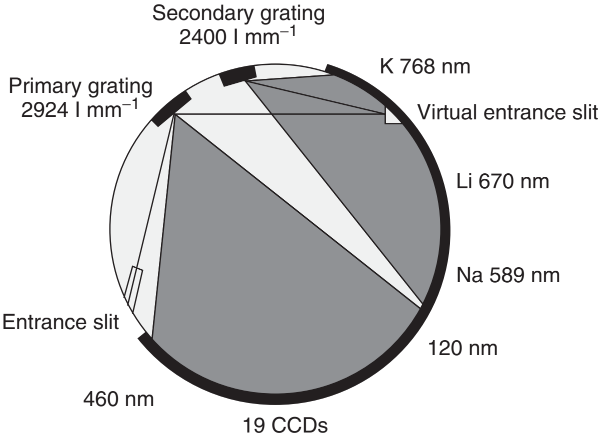

Figure 16.7 Optical setup for CCD-ICP-OES (CIROS) (Spectro Analytical Instruments GmbH).

the pixels and in signal-to-noise ratios as compared to classical photomultipliers especially at low UV wavelengths remain.

For the detection of radiation in the range of 150–500 nm, photomultipliers have been used for decades.

The photomultiplier has a photocathode and a series of so-called dynodes (for an in-depth treatment, see Ref. [46]). The radiation releases photoelectrons from the photocathode as a result of the Compton effect. After acceleration, these photoelectrons impact on the dynodes so that a large number of secondary electrons are produced, which, after successive action on a number of dynodes, leads to a measurable photocurrent at the anode (I_a). For a photon flux N_φ passing through an exit slit of a spectrometer and impacting on the photocathode, the flux of photoelectrons produced (N_e) is

$$N_e = N_\varphi \cdot \text{Q.E} \cdot (\lambda) \tag{16.60}$$

where Q.E. is the quantum efficiency (up to 20%). The cathode current (I_c) is given by

$$I_c = N_e \cdot e(e = 1.9 \times 10^{-19}\,\text{A} \cdot \text{s}) \quad \text{and } I_a = I_c \cdot \theta(V) \tag{16.61}$$

where $\theta(V)$ is the amplification factor (up to 10^6). The dark current I_d is the I_a measured when no radiation enters the photomultiplier (about 1 nA) and together with $\theta(V)$ and Q.E.(λ) is a characteristic for each photomultiplier. I_a is then fed to a preamplifier, amplifier, integrator, and digitizer. Photomultipliers for the spectral range between 160 and 500 nm usually have an S20 photocathode, but red-sensitive photomultipliers are also available. Below 160 nm, photomultipliers with a MgF_2 or LiF window are required. They have been the standard devices for high-precision measurements of radiation for decades.

Charge-transfer devices (CTDs) [47] are solid-state multichannel detectors and integrate signal information as radiation strikes them, just as a photographic film does. An individual detector in a CTD array consists of several conducting electrodes overlaying an insulating layer that forms a series of metal semiconductor (MOS) capacitors. The insulator separates the electrodes from a doped silica region used for photogenerated charge storage. In this n-doped silicon, the major current carrier is the electron, and the minor carrier is the hole. When the electrodes are negatively charged with respect to the silicon, a charge inversion region is created under the electrodes. This region is an energetically favorable location for mobile holes to reside in. The promotion of an electron into the semiconductor conducting band, such as by the absorption of a photon, creates a mobile hole that migrates to and is collected in the inversion region. The amount of charge generated in a CTD detector is measured either by moving the charge from the detector element, where it is collected to a charge-sensing amplifier, or by moving it within the detector element and measuring the voltage change induced by this movement. These two modes of charge sensing are employed by the CCD and the charge-injection device (CID), respectively. In the CCD, the charge from each detector element is shifted in sequence to an amplifier located at the end of a linear array or the corner of a two-dimensional array of detector elements. Charge

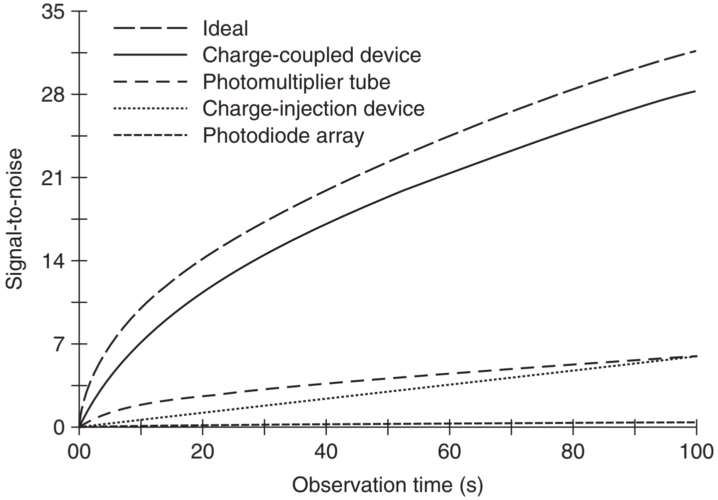

Figure 16.8 Calculated signal-to-noise ratios for different detectors at a photon flux of 10 photons s^{-1} for observation times ranging from 1 to 100 s at a wavelength of 600 nm. (Reprinted with permission from Ref. [47].)

is transferred to the on-chip amplifier by sequentially passing the charge packets through a row of detectors. Columns are read in parallel. With each reading, all of the charge in the imaging array is shifted toward the serial register by one row, whereas charge from the row adjacent to the serial register is transferred into the serial register. Once this is done, the charge packets are shifted sequentially to the on-chip amplifier. Modern CCDs are capable of thousands of transfers with almost immeasurable charge-transfer losses. By their ability to transfer the photogenerated signal from the photoactive element to an on-chip amplifier, high signal-to-noise ratios can be obtained, as compared with other detectors (Figure 16.8) [47]. With CIDs, the charge information can be read out nondestructively, further increasing the signal-to-noise ratios. With CCDs, binning can be applied, which is the process of summing the charge contained in multiple elements on the detector before sensing the total charge [48]. CTDs that can be used from the soft X-ray region to the IR are now commercially available and the signal-to-noise ratios achievable have become as high as with photomultipliers. The dynamic range has risen up to seven orders of magnitude in the case of a CID [49]. These two-dimensional detectors are ideally suited for coupling with Echelle spectrometers also for use as an alternative to photomultipliers in conventional spectrometers, where they allow simultaneous line measurements within a limited spectral range.

The ICP can be viewed axially and radially, of which the analytical possibilities are slightly different, as discussed further. In both cases, the radiation is focused through the entrance slit so that the entrance collimator is fully filled with radiation. This can be done with the aid of a lens, enabling a magnification of the relevant emission zone in the plasma (x) to the dimensions of the collimating mirror (W) by using the formulas:

$$\frac{1}{f} = \frac{1}{a} + \frac{1}{f_\mathrm{k}} \tag{16.62}$$

and

$$\frac{\mathrm{x}}{\mathrm{W}} = \frac{a}{f_\mathrm{k}} \tag{16.63}$$

Here, a is the distance between the source and the entrance slit, f is the focal length of the lens, and f_k is the focal length of the spectrometer.

Also, quartz fibers may be used to make the radiation transfer to the spectrometer more flexible. However, then the lower limit for the radiation transferred is at 220 nm. As an alternative, nowadays so-called light pipes, which make use of the total reflection of radiation, are also used.

16.2.2
Figures of Merit

16.2.2.1 Power of Detection

The detection limits (c_L), when determined according to the 3σ-concept [50], can be calculated from

$$c_\mathrm{L} = \left(\frac{I_\mathrm{X}}{I_\mathrm{U}}\right)^{-1} \cdot \left(\frac{1}{c}\right) \cdot 3\sqrt{2} \cdot 3\sigma_\mathrm{r}(I_\mathrm{U}) \tag{16.64}$$

where $I_\mathrm{X}/I_\mathrm{U}$ is the line (I_X) to background (I_U) intensity ratio measured for an analyte concentration c and $\sigma_\mathrm{r}(I_\mathrm{U})$ is the relative standard deviation of the background intensities. $I_\mathrm{X}/I_\mathrm{U}$ is a function of the nebulizer gas flow especially, the observation zone selected and the power, all of which have to be optimized so as to obtain the lowest possible detection limits for a given element or under compromise conditions. Generally, a power level of 1–1.5 kW is used and the observation window selected between 2 and 4 mm above the load coil.

The detection limits for most elements are at the 0.1 (Mg, Ca, ...) to 50 ng ml^{-1} level (As, Th, ...). In particular, for elements that have refractory oxides (such as Cr, Nb, Ta, Be, rare earths, ...), a fairly low ionization potential, and sensitive ion lines, the detection limits are lower than in AAS. On the contrary, the detection limits for elements with high excitation potentials, such as Cd, Zn, and Tl, are lower in AAS than in ICP-OES. For P, S, N, O, and F, the most sensitive lines are at VUV wavelengths and here with vacuum spectrometers and VUV transparent pathways and optics, values of 450 ng ml^{-1} (Br), 200 ng ml^{-1} (Cl), 3.9 ng ml^{-1} (P), and 3.5 ng ml^{-1} (S) can be obtained [51].

The detection limits obtained by radial and axial observation were found to be up to one order of magnitude lower in the axial as compared with the radial viewing, as reported by Ivaldi and Tyson [27]. These results were obtained with an Echelle spectrometer using CCD detection. The results were found to be partly due to better signal-to-noise ratios and also to lower RSD values. The latter may be understood from a better stabilization of the plasma.

In organic solutions, determinations can also be performed with ICP-OES using pneumatic nebulization. Indeed, solvents such as MIBK, xylene, or kerosene can also be nebulized (see, e.g., Ref. [52]). The addition of oxygen or the use of higher power is helpful so as to avoid carbon deposits. It also has been suggested that the use of burners with sharp edges and improved flow dynamics is helpful in preventing carbon deposits [53]. Oils can be analyzed after dilution 1 : 10 with xylene (c_L: 0.5–1 $\mu g\, g^{-1}$).

16.2.2.2 **Interferences**

Most interferences in ICP-OES are additive interferences and relate to coincidences of analyte lines with spectral background structures. These can be decreased by the use of high-resolution spectrometers and background correction procedures. Also, the line selection must be optimized in view of the sample matrix, for which atlases (see, e.g., Ref. [54] or tables where the resolution of the spectrometer also is considered, as worked out by Boumans [55], are useful.

Multiplicative interferences, however, also occur in ICP-OES. They may have several causes:

- *Nebulization effects*: as discussed earlier, differences in the physical properties of the different samples and calibration solutions lead to variations in the aerosol droplet size and thus also in the efficiency of the nebulizer and the sample introduction. This effect is strongest in the case of free sample aspiration and relatively low nebulizer gas flow and can be minimized.
- *Easily ionized elements have a complex influence*: first, they may shift the ionization equilibrium for partially ionized elements as they may influence the electron number densities through their easy ionization. They may also cause changes in the plasma volume as a result of ambipolar diffusion or eventually quench excited species such as metastables [15]. After correcting for the influence of easily ionized elements on the spectral background, signal enhancements or suppressions are negligible up to concentrations of 500 $\mu g\, ml^{-1}$ of Na, K, Ca, or Mg. At larger concentrations, matrix matching is required. It also was found that interferences caused by NaCl were nearly twice as large in the case of axial viewing than in radial viewing and that atom-to-ion line intensities were influenced more severely in the case of axial viewing [51]. Therefore, axial viewing allows it to exclude any air from entrainment into the ICP, by which many VUV lines can be used free of spectral interferences [56].

16.2.2.3 **Analytical Precision**

As the sample introduction is stable in ICP-OES using pneumatic nebulization, RSDs in ICP-OES can easily be brought down to below 1%. The dominant noise sources are nebulizer noise, fluctuations of the power and of the gas supply, especially. These sources can be at least partially eliminated, especially in the case of a CCD spectrometer where the signals can be freed from correlating spectral background fluctuations as the line and background intensities can be measured simultaneously. Accordingly, for PbBiSrCaCuOxide high-temperature supraconductor precursor materials, the main components could be determined with a precision of up to 0.25% [57] and this can still be improved by internal standardization, which, however, is critical with respect to internal standard element and line selection. The principles hereof have been discussed in detail by Fassel *et al.* [58]. For an intensity ratio of two atomic emission lines from two elements:

$$\frac{I_{\mathrm{qp(Xo)}}}{I_{\mathrm{sr(Ro)}}} = \left\{ \frac{\left[n_{\mathrm{(Xo)}} \cdot A_{\mathrm{qp}} \cdot \nu_{\mathrm{qp}} \cdot g_{\mathrm{q}} \cdot Q_{\mathrm{(Ro)}} \right]}{\left[n_{\mathrm{(Ro)}} \cdot A_{\mathrm{sr}} \cdot \nu_{\mathrm{sr}} \cdot g_{\mathrm{s}} \cdot Q_{\mathrm{(Xo)}} \right]} \right\} \cdot \left\{ \exp\left[\frac{\left(E_{\mathrm{s}} - E_{\mathrm{q}} \right)}{(k \cdot T)} \right] \right\} \tag{16.65}$$

Fluctuations in number densities of both elements X (analyte) and R (reference element) are canceled. In order to keep the influence of fluctuations in the temperature low, lines with similar excitation energies should be used and also the partition functions should be of the same order of magnitude. As ionization also has to be considered, the ionization energies should be similar, rendering the choice difficult. Finally, ICP-OES becomes as powerful as the most precise analytical methods, as, for example, shown for the determination of the mass fractions of Li and Al in $\mathrm{LiAlO_2}$ for which the Li/Al amount of substance ratio was 0.9793 ± 0.0017 (i.e., $\pm$ 0.17%) [59]. Internal standardization also could be used to minimize concomitant influences, as shown by Bauer and Broekaert [60], where matrix effects amounting up to 20% could be corrected for to below some percent, however, again with a very critical influence of the internal standard element and line selection.

16.2.2.4 **Multielement Capacity**

The multielement capacity of ICP-OES is high, as is the linear dynamic range (up to five orders of magnitude). It is restricted on the lower side by the limits of determination and at the higher concentrations by the beginning of self-reversal of the spectral lines. This only starts at concentrations of about $20\,000\,\mu\mathrm{g\,ml^{-1}}$, which is due to the fact that analyte atoms hardly occur in the cooler plasma zones. The linear range for axial viewing is lower than for radial viewing. The latter, in particular, is due to the somewhat longer optical pathway [27].

16.2.2.5 **Miniaturized ICPs**

While ICP-OES, as such, has reached maturity instrumentally, research now is being done with respect to the miniaturization of ICP-OES. This line of research is in the trend of the lab-on-a-chip approach. Of course, here one does not aim at robust plasma sources coping with a high variety of samples but to have sources with which well-defined tasks can be taken care of, online and in the field. Small ICPs with low power and gas consumption were developed along with other miniaturized sources, as reviewed by Karanassios [61] and is an ongoing line of research.

An ICP realized as μICP, for which the setup has planar load coils produced by photolithography and micromachining technology, was developed in the group of Hopwood (see Ref. [62]). Here, neither the load coil nor the matching network needed cooling and the device could be operated at low pressure (0.1–10 Torr) at a power of 4 W and with a frequency of 493 MHz. In the source (Figure 16.9),

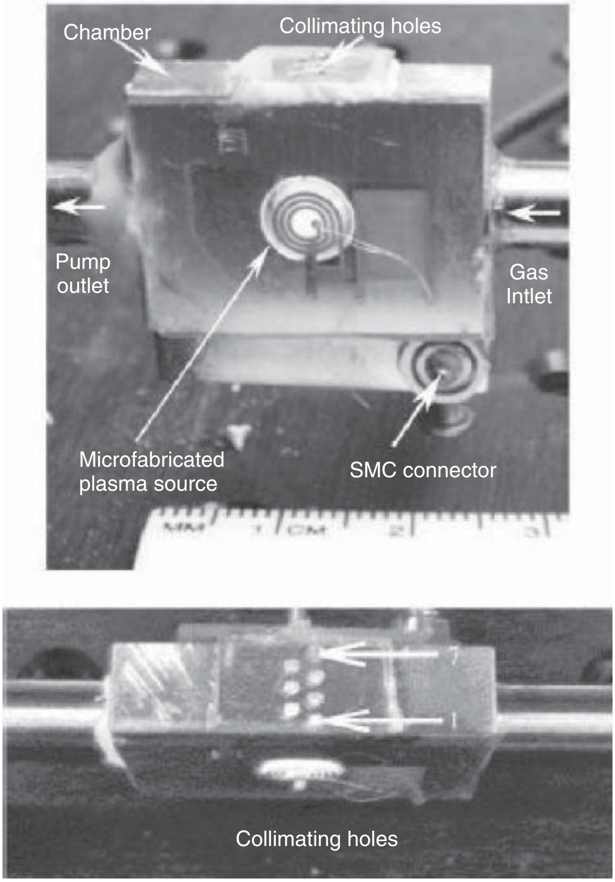

Figure 16.9 The microfabricated inductively coupled plasma-on-a-chip system is shown from the side and the top. The system includes a generator that is fabricated on a glass wafer and a miniature aluminum reaction chamber. (Reproduced with permission from Ref. [62].)

SO_2 could be detected in argon down to a concentration of 47 ppb using molecular bands (with the atomic S lines, the detection limits are four times higher). Thus, it was shown that the μICP could be of use for gas analysis. Even the ICP generator could be micromachined and its final dimensions reduced to 5 mm. Ichiki *et al.* [63] reported on an atmospheric pressure microplasma jet source exiting from a wafer. Here, the output power was 50 W at 144–146 MHz and the typical argon flow was $0.7\,\mathrm{l\,min^{-1}}$. Electron number densities on the order of $8 \times 10^{14}\,\mathrm{cm^{-3}}$ and excitation temperatures of 4000–5000 K were reported. With a miniaturized pneumatic nebulizer, in practice a capillary introduced directly into the discharge, a detection limit for sodium of $5\,\mathrm{\mu g\,ml^{-1}}$ was obtained, but no success could be achieved for other elements when introducing solutions. A number of other plasmas, especially microwave plasmas, were miniaturized and could be very well used in combination with gas-generating devices for spectrochemical analysis. Here, exemplarily, reference is to be made to the microwave strip plasma (MSP), designed by Engel *et al.* [64], which can also be used for the determination of volatile hydride-forming elements [65]. Further applications of the miniaturized sources certainly lie in their use for element-specific detection in gas chromatography.

16.2.3
Application Fields

ICP-OES is now a routine analytical method, which is of specific use when a large number of elements have to be determined in many samples. The latter can be solutions or dissolved solids. Therefore, in many cases, ICP-OES is complementary to AAS as the power of detection of furnace AAS cannot be rivaled for most elements. ICP-OES is of special interest in the analysis of geological samples, environmental analysis, clinical analysis, food analysis, metal analysis, chemical analysis, and for the certification of reference materials.

16.2.3.1 Geochemical Analysis

In the analysis of geological samples, sample dissolution with respect to not only nebulization but also to ionization interferences is important [15]. Indeed, in a number of cases, such as with carbonaceous minerals, a treatment with HCl will be sufficient; however, in a number of cases, it will be required to use strongly oxidizing acids. For samples with higher silicate contents, a treatment with HF even under the use of perchloric acid will be unavoidable. Here, fuming off will have to be performed carefully. Even fusion, for example, with sodiumtetraborate in a number of cases will be required, by which high amounts of alkali salts are entered into the sample solutions.

16.2.3.2 Environmental Analysis

The analysis of environmentally related samples is a major field of application of ICP-OES. On the basis of the early work of Garbarino and Taylor [66], a method has been proposed by the US EPA (Environmental Protection Agency) [67] and later on by DIN [68] for waste water analysis. The latter, standardized procedure describes the sample decomposition, the analytical range for 22 elements, and frequent interferences of ICP-OES in waste water analysis. For the analysis of natural waters, hydride generation [69], preconcentration based on liquid–liquid extraction of the dithiocarbamate complexes [70], adsorption of trace elements onto activated carbon [71], and also co-precipitation (e.g., with $In(OH)_2$)[72], and so on, have been reported; special emphasis has been given to online preconcentration as well [73]. For airborne aerosols, multielement determinations in large amounts of samples, collected with the aid of cascade impactors, allowing size-class differentiation can be performed by simultaneous ICP-OES subsequent to sample dissolution in HF/HNO_3 and complexation of the excess of HF with boric acid [74]. Here, many relevant elements, such as Ca, Mg, Fe, Ni, Pb, Cd, and so on, can be determined, which allows air pollution source appointment. The direct analysis of stack gases by

ICP-OES on the site has been investigated as well. However, the introduction of the air is difficult and therefore, other sources such as high-power microwave plasmas, which can be run on an air base, may be more suitable [75]. For the determination of heavy metals in soils, leaching under standardized conditions and analysis of the leachates by ICP-OES is a frequently applied procedure. In the case of fly ash, determinations of refractory elements are possible after decomposition of the samples by fusion or under the use of HF.

16.2.3.3 Analysis of Biological and Medical Samples

For the analysis of biological and medical samples, ICP-OES has some possibilities as well. In the clinical analysis, Ca, Fe, Cu, Mg, Na, and K can be determined directly even in microsized serum samples when calibrating with aqueous solutions of the elements to be determined, of which the viscosity has been adapted to one of the diluted serum samples (1 : 5) with Herrmann solution [76]. More elements can be determined in body fluids and tissues by the use of electrothermal evaporation of dry sample residues or by direct sample insertion; however, these techniques are not commercially available. For plant samples, sample drying and dissolution of the samples with oxidizing acids also allows the determination of a number of metals by ICP-OES. Furthermore, the power of detection of ICP-OES is too low for most of the analytical problems encountered in life sciences.

16.2.3.4 Analysis of Chemicals

This generally also applies to the analysis of high-purity chemicals. Therefore, however, online analysis of process fluids by ICP-OES is well possible and applied in the chemical industry.

16.2.3.5 Metals Analysis

Metals analysis, in particular, should be mentioned in the field of industrial products for which ICP-OES is of great use. It is used both in the ferrous industry and in the analysis of copper and aluminum samples. Also, for the analysis of by-products in the metal industry such as slags, the use of ICP-OES subsequent to fusion is useful. In the case of the metal bases, ICP-OES subsequent to acid dissolution of the samples is used for the characterization of laboratory samples, which are used for calibration of direct solids analysis methods such as XRF and spark OES. Apart from solution analysis, direct metals analysis by spark ablation is also useful [77]. This also applies for the use of a rotating laser sampling technique such as the LINA Spark coupled to ICP-OES, with which for a number of elements in different matrices low detection limits and linear calibration curves can be obtained [78].

In addition, the analysis of refractory powders by slurry nebulization for Al_2O_3 [79], SiC [80], and ZrO_2 [81] powder samples is to be mentioned. Here, a Babington nebulizer is used and calibration is done by adding aqueous solutions to slurries prepared from the powders. The results for sufficiently fine powders were found to be in good agreement with those of analyses subsequent to established sample decomposition methods, including the use of decomposition at high pressure with acids in autoclaves as well as under the use of microwave-assisted dissolution [79].

16.3
ICP Mass Spectrometry

Towards the end of the 1970s the ICP, which then was commercially available from a number of manufacturers in combination with different types of optical emission spectrometers, was first used as an ion source for quadrupole mass spectrometry by Houk in AMES Laboratory, and at the same time experiments were done by Gray *et al*. in the United Kingdom. The experimental realization of ICP-MS and its figures of merit were first described in a common paper in 1980 [8] and soon the approach became commercially available (for an in-depth treatment, see Ref. [82]).

16.3.1
Instrumentation

ICP-MS makes use of the ICP in the form it has been used for ICP-OES in a first approximation. The source, in all currently used instrumentation, is positioned horizontally and the ions are sampled from the plasma with the aid of a so-called sampler. This is a cone-shaped interface with an aperture of about 600 μm, which is water cooled. It separates the plasma, which is operated at atmospheric pressure, from the intermediate vacuum, which is realized with the aid of a powerful rotary oil pump. In the so-called interface region, a supersonic beam is formed and a number of collision processes take place as well as an adiabatic expansion. From this beam, ions are sampled into the vacuum of the mass spectrometer through a second aperture, named *skimmer*, which has a hole with a diameter similar to that of the sampler. The sampler and the skimmer are usually made of stainless steel and are both conically shaped with different cone angles. The sampler can also be made of copper, which has a better heat conductivity. In the case of HF-containing solutions, platinum cones can also be used. The distance between the sampler and the skimmer is critical with respect to maximum power of detection and minimal ionization interferences. This also applies to the power transmission to the RF coil, where considerable differences were found for coils powered centrally and coils powered at one of the ends [83]. The vacuum in the mass spectrometer itself is at the order of 10^{-5} mbar and is realized with the aid of turbomolecular pumps. The vacuum in the interface is monitored often with a capacitance pressure gauge, whereas in the mass spectrometer it is monitored with the aid of a Penning gauge.

16.3.1.1 Mass Spectrometers

Present day commercial instrumentation falls into three groups, namely, quadrupole-based instruments, high-resolution instruments, and time-of-flight instruments.

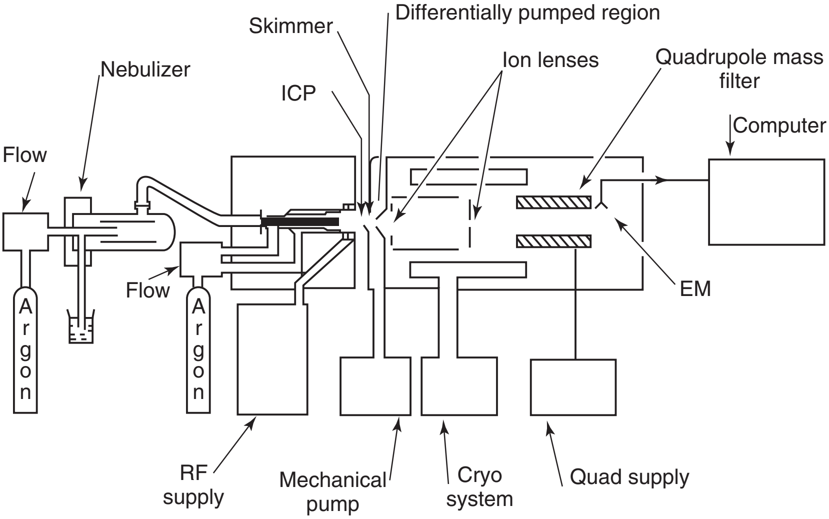

Figure 16.10 Instrumentation for quadrupole-based ICP-MS: (a) nebulizer, (b) sampler, (c) ion optics, (d) quadrupole, (e) electronics, (f) detector, (g) RF generator, (h) roughing pump, (i) turbomolecular pump, and (j) quadrupole RF generator. (Reprinted with permission from Ref. [2].)

In a *quadrupole-based* instrument, the spectrometer principally consists of four equidistant and parallel mounted rods (diameter: 10–12 mm) between which a DC voltage and in addition a high-frequency field (frequency up to 1 MHz) or $U + V.\cos(\omega t)$ is provided (Figure 16.10). By varying the alternating electrical field, ions with different m/z can leave the analyzer sequentially and scanning becomes possible. Ions within a narrow m/z range have a zone for stable oscillation at a well-defined DC voltage and a high-frequency field. Accordingly, ions of a certain mass can be filtered out by manual setting of the field or the spectrum can be scanned. The scanning velocity is normally limited to 30 000 Da s^{-1} as a result of the high frequency and the DC components used in a spectrometer. Thus, a mass interval of 0–300 Da can be scanned in about 30 ms. The mass resolution in the best case is about 1 Da. Spectral interferences occur as a result of line broadening, the isotopic abundances, and the occurrence of cluster ions. Quadrupole ICP-MS systems are rapid sequential measurement systems. Accordingly, the precision obtainable and the figures of merit of isotopic dilution techniques for calibration are limited by the noise occurring in the source. Therefore, the price of quadrupole instruments is reasonable and the transmission is high.

Magnetic mass analyzers make use of a curved flight tube located between the poles of an electromagnet, so that the field is perpendicular to the flight direction of the ions. The ions first pass through an electrical field and then enter a magnetic field where mass selection takes place. The electrical field is used to extract the ions, which then enter the magnetic field and start to follow a curved trajectory on which they are held by a centrifugal force. The radius of the curved trajectory depends on

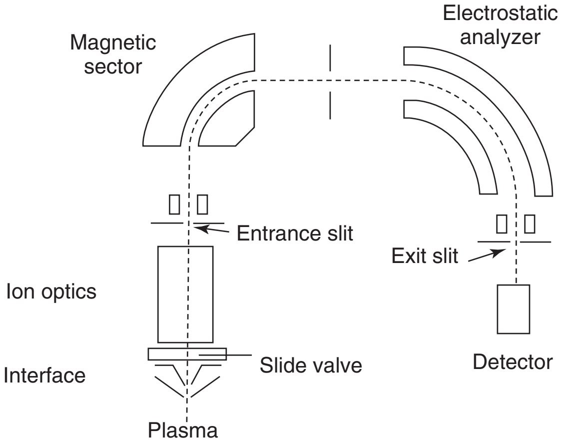

Figure 16.11 High-resolution ICP mass spectrometer. (Reprinted with permission from Ref. [85].)

m/z and the magnetic field. By sweeping the field, it is possible to scan the mass spectrum at an exit slit. As ions with different masses are deflected toward different locations in the focal plane, simultaneous detection of ions is thus possible with these spectrometers, provided that multichannel detection is applied. As the energy spread of the ion beam limits the resolving power of a deflecting magnetic sector mass analyzer, energy focusing must be applied. This can be done by providing an electrostatic analyzer in the ion optics. This electrostatic analyzer consists of two curved plates with a voltage on the order of 1.5 to 1 kV applied between them. When bringing the magnetic sector and the electrostatic sector together (Figure 16.11), a double-focusing instrument is obtained, where ions are selected by mass only and where the ion energy of the particles does not play a role. The use of a sector field mass spectrometer requires the source or the whole spectrometer to be brought at a high voltage, so as to realize a sufficient extraction yield. With sector field instruments, the resolution can easily be improved to below 0.1 Da (resolving power often up to 5000), enabling a number of spectral interferences in plasma mass spectrometry to be eliminated. The scanning speed cannot be increased in an unlimited manner, as hysteresis may hamper this. When the signals are transient and multielement detection is required, there are certainly limitations here. As the spectral background intensities are low, detection limits are lower than in quadrupole mass spectrometers, not only as a result of the absence of a number of spectral interferences but also because of better signal-to-background ratios [84].

The *time-of-flight mass spectrometer* is based on the detection of ions produced from a single well-defined event with high time resolution. The ions get an initial energy by passing an electrical field and then drift in a field-free region according to their mass. The principle is well known and has long been applied, for example, in secondary ion mass spectrometry (SIMS) [86]. As the velocity obtained by ions of a mass m in a field U is given by $1.4 \times 10^4 \sqrt{\left(\frac{U}{m}\right)}$ [87], the insertion of ions

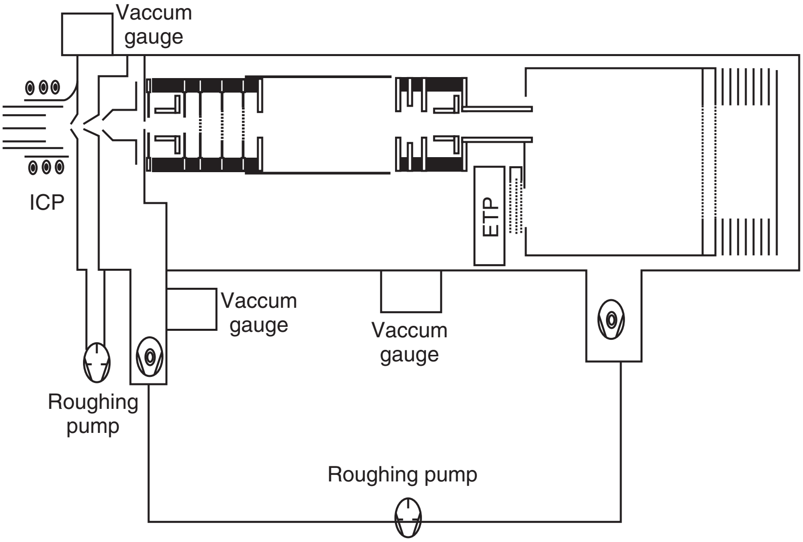

Figure 16.12 On-axis ICP time-of-flight mass spectrometer. (Courtesy of Leco Corporation, St. Joseph, MI (USA).)

of 50 Da in an electrostatic field of 5000 V results in a velocity of 1.4×10^5 m s^{-1}. Hence, for a flight tube with a length of 1.4 m one obtains, neglecting the time required to accelerate the ions, a flight time of 10^{-5} s. With modern electronics, one can differentiate very short times and thus obtain a mass resolving power of 2000. With this type of instrumentation, high transmission can be achieved and high mass resolution as well as high multiisotope capacity also for transient signals (see Ref. [88]). For time-of-flight ICP-MS, both orthogonal as well as linear end-on arrangements are used. The instruments commercially available use a reflectron to double the flight path (Figure 16.12) [89]. Now, *multicollector magnetic mass analyzers* are also used. They are particularly useful when a highly accurate recording of ratios of ion currents for different isotopes is required.A double-focusing instrument with a stigmatic focusing magnet and several individual detectors placed in the focal plane can be used to achieve such a system [90]. As in ICP-MS, isotope dilution is important for tracer work as well as for highly accurate calibration, these systems may gain considerable importance.

16.3.1.2 **Ion Detection**

As in ICP-MS ion currents between 10^{-20} and 10^{-9} A have to be measured, several detectors must be used. For a precise ion detection and relatively low signals ($<10^6$ ions s^{-1}), ion electron multipliers and pulse counting, as a rule, are used, whereas for higher ranges analog detection is used. In an ion counting device (Figure 16.13), the ions entering the analyzer are directed to a suitable surface held at high potential, so that the incident ions release several electrons. The surface may consist of a continuous dynode, the curvature of which guides the electrons, which

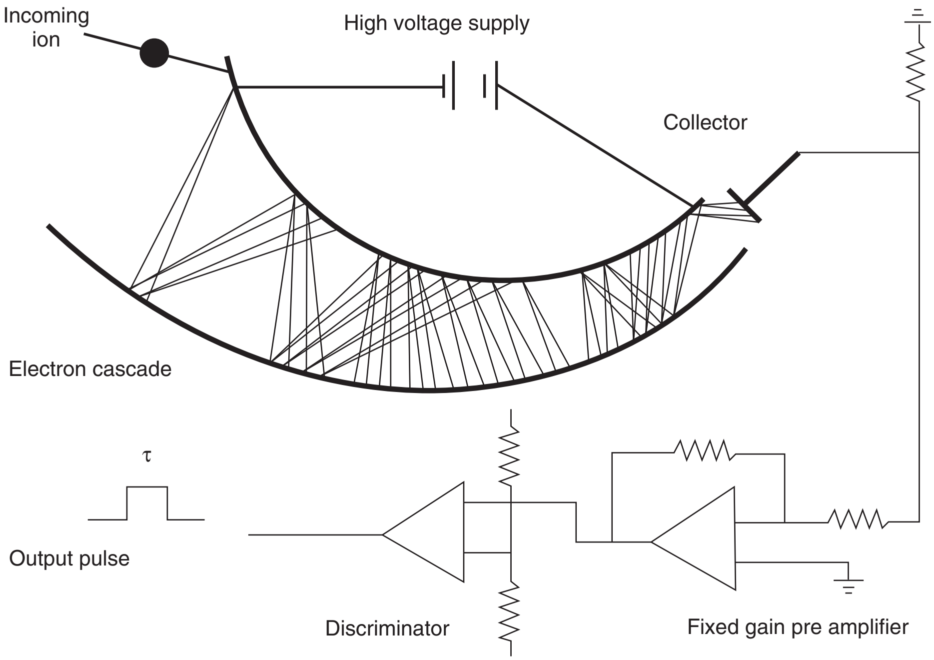

Figure 16.13 Continuous dynode electron multiplier. (Reprinted with permission from Ref. [94].)

increase in number at each interaction with the dynode surface. These detectors have a dead time, as the interaction of an ion takes a finite time (usually less than 10 ns), during which the detector is blind to the next ion. Accordingly, count rates beyond 1 MHz corrections are required, but damage to the detector may also occur. Further problems are related to the fact that the mass and ionization potential of the respective elements may influence the number of electrons released by the impact, which introduces bias, and, in addition, when high masses impact on a dynode, the lifetime of a diode may decrease considerably. Therefore, the ion current can be deflected onto a conversion dynode, which is more robust and is at a high negative potential for the ion impact, and the current carried by electrons then enters the dynode system. For the registration of larger signals, the voltage applied at the electron multiplier can be decreased and then a current is obtained, which in the case of ion currents above 10^6 ions s^{-1} is directly proportional to the input current. Another solution is the use of a so-called Faraday collector (Figure 16.14). With this system, currents of down to 10^{-15} A (10^4 ions s^{-1}) can be measured, corresponding to the upper range accessible with ion counting. The variable feedback resistor allows the measurement range to be adjusted and voltage-to-frequency conversion is applied for read-out. Faraday collectors have low mass bias and are robust but small. Through the use of novel microstructuring techniques, integrated multicollector array detectors for ions have also been realized. The most

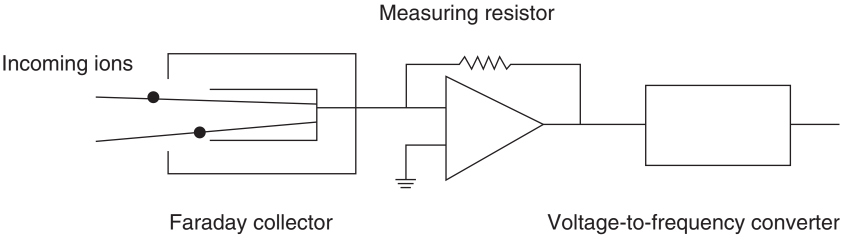

Figure 16.14 DC analog detector for mass spectrometry. (Reprinted with permission from Ref. [94].)

advantageous ion detectors are basically arrays of micro-Faraday cups. The charge-integrating detector, as described by Giffin *et al.* [91], responds to both positive and negative ions and also allows nondestructive read-outs. On top of each pixel of the charge-transfer detector, an island of electrically isolated conductive material is deposited. Each of the islands serves as a Faraday cup for the pixel below it. The conductive material responds to the incoming ion flux by supplying a neutralizing electron derived from the semiconductor band material beneath it. Each Faraday cup has its own low-capacitance integrator with a multiplexed read-out. In addition, each integrator can be read out nondestructively, which leads to an improved signal-to-noise ratio. The use of such a detector with a limited number of Faraday cups (128 strips of each 45 μm wide and set on 50 μm centers) [92] was described and with similar arrangements in the case of ICP-MS a relative precision for Ag isotope signals of 0.007% obtained [93].

16.3.1.3 **Ion Extraction and Optics**

For ion extraction in ICP-MS, Turner *et al.* [94] formulated the following requirements for the interface:

1) The pressure in the interface should be sufficiently low as to minimize chemical reactions.
2) The diameter of the sampling aperture should be as large as possible to maximize the analyte signal and to minimize orifice clogging, while keeping the pumps used for this section to a reasonable prize.
3) To sample the plasma in as undisturbed a state as possible, the diameter of the sampling orifice must be large compared with the Debye length in the plasma, which is a measure of the distance of the electrical field of an ion as ‘‘seen’’ by an electron, and is given by

$$\lambda_D = 6.9\sqrt{(T_e \cdot N_e)} \tag{16.66}$$

   Here, N_e is the electron number density and T_e is the electron temperature.
4) The gas flow through the sampler should not exceed the whole gas flow in the plasma, as only well-defined zones of the plasma (namely, those with the highest analyte concentrations) should be sampled.
5) Behind the sampler a concentric shock wave structure is formed, which surrounds a zone of silence and ends in a shock wave front called the *Mach*

disc. The interface should be such that the skimmer aperture still lies in the zone of silence for the optimal extraction.

In the case of the ICP a cooled sampler is used. Owing to the large pressure difference between the ICP and the first vacuum stage, the ions enter the interface with high energy. There is also a considerable adiabatic expansion of the plasma in the interface. This jet expansion is critical with respect to the analytical performance. Behind the skimmer the mutual repulsion of ions within the ion beam, known as *space charge effects*, also influence the ion trajectories. The magnitude of this effect depends on the total radial voltage drop (E_i), the current density (j), the total current (I), and the velocity (v) and is given by

$$\Delta\varphi = \int_0^a E_r \cdot \mathrm{d}r = \int_0^a \left[2 \cdot \pi j \cdot \left(\frac{r}{v}\right)\right] \mathrm{d}r = (9 \times 10^{11})\frac{I}{v} \tag{16.67}$$

Here, $v = 2.5 \times 10^5\,\mathrm{cm\,s^{-1}}$ and $\mathrm{I} = 10^{-6}\,\mathrm{A}$, $\Delta\varphi = 3.6\,\mathrm{V}$. With a field such as this, ions will move away from the beam axis and this movement is mass dependent and has to be corrected for with the aid of suitable ion optics. A cylindrically symmetric lens is used to transfer the ions sampled through the skimmer to an analyzer. To reduce the noise level, a metallic disk denoted as the ‘‘photon stop’’ is often placed in the center of the so-called Bessel box. Thus, radiation coming from the plasma sampled as it enters through the axially centered sampler and skimmer can be eliminated. Furthermore, the voltage at the lens is optimized so as to obtain as low a background (stemming from radiation and neutrals) as possible without decreasing the sensitivity. Alternatively, the mass spectrometer and/or the detector can be placed off-axis. A series of various lenses at different voltages is usually provided so as to direct the analyte ions as efficiently as possible into the analyzer. Often, three so-called Einzel lenses at negative potentials relative to the skimmer (varying from around −10 to −150 V) are used. The voltages applied determine the trajectories of the ions, which, however, also depend on their kinetic energies. The latter are element dependent and also relate to the zones in the ICP zones sampled. Computer programs, such as MacSimion (see Ref. [95]) and its more recent equivalents can be used to model the ion trajectories in ion optics after various assumptions. From these considerations, it becomes clear that in multielement determinations compromises must be made and that the analytical figures of merit at compromise conditions considerably can differ from those of single-element optimization.

16.3.2
Figures of Merit

The analytical features of ICP-MS are related to the production of ions in analytical ICPs as well as to the highly sensitive ion detection and the nature of the mass spectra themselves.

16.3.2.1 ICP Mass Spectra

In low-resolution ICP-MS, the resolution in the spectra at best is 1 Da and cluster ions are found, particularly in the low mass range, which in a number of cases cause spectral interferences with singly charged analyte ions, stemming from the analyte atoms for which the ionization degree is between 10^{-5}% (for Cl) and 9% (Ba). Cluster ions may be formed from different types of compounds, namely:

- solvents and acids: H^+, OH^+, H_2O^+, … , NO^+, NO^{2+}, … , Cl^+, … , SO^+, $SO_2{}^+$, SO_3H^+ (when residual H_2SO_4 is present in the measurement solution);
- radicals of gases in the surrounding atmosphere: $O_2{}^+$, CO^+, $CO_2{}^+$, $N_2{}^+$, NH^+, NO^+, …;
- reaction products of the above-mentioned species with argon: ArO^+, $ArOH^+$, … , $ArCl^+$, $Ar_2{}^+$, …

These cluster ions give strong signals in the mass range up to 80 Da and may hamper the determination of the light elements as a result of spectral interferences. At higher masses, the singly charged ions of the heavier elements are found, as are doubly charged ions of the light elements. They occur particularly for elements with low ionization energies.

In the mass spectra, signals for compounds of the analyte with various other species also occur, such as MO^+, MCl^+, MOH^+, $MOH_2{}^+$, …. These ions may be formed by the dissociation of nitrates, sulfates, or phosphates in the plasma or they may result from reactions between analyte ions and solvent residuals or oxygen in the plasma or eventually in the interface between the plasma and the mass spectrometer inlet.

In early work it was already recognized that the selection of the sampling zone in the plasma and the aerosol carrier-gas flow may strongly influence the occurrence of cluster ions and doubly charged analyte ions [85, 96]. This is clearly demonstrated by the results for lanthanum, where doubly and even triply charged ions may be expected in the argon plasma. This necessitates specific optimization of the power and especially of the carrier-gas flow, which influence both temperature and residence times of the sampled substance in the plasma. This is documented for the intensities of the signals for the ArO^+ and Cu^+ ions in Figure 16.15 [83]. Signals of all isotopes of the elements present in the sample are obtained. Their intensity ratios correspond to the isotopic abundances in the sample. Use can be made of this fact for calibration by isotopic dilution with stable isotopes and in tracer experiments. The isotopic abundances of the elements, however, are also useful for the recognition of spectral interferences. The spectra in ICP-MS are less line rich than in ICP-OES. With quadrupole mass spectrometers, however, the resolving power of the spectrometers is also lower than in ICP-OES. Accordingly, cluster ions will often cause spectral interferences, and appropriate correction procedures must be worked out. With high-resolution sector field instruments, which have a resolution of 5000 and more, a number of these interferences will not occur. This is shown by calculations of the minimum resolution that should be obtained so as to avoid the most frequent interferences occurring in ICP-MS (Table 16.1) [84]. In ICP-MS, the background intensities, mainly due to the dark current of the detector

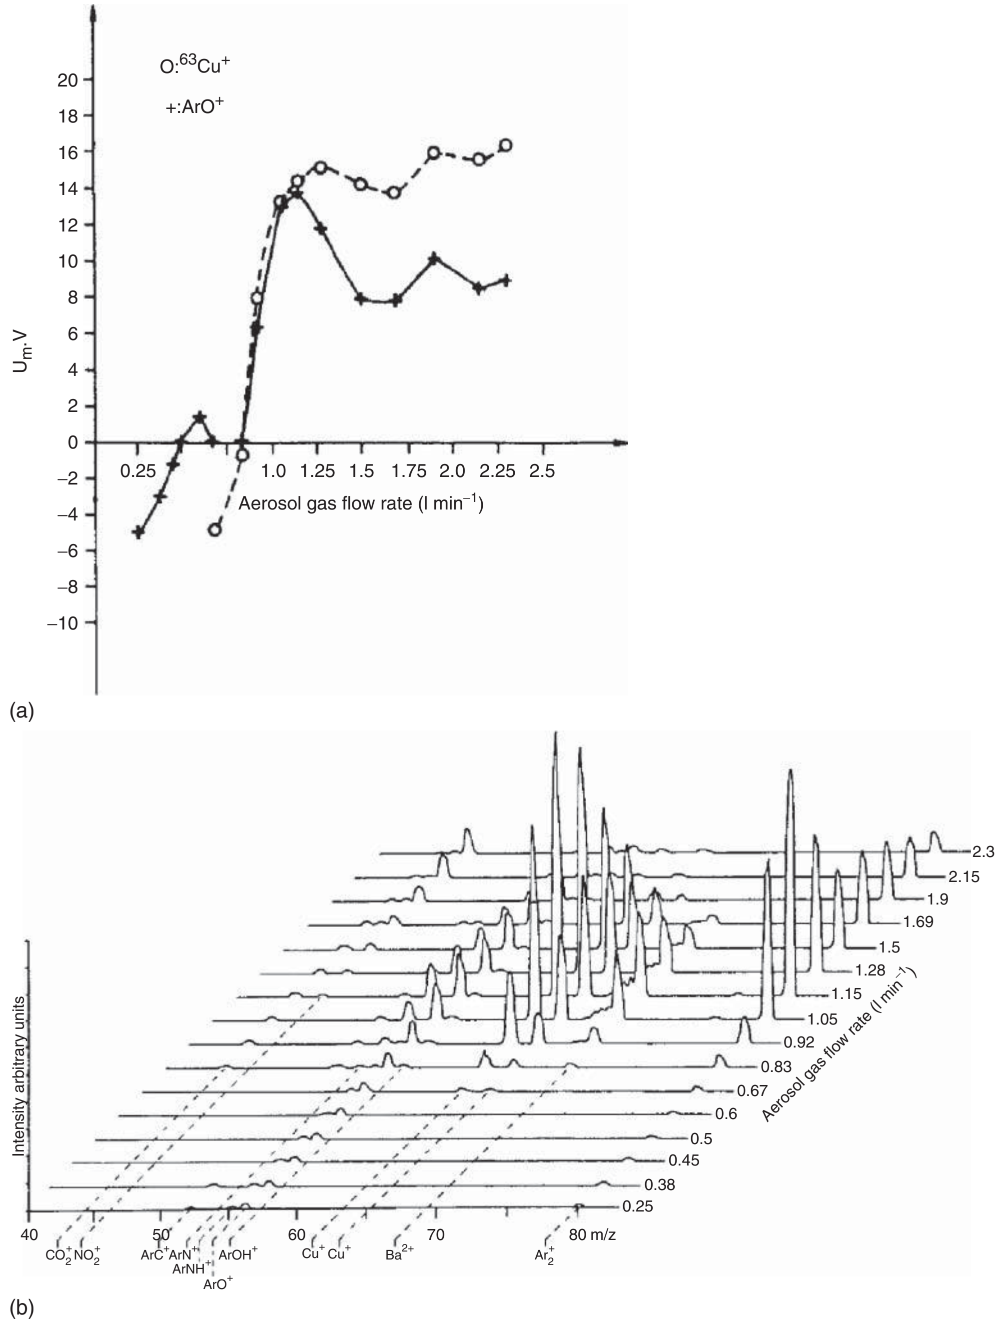

Figure 16.15 Maximum values of ion energies for two ion species (a) and mass spectra in the mass region 42–82 Da in ICP-MS (b) when sampling ions at different gas flow rates for a 1 μg ml^{-1} standard solution of Cu at radial distance 0 mm and 1.5 kW. (Reprinted with permission from Ref. [83].)

Table 16.1 Minimum required resolving power (*R*) in order to avoid spectral interferences in ICP-MS.

Isotope	Polyatomic ion	*R* required
^{27}Al	$^{12}C^{15}N$, $^{13}C^{14}N^+$, $^{12}C^{14}N^1H^+$	1454
^{51}V	$^{35}Cl^{16}O^+$	2572
^{52}Cr	$^{40}Ar^{12}C^+$	2375
	$^{35}Cl^{16}O^1H^+$	1671
^{53}Mn	$^{39}K^{16}O^+$	2670
	$^{37}Cl^{18}O^+$	2034
^{56}Fe	$^{40}Ar^{16}O^+$	2502
	$^{40}Ca^{16}O^+$	2479
^{60}Ni	$^{44}Ca^{16}O^+$	3057
	$^{23}Na^{37}Cl^+$	2409
^{63}Cu	$^{40}Ar^{23}Na^+$	2790
	$^{31}P^{16}O_2{}^+$	1851
^{64}Zn	$^{32}S^{16}O_2{}^+$	1951
^{75}As	$^{40}Ar^{35}Cl^+$	7775
^{77}Se	$^{40}Ar^{37}Cl^+$	9191

(Extracted from Ref. [84]).

and signals produced by ions scattered inside the mass spectrometer as a result of collisions with residual gas species or reflection, is generally low in contrast to ICP-OES.

16.3.2.2 **Optimization**

For the optimization of ICP-MS with respect to the highest power of detection, minimal spectral interferences and signal enhancements or depressions, as well as highest precision, the most important parameters are the power of the ICP, its gas flows (especially the nebulizer gas flow), the burner geometry, and the position of the samples, as well as the ion optics parameters. These parameters determine the ion yield and the transmission and accordingly also the intensities of the analyte and interference signals. At increasing nebulizer gas flow, the droplet size decreases; thus, the analyte introduction efficiency goes up, however, at the expense of the residence time in the plasma, the plasma temperature, and also of the ionization. The optimization of the carrier-gas flow, the ion sampling location, and the power also is more critical than in ICP-OES. This is due to the small sampling area. Furthermore, changes in the nebulizer gas flow also influence the formation and breakdown of cluster ions, requiring optimization with respect to minimum spectral interferences as well. The carrier gas flows also influence the ion energies and the geometry of the aerosol channel. Normally, it is between 0.5 and $1\,\mathrm{l\,min^{-1}}$. It must be optimized together with the power, which influences the plasma volume and thereby the kinetics of the processes taking place, and the position of the sampler. By changing the voltages at the different ion lenses, the transmission for a given ion can be optimized, enabling the optimization of the detection limits and the minimization of interferences. In multielement determinations, a compromise must always be made. For the easily ionized elements, working at so-called cool plasma conditions has been shown to be very successful. From the calculation of the degrees of ionization, it can be seen that mainly singly ionized species are formed instead of multiply ionized species (see detection limits listed in Ref. [84]). For Na, K, Ca, and Al, detection limits in the sub-parts per trillion range then become achievable.

16.3.2.3 Power of Detection

The lowest detection limits generally are obtained at a power between 0.6 and 2 kW and the sampler at about 10–15 mm above the tip of the injector. In general, it can be said that for the heavy elements the detection limits in ICP-MS are much lower than those in ICP-OES (Table 16.2) [2]. For most elements they are similar, except for the elements for which spectral interferences are a limiting factor. This

Table 16.2 Detection limits in ICP-OES and ICP-MS.

Element	**Detection limit**		
	ICP-OES (ng ml^{-1}) [97]	**ICP-MS (ng ml^{-1}) [98]**	**High-resolution ICP-MS (ng ml^{-1}) [84]**

applies to As ($^{75}As^+$ with $^{40}Ar^{35}Cl^+$), Se ($^{80}Se^+$ with $^{40}Ar^{40}Ar^+$), and Fe ($^{56}Fe^+$ with $^{40}Ar^{16}O^+$). The detection limits for elements with high ionization potential are usually very low because of the limited formation of positive ions.

The acids present in the measurement solution and the material of which the sampler is made (Ni, Cu, . . .) may influence the occurrence of spectral interferences considerably and accordingly the detection limits for a number of elements. This is particularly important when analyzing solids after dissolution by treatment with acids. Here, the measurement solution should not contain chlorine, phosphate, or sulfate ions. If it does, it is advantageous to remove these by precipitation or fuming off and taking up the analytes in dilute nitric acid. The detection limits for ICP-MS in the case of solids suffer from the necessary sample dilution, as the concentration of the sample in the measurement solution often is limited to $500\,\mu g\,ml^{-1}$ and is in contrast to ICP-OES where sample concentrations in the measurement solutions of 5 or even $50\,mg\,ml^{-1}$ often are possible. This is due to the risks in blocking the sampler. For elements such as B, Mg, Fe, and so on, the detection limits in solids in the case of ICP-OES thus may even become lower than in ICP-MS.

The detection limits obtained also depend on the type of mass spectrometer used. With quadrupole mass spectrometers, they are higher than in the case of high-resolution mass spectrometers. This applies particularly for strongly interfered elements such as Fe. With time-of-flight mass spectrometry, the detection limits in the case of the light elements were found to be one order of magnitude lower than in quadrupole-based ICP-MS. However, for the heavy elements, they are up to a factor of 5 worse [99].

16.3.2.4 Precision and Memory Effects

The constancy of the nebulizer gas flow is of prime importance for the precision achievable in ICP-MS. After stabilizing the nebulizer gas flows, relative standard deviations can be below 1%. They can be improved still further by internal standardization [100]. The tolerable salt contents (often below $500\,\mu g\,ml^{-1}$) are much lower than in ICP-OES, because of the risks of sampler clogging, and depend on the respective salts. The memory effects may become limiting, and in the case of a high matrix load rinsing times of 1–2 min are required.

A considerable portion of the noise originates from the nebulizer and the noise can generally be decreased by cooling the spray chamber. The latter is shown to decrease the white noise somewhat as well as some $1/f$ contributions and also the standard deviations for the blanks [101]. This directly leads to an improvement in the detection limits.

16.3.2.5 Interferences

Signal enhancements and depressions resulting from the matrix relate to the nebulization, influences on the ionization in the ICP, and to changes in the plasma geometry as well as in the ion energies. Changes in the nebulizer gas flow influence the nebulization effects (see Section 16.2.2.3); however, they also induce changes in the aerosol channel geometry and the plasma temperature and hence also the interferences of easily ionized elements [102]. Space charge effects have also been shown to play an important role in the suppression of signals as a result of alkali metals [103]. Up to a certain amount, these effects can be adequately corrected for by using an internal standard, the selection of which is only possible empirically. However, it is a guideline that elements with similar masses and ionization potentials should be chosen. Thus, it is often advisable to select more internal standards to cover elements in the whole analytical mass range, such as Sc for the low mass elements and Rh for the heavier elements. The use of internal standards was shown in early work to be successful for serum samples [100]. The matrix effects can be eliminated to such a degree that calibration with aqueous solutions in the case of diluted serum samples becomes possible.

In mass spectrometry, signals are obtained for each isotope present. With the low mass resolution of quadrupole mass spectrometers ($\approx$1 Da), this leads to a number of isobaric interferences, which can be corrected for with appropriate software. This type of interference depends only slightly on the working conditions, which is not the case for spectral interferences resulting from doubly charged ions, background species, or cluster ions. The background species at low masses [104] cause considerable spectral interferences, for example, for $^{28}Si^+$ (with $^{14}N^{14}N^+$), $^{31}P^+$ (with$^{16}N^{16}OH^+$), $^{80}Se^+$ (with $^{40}Ar^{40}Ar^+$), and so on. Species such as $^{40}Ar^{16}O^+$ not only interfere with $^{56}Fe^+$ but, due to all isotopic combinations and any hydrides present, also with other transition metal isotopes (^{52}Cr, ^{53}Cr, ^{54}Cr, ^{54}Fe, ^{55}Mn, ^{56}Fe, ^{57}Fe, ^{58}Ni, and ^{59}Co). In the case of HCl, additional interferences for further transitional metal isotopes will result from Cl^+, ClO^+, ClN^+, and $ArCl^+$ species. Under fixed working conditions, these interferences do not change very much with the matrix composition and can be corrected for by subtraction. However, they limit the power of detection. The interaction of signals from doubly charged ions and cluster ions change considerably with the power, the sampler position, and the nebulizer gas flow. These interferences are particularly important for elements that have relatively low ionization potentials or that form thermally stable oxides (e.g., Ba, Sr, Mg, Ti). This has been shown by measurements of the signals of singly charged (M^+) and doubly charged (M^{2+}) ions, as well as of metal oxides (MO^+) and hydroxides (MOH^+), for example, in the case of Ba [96, 105].

Considerable progress with respect to the elimination of spectral interferences in quadrupole mass spectrometry has been possible through the use of *collision- and reaction-induced dissociation of cluster species*. This approach goes back to the research of Douglas and French [106] and Barinaga *et al.* [107]. The theoretical aspects of collision- and direct-reaction cells, including the use of multipole devices have been treated in detail by Tanner *et al.* [108]. Ion-molecule reactions are of importance in decreasing the occurrence of polyatomic species in elemental mass spectrometry in two ways:

- *Collision-induced dissociation*: a transfer of energy from monoenergetic species such as He, Xe, and so on, during inelastic collisions results in an excitation of polyatomics, which may result in their subsequent dissociation. Here, purely mechanistic considerations are helpful to select appropriate gases for selected polyatomic species.

- *Reaction-induced dissociation*: through the chemical reaction of small molecules with the polyatomic species, unstable intermediates that subsequently dissociate may be formed. Here, thermodynamic considerations have been shown to be very helpful in predicting, or at least explaining, the effectiveness of gases with respect to the dissociation of polyatomic species.

Both types of process depend on the collision frequencies and hence on the pressure. The latter enhances the residence times of the polyatomic species in the collision or the reaction cell, respectively. The two principles have been realized in commercial ICP-MS instruments available from Agilent, Micromass, Perkin Elmer, Thermo, and Varian. It is possible to use several collision or reaction gases at different pressures and a lot of data are available on the effectiveness of the partial or complete removal of a number of potential interferents.

H_2 has been shown to be effective in the removal of polyatomics such as ArO^+ and ArH^+ for Fe and Ca, respectively, in work with dry aerosols as is the case in laser ablation ICP-MS [109]. This also is the case for Ne and CH_4 [110, 111]. He was also found to be of use for the dissociation of ArO^+ and $Ar_2{}^+$, interfering in the determination of Se and its species [112]. As shown for a hexapole cell, the ion energies are also relevant to the effectiveness of the according processes [113]. Much work has been done with NH_3 as the cell gas as well. Tanner *et al.* [114] proposed its use in a quadrupole reaction cell. Ben-Younes *et al.* [115] showed that it was useful for the removal of carbon-based interferents for the Si isotopes in ETV-ICP-MS, whereas Liu and Jiang [116] showed that NH_3 is effective in the reduction of interferences from $^{12}C^{16}O^+$ and $^{14}N_2{}^+$ for Si in steel. The use of O_2 was found to reduce the interferences of Hf, Ce, Ta, and Nb in noble metal determinations as a result of the formation of their oxides [117]. Pröfrock *et al.* [118, 119] showed that the use of Xe and an octopole cell may be effective in decreasing the interference signals for Cd, Cu, Zn, and S in the determination of metalloproteins by HPLC coupled to ICP-MS.

Further, the use of ion traps filled with He or Ne was mentioned to be effective in the removal of biatomic interferents such as GdO [120, 121].

16.3.2.6 **Isotope Dilution Analysis**

Dilution with stable isotopes not only offers the possibility of performing tracer experiments but also of circumventing systematic errors. The principle [122] can be applied to every element that has at least two stable or long-life isotopes. For its application, the analyte with a known isotopic composition but which differs from that of the sample is added to a known amount of sample, and mixed thoroughly. The isotopic abundance ratio then is given by

$$R = \frac{[N_S \cdot h_S(1) + N_A \cdot h_A(1)]}{N_S \cdot h_S(2) + N_A(2)} \tag{16.68}$$

N_S is the number of atoms of the element to be determined in the sample and N_A the number of atoms in the amount of standard added; h_S and h_A are the abundances of the isotopes (1) and (2) in the sample and the added standard. Thus,

N_S or the absolute mass G_S is given by

$$G_S = G_A \cdot \frac{[h_A(1) - R \cdot h_A(2)]}{[R \cdot h_S(2) - h_S(1)]} \tag{16.69}$$

R results from the signals for the isotopes; $h_S(1)$ and $h_S(2)$ as a rule are the natural abundances. G_A is the absolute amount of standard added, $h_A(1)$ and $h_A(2)$ are known from the isotopic composition. Isotope dilution in ICP-MS has been applied in studies on Pb (see, e.g., Ref. [123]). Tracer experiments for Fe in biological systems (see, e.g., Ref. [124]) have also been described. The precision achievable in the determination of isotope ratios for abundances that differ by a factor of less than 10 is in the lower percentage range.

For the determination of isotope ratios, the precision of TOF-ICP-MS has been studied and compared to the one obtained with other mass spectrometer systems. In a preliminary study already, typical isotope ratio precisions of 0.05% were obtained, thus overtaking sector field mass spectrometry with sequential detection, for which values of 0.1–0.3% for ^{63}Cu/^{65}Cu in Antarctic snow samples have been reported [125]. Similar results were obtained by Becker and Dietze [126] for Mg and Ca in biological samples (0.4–0.5 %). In principle, the features of TOF-ICP-MS may be superior to those of sequential sector field or quadrupole mass spectrometry; however, true parallel detection of the signals, as is possible with multicollector systems is more powerful, as shown by Hirata and Yamaguchi [90]. In fact, mass spectrometers with array detectors, as described by Schilling *et al.* [127] and investigated in detail in the Hieftje group, might be the perfect answer for isotope ratio measurements, as true parallel measurements of the signals within the relevant mass range, just as with CCDs for optical atomic emission spectrometry, are possible. Such systems allow it to obtain the full precision as the ratio signals are measured simultaneously and the impact of the noise of different signals, which is partially correlated here, can be canceled out. Indeed, in the case of the Ag isotopes, isotope ratio measurements with a precision of down to 0.015% have already been reported.

16.3.3
Alternative Methods for Sample Introduction

Apart from continuous pneumatic nebulization, all sample introduction techniques known from ICP-OES have been used and are of use for ICP-MS. In a number of cases, the advantages and limitations as compared to ICP-OES are quite different.

Similar to the situation with ICP-OES, the analysis of organic solutions is possible but somewhat more difficult [128]. The addition of oxygen was found to be helpful when nebulizing effluents from HPLC-containing organic eluents such as acetonitrile. This was useful when employing ICP-MS for online detection in speciation as well as in trace-matrix separations. Here, however, it is useful to use desolvation, even in the case of low-consumption, high-efficiency nebulizers, such as HEN or DIHEN. This can be done efficiently with membrane desolvation using Nafion membranes.

The use of ultrasonic nebulization just as in the case of ICP-OES allows the sampling efficiency to be increased. High water loading of the plasma has to be avoided, as is possible with desolvation, not only to limit the cooling of the ICP but also to keep the formation of cluster ions and the related spectral interferences low. These processes are complex, as, for example, a change in water loading also influences the pressure in the intermediate stage [129]. The use of high-pressure nebulization in ICP-MS has similar advantages and is suitable for coupling ICP-MS with HPLC. The setup that can be used is the same as the one that can be used for online trace-matrix separations [130].

With the formation of volatile hydrides, the detection limits for elements such as As, Se, and Sb can also be improved. As shown in Ref. [131], improvements for Pb were also obtained. They are due to improved analyte sampling efficiencies but also to the decrease in cluster ion formation, resulting from the introduction of a water-free analyte, which also applies to the cold vapor technique in the case of Hg.

ETV, in addition to its features for the analysis of microsamples, has the additional advantage in ICP-MS of introducing a dry analyte vapor into the plasma. Hence, it has been found to be useful for elements for which the detection limits are high as a result of spectral interferences with cluster ions. In the case of ^{56}Fe, which is subject to interference by ^{40}ArO^{+}, Park *et al.* [132] showed that the detection limit could be improved considerably by ETV. For similar reasons, the direct insertion of samples in ICP-MS leads to the highest absolute power of detection (detection limits in the picogram range and lower [133, 134]. Transient signals arise from ETV, where accordingly the number of elements that can be determined for one vaporization event is limited, unless drastic decreases in analytical precision and power of detection are accepted. In this respect, TOF-ICP-MS offers some advantages. Here, simultaneous measurements of different isotopes are possible during one evaporation event without losses in analytical performance. It is even possible to monitor the separation of the volatilization of interferents from the evaporation of the analytes in real time, which is helpful for removing both spectral and ionization interferences, as shown by Mahoney *et al.* [88].

Despite ICP-MS being mainly a method for the analysis of liquids and solids subsequent to dissolution, techniques for direct solids analysis have also been used. They are of use particularly when the samples are powders, which are difficult to bring into solution or, in addition, are electrically nonconducting and thus difficult to be analyzed with glow discharge or spark techniques. In the case of such powders, such as coal, slurry nebulization with a Babington nebulizer can be applied in ICP-MS as well [135]. ETV offers good possibilities not only for powders but also for granulates. With a novel furnace into which graphite boats can be introduced and where halogenated hydrocarbons can be used as volatilization aids, different volatile halide-forming elements can be successfully evaporated from Al_2O_3 [41]. When applying slurry sampling under continuous ultrasonic treatment of the slurry, accurate results for powered biological substances [136], and also for refractory powders such as Al_2O_3, down to the sub-micrograms per gram level [137] can be obtained. It could be shown that substances used as matrix modifiers in graphite AAS work, such as mixtures of Mg, Pd-nitrates, and soon, also may have a favorable influence here, as their use results in signal enhancements.

For the direct analysis of compact metals spark ablation can be used and the detection limits are in the nanograms per gram range as shown for steels [138]. The high ablation rates necessitate that measures be taken to limit a too high matrix load in the ICP. For the analysis of compact electrically nonconductive samples such as glasses, ceramics, rocks, and so on, laser ablation combined with ICP-MS is very powerful, commercially available, and widely used at present. The approach is treated in a separate chapter by Hattendorf and Günther.

Special attention is also to be given to the use of ICP-MS as an element-specific detection method in gas and liquid chromatography for speciation work. Here, special efforts had to be made in the coupling of the chromatographic and the spectrometric system and deals with

- suitable interfacing not to spoil chromatographic resolution;
- optimum sampling efficiency without analyte dilution to preserve the highest possible power of detection;
- optimization to allow a number of organic solvents entering the ICP without decreasing its stability of operation.

This field and its use in life sciences is especially addressed in a separate section by Rosenberg (see Chapter 15).

16.3.4
Time-of-Flight ICP-MS

Time-of-flight mass spectrometry has since long been known in instrumental analysis with SIMS, and so on, and been developed into a feasible detection system in ICP-MS [139]. Because of the mass range to be covered (1–238 amu), reasonable acceleration voltages (2 kV), and flight-tube lengths (1 m) permit the generation of 20 000–30 000 mass spectra per s. Both end-on and orthogonal geometry are possible and commercially available (LECO Renaissance and GBC Scientific Optimass 8000). In the end-on geometry, ions can be sampled from the ICP into the MS with an axial flight path, whereas with orthogonal geometry the incoming ions have a velocity component perpendicular to the extraction field, which can be compensated for by the use of steering plates. Therefore, in the axial geometry, the throughput is higher [140]. The figures of merit published with the two arrangements are rather similar. Indeed, as published for the axial geometry by Tian *et al.* [99], detection limits for 64 elements were at 0.5–20 pg ml^{-1}; with a long-term stability over 4 h between 1.0% for Li and 2.1% for ^{40}Ca under cool plasma conditions, and with RSDs between 0.07 and 0.7% for isotope ratios in SRM NIST 1643d. Sturgeon *et al.* [141] reported for the orthogonal geometry detection limits of 1 pg ml^{-1} and a resolution of 500 between ^{7}Li and ^{238}U.

Water-jacketed spray chambers have been shown to be helpful in reducing oxide signals [142], as well as the $1/f$ noise component on the signals [143]. Sanz-Medel and coworkers [144] found that the isotope ratio precisions and accuracies of TOF-ICP-MS surpassed those of quadrupole-based systems. This was impressively demonstrated for Pb by Carrion *et al.* [145], who reported RSDs of 0.08% for ^{85}Rb/^{87}Rb, 0.04% for ^{207}Pb/^{206}Pb, 0.49% for ^{204}Pb/^{206}Pb, and 0.07% for ^{208}Pb/^{206}Pb in the analog detection mode and respective values of 0.2, 0.3, 1.0, and 0.3% in the transient detection mode.

Besides isotope ratio measurements, a great strength of the ICP-TOF-MS lies in work with transient signals, where many isotope signals can be detected without spectral skew. By coupling flow injection to ICP-TOF-MS, Benkhedda *et al.* [146] were able to pre-enrich Pd, Pt, and Rh on diethylurea on the inner walls of a PTFE knotted reactor within 120 s and thereby could determine the elements in urine, blood serum, and road dust samples. For speciation, the online coupling of chromatography and ICP-TOF-MS has also been shown to be useful. Also, for a coupling with ETV where the signals are also transient, ICP-TOF-MS is very well suited. Mahoney *et al.* [88] already showed that in the case of Cd, Sn, and In, temperature programming could be used to avoid isobaric overlaps. Here, the interferences of Sn and Cd signals as a result of differences in their thermal volatilities could be removed, and absolute detection limits in the 10–80 fg range were obtained. Bings and Stefanka [147] showed that in the case of ETV from a tungsten filament, multielement determinations of Cr, Cu, Li, and Pb in 10 μl aliquots of blood serum could be directly performed when using a phosphate-based modifier. Here, all the elements present could be detected without any skew, as would have occurred with a sequentially measuring mass spectrometer. Moreover, laser ablation TOF-ICP-MS, can be efficiently used for the direct analysis of solids. Bings [148] optimized the method for the direct analysis of oils, such that a dilution with an organic solvent became unnecessary, and oils with particles suspended in them could be directly analyzed. Detection limits were at the 0.5 (Pb) to 28 $\mathrm{ng\,g^{-1}}$ level (Cr). Leach *et al.* [149] showed that a multitude of elements, in principle, can be determined from one laser pulse and, provided that all elemental signals are measured, absolute analyses of alloys become possible with a fairly good precision and accuracy. Indeed, one only has to add the signals for the various elements, to correct for their abundances, and to calculate the ratio of the signals for the respective elements. Finally, hydride and volatile species generation are also useful sampling techniques in ICP-TOF-MS. Bings *et al.* [150] used miniaturized electrochemical hydride generation, as described earlier, and obtained detection limits of 10–160 pg for As, Bi, Ge, Hg, and Sb and 1.1 ng for Se in simultaneous determinations of 12 isotopes in 200 μl samples; the method was shown to be useful for the analysis of natural waters.

16.3.5
Fields of Application

ICP-MS is a powerful method for multielemental trace determinations and therewith is especially promising for the areas where ICP-OES is applied, but where a higher power of detection is required. This is the case in trace analysis of geological samples, and especially of hydrogeological samples, as well as for trace determinations in metal samples, in the field of biology and medicine, as well as in environmental sciences.

16.3.5.1 Geological Samples

In the case of geological samples, ICP-MS especially is of interest where multi-element determinations are required and ICP-OES cannot be used because of the lack of power of detection or spectral interferences. This applies, for example, to the determination of low concentrations of the rare earth elements (see, e.g., Ref. [98, 151]). The optimization of the sample dissolution procedures with respect to ICP-MS has especially to be given attention to. When fusion is used to bring the samples into solution, the total salt contents of the solutions may necessitate a dilution of the measurement solutions in accordance with the consequences for the detection limits obtainable. Also, in the case of chemical dissolution involving oxidizing acids, problems may occur. Indeed, the presence of Cl in the measurement solutions may enhance the risks for cluster ion formation. Further, the use of HF may necessitate the use of HF-resistent nebulization systems (made of Ryton, e.g.) and ceramic injection tubes in the ICP burner. Clogging and corrosion of the sampler may be critical and requires rinsing and working with solutions having concentrations below 0.1%. Also, the use of a sampler made of Pt or a brass sampler covered with a ceramics layer may be required. Hydrogeological samples, as described by Garbarino and Taylor [152], can be analyzed very accurately for Ni, Cu, Sr, Cd, Ba, Tl, and Pb by isotope dilution ICP-MS. Isotope ratio work can be useful in dating or provenance studies and is well possible thanks to the high precision achievable with multicollector ICP-MS. For a series of trace elements, ETV was found to be useful so as to reduce spectral interferences. This applies particularly to volatile elements such as Tl [153], but in the case of a metal filament vaporizer also to Pt, Pd, Ru, and Ir [154]. For the investigation of inclusions in minerals, laser ablation ICP-MS is very powerful. It can even be used for the analysis of liquid inclusions in minerals, which can provide important information for geologists [155].

16.3.5.2 Metals and Ceramics

Trace determinations down to the sub-micrograms per gram level are possible in metals and ceramics, as the sample concentrations may be up to $5\,\mathrm{g\,l^{-1}}$. ICP-MS, therefore, is really an alternative for materials with line-rich matrix element optical emission spectra. This has been shown in the case of high-temperature alloys [156]. However, matrix interferences in ICP-MS may also limit the power of detection and the precision and the accuracy achievable, and matrix removal may be required so as to make further progress in these directions. All classical principles of trace-matrix separations are helpful in this respect. Innovative approaches where the classical trace-matrix separation principles are performed online with the determination step here are especially interesting. This has been shown by experiments with Al_2O_3 powders. After dissolution with strong acids, Al can be separated off by fixing the APDC complexes of the trace impurities on an Al_2O_3 column while the matrix passed through the column and nebulizing the liquid with which the complexes are eluted [157]. In the case where high-boiling inorganic acids are required so as to bring the samples into solution, as is the case with SiC, the acid residues have to be fumed off and the traces taken up in diluted HNO_3, by which the detection limits in ICP-MS can be decreased considerably [158]. Using high-resolution mass spectrometry can make it possible to prevent spectral interferences of the most abundant isotope signals with cluster ions, as is the case for $^{56}Fe^+$ and $^{40}Ar^{16}O^+$ or $^{52}Cr^+$ and $^{40}Ar^{12}C^+$ [85]. For a coupling of online matrix removal and ICP-MS, the use of suitable nebulization systems, such as high-pressure nebulization coupled with desolvation to HPLC or HENs in combination with capillary electrophoresis is very attractive. In the latter case, transient signals are obtained, which could be best measured in a multielemental mode with TOF-ICP-MS.

For material analysis also, direct solids analysis is possible in ICP-MS. For the direct analysis of steels by ICP-MS, Jiang and Houk [159] used arc ablation and reported detection limits down to the $0.1\,\mu g\,g^{-1}$-level. Further results were obtained by many groups by the use of laser ablation. Further, the direct coupling of slurry ETV to ICP-MS enabled trace determinations in ceramic powders very well, as shown in the case of Al_2O_3 by Wende *et al.* [41].

16.3.5.3 **Life Sciences**

For biological and medical samples, ICP-MS has considerably enlarged the series of elements that can be determined directly, and thus ICP-MS is of great importance for bioavailability studies. This is especially the case as the power of detection is sufficient to also determine different elemental compounds by coupling chromatography to ICP-MS, being the strongest approach for speciation studies. Speciation and the studies of the metal compounds in biotic materials under the name of metallomics [160] became a new field of research in the biosciences, where ICP-MS is one of the major tools. The determination of metalloproteins by a wide variation of methods and even sequencing of DNA became fields of research. At the ultratrace level, normal levels for many elements now can be determined in body fluids by ICP-MS, allowing biochemical studies [161]. In urine, for example, a good agreement of ICP-MS results with those of other techniques was obtained for Pb, Cd, Hg, and Tl. Deviations were found for As, Fe, and Se, which could be partly removed by a precipitation of the chlorides from the measurement solutions. With ICP-MS, Pb can be determined in blood [162] and the bioavailability of Zn has been studied [163]. For the analysis of small-volume samples, flow injection analysis found wide spread as well, as shown for blood analysis [164]. Also, in biotechnology, ICP-MS became a powerful tool for the determination of many metals and nonmetals within a wide concentration range.

16.3.5.4 **Environmental Sciences**

ICP-MS is a powerful method of analysis for chemical analysis in environmental work. Many elements can be determined directly in drinking water. In waste water analysis, sample digestion by a treatment with HNO_3/H_2O_2 is often required, and the most frequently occurring isobaric interferences have been described [165]. For seawater analysis, the salt content makes sample pretreatment necessary, and this can be done by chelate extraction. Beauchemin *et al.* [166] obtained a preconcentration of a factor of 50 by sorption of the trace elements onto a SiO_2 column treated with 8-hydroxyquinoline, and determined Ni, Cu, Zn, Mo, Cd, Pb, and U in seawater. In the case of river water, Na, Mg, K, Ca, Al, V, Cr, Mn, Cu, Zn, Sr, Mo, Sb, Ba, and U could be determined directly and Co, Ni, Cd, and Pb after the above-mentioned preconcentration procedure. For As, preconcentration by evaporation of the water from the sample was sufficient. Isotope dilution delivers the highest accuracy [167] and the procedure has been applied to the characterization of a standard reference sample [166]. ICP-MS, following sample decomposition with HNO_3/H_2O_2, has also been applied for trace determinations in marine sediments [168] and for the trace characterization of marine biological samples [169, 170]. Owing to the very high power of detection, ICP-MS can be used to determine very low background concentrations in unpolluted areas. With high-resolution ICP-MS and a microconcentric HEN, Rh, Pd, and Pt can be determined in ice samples with detection limits down to 0.02, 0.08, and 0.008 $pg\,g^{-1}$, respectively [171], as can be the actinides in environmental samples [172]. For speciation in the environment, ICP-MS coupled to chromatography also is very powerful.

16.4
Outlooks and Comparative Aspects

For elemental trace determinations, both ICP-OES and ICP-MS are now mature methods, and different types of instrumentation in the case of both methods are commercially available with a variety of sampling equipment. In the case of ICP-OES, the availability of different types of CCD optical emission spectrometers, especially, has widened the possibilities of the method in terms of interference recognition and correction for a broad range of real-life samples. Future developments may lie in the availability of more robust and still more stable RF power generators and burner technology. Fine work certainly will still be made on the side of sample introduction, where novel types of nebulizers can further improve the figures of merit. ICP-OES, however, is available in most laboratories just as AAS is. Especially for tasks such as waste water analysis, serum analysis, the characterization of metal standard samples, and so on, the method is a routine tool, which can also be handled by nonspecialists. The ease of calibration with synthetic elemental standard solutions is very attractive. Also, ICP-OES is valuable for in-line automated analyses.

ICP-MS now is the most accessible method for ultratrace element determinations. Both the quadrupole-based instrumentation, eventually with direct-reaction cell or collision cell, high-resolution sector field instruments, as well as time-of-flight and multicollector approaches have their respective strengths in terms of cost-effectiveness, the removal and prevention of spectral interferences, work with transient signals, or the achievement of high precision in isotope ratio measurements. ICP-MS will remain of prime importance for the analysis of samples with low matrix load, as they occur in water analysis, in the analysis of digested biological samples, in quality control for high-purity acids, and so on.

Much work is being done on lower cost alternatives to the ICP, especially when gases or vapor compounds are generated and the plasma used only serves for the excitation and or ionization of a gaseous compound. Here, low-power microwave plasmas and glow discharges, both at atmospheric and under reduced pressure, are good prospectives and will enable it to lower the supply and operation costs, without losing the required multielement detection capabilities or the required power of detection. These sources now play an important role in speciation work.

The field of solids analysis is only attractive for ICP atomic spectrometry when dissolution and calibration with synthetic solution samples can be used. This is the most common way for the characterization of new standard reference materials. For direct solids analysis, X-ray-based methods may be the more direct way, however, with the known limitations of the light elements and the restrictions on calibration, as a result of the absence of well-characterized standard reference samples in the case of most matrices. This also applies to glow discharge atomic spectrometry for bulk and microdistributional analysis of solids.

Laser Ablation Inductively Coupled Plasma Mass Spectrometry (LA-ICPMS)

Bodo Hattendorf and Detlef Günther

17.1

Introduction

In laser ablation inductively coupled plasma mass spectrometry (LA-ICPMS) the aerosol analyzed by ICPMS is generated by evaporating (ablating) a solid sample by means of a high-energy pulsed laser beam, which is focused on the sample surface. The ability to concentrate laser energy into an area as small as 4 µm in diameter for current equipment enables spatially resolved elemental analysis of major, minor, and trace elements and isotope ratio measurements in almost any solid material [1–5]. The development of this technique started in 1985 when Alan Gray presented the very first attempt at quantitative analysis of geological materials using LA-ICPMS [6]. The general setup of LA-ICPMS has not undergone fundamental changes since this initial configuration, while technical improvements of laser sources, beam delivery optics, and ICPMS instrumentation led to better performance and an increasing range of applications until today. These applications range from geochemical studies over material sciences and technology into biochemical and even medical applications. Forensic studies of many kinds are routinely carried out, and quality control of production processes is an increasing field where this technique is employed. In general, LA-ICPMS is a valuable tool in elemental trace and ultra trace analysis whenever spatially resolved determinations are required or when sample consumption shall be minimized. Even for bulk analysis, LA-ICPMS may be considered as it eliminates the need for sample digestion and minimizes the occurrence of solvent-based spectral interferences, which can be a severe limitation in ICPMS when using conventional solution nebulization.

LA-ICPMS basically consists of the following components:

- *The laser source and beam delivery*. Different pulsed lasers are currently available for LA-ICPMS, which primarily differ in wavelength, pulse duration, and pulse energy as well as in beam geometry and energy distribution. The beam delivery in most cases consists of energy adjustment, steering and shaping elements, and an objective for focusing and observation. Beam shaping is carried out to

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

minimize the variability of the energy density across the final beam in order to achieve a so-called flat-top energy distribution and to adjust the beam diameter at the sample surface, that is, the crater size at the ablation site.

- *The ablation cell and transport system*. The ablation cell forms an airtight enclosure around the sample area under investigation. It is usually mounted on a manually operated or computer-controlled x–y–z-stage for sample positioning under the laser beam. The cell interior, where the aerosol is generated by the laser pulse, is continuously flushed with argon or helium as carrier gas, transporting the material toward the ICPMS via flexible tubing. The transport system may contain devices for addition of a make-up gas or further aerosol manipulation such as removal of excessively large particles or pulse mixing to stabilize conditions inside the ICPMS.
- *The ICPMS instrument*. Many different types of ICPMS are available for elemental analysis of a laser-generated aerosol. The major difference with respect to the requirements of laser ablation (LA) may be seen in the type of mass spectrometer and detection system employed. Quadrupole systems represent the most widely used type here because of their simple operation and reliability. Sector field instruments can provide higher sensitivity and the capability of higher mass resolution. Comparably long magnet settling times however can lead to lower scan speed if the difference in m/z is large. The ability to detect ion signals for multiple isotopes simultaneously, when equipped with detector arrays, makes them ideally suited for isotope ratio measurements. Time of flight (TOF) systems probably resemble the smallest fraction of mass spectrometry (MS) used with LA, even though they would provide a quasi-simultaneous detection of the entire m/z range of interest. These instruments, however, appear to be limited in sensitivity and dynamic range.

Modern ICPMS instruments typically provide a linear dynamic range for detection of about 9–12 orders of magnitude, which is a valuable feature for LA sampling as it allows to register abundant isotope signals of major elements together with low abundant trace and ultra trace elements.

A typical set up of LA-ICPMS is shown in Figure 17.1. Commercial LA instruments typically utilize neodymium-doped yttrium aluminum garnet (Nd:YAG) lasers, operating at UV wavelengths (frequency quadrupled at 266 nm [7] or quintupled at 213 nm [8]) or gas lasers, almost exclusively employing an argon fluoride (ArF)-excimer laser (193 nm) [9–11]. Prototype instruments that were investigated included the F_2 excimer laser operating at 157 nm [12] or an all-solid-state Nd:YAG pumped OPO (optical parametric oscillator) system at 193 nm [13]. These laser are all nanosecond lasers with a pulse duration of approximately 5 ns (Nd:YAG) to 20 ns (excimers) and operate with pulse repetition rates of several tens of hertz. They exhibit a characteristic beam profile, with approximately Gaussian energy distribution in the radial direction (Nd:YAG) or perpendicular to the main axis (excimer). Since a constant energy density across the entire laser beam (the so-called flat top beam) leads to more uniform ablation craters [10], beam homogenization can be achieved by different approaches. In the so-called spatial filtering, the beam is expanded

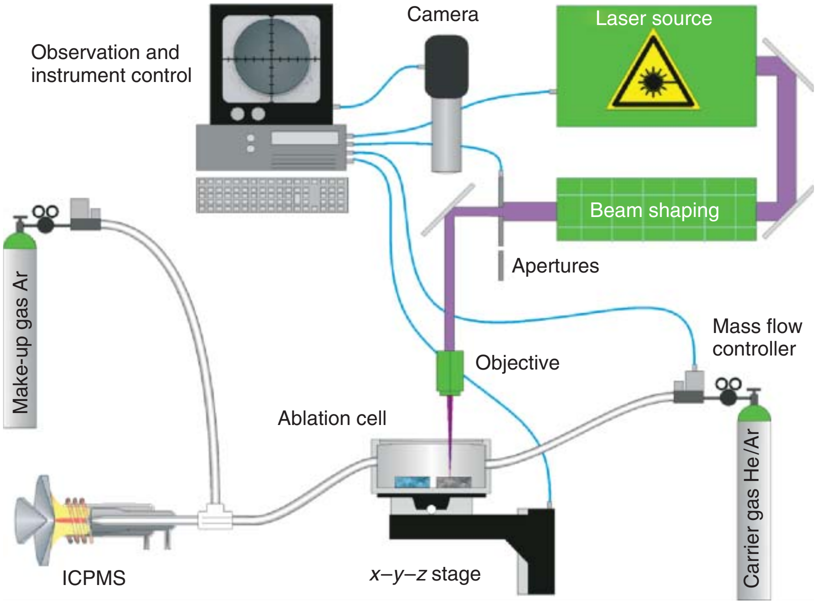

Figure 17.1 Schematic view of a typical LA-ICPMS configuration (MS not shown).

and only the central part of the beam, where variation of the energy is minimal, is transmitted and imaged onto the sample surface [11]. Lens array homogenization on the other hand achieves a homogenous field by splitting the raw beam into individual rays, which are subsequently superimposed at an image plane so that high-energy parts of the original beam coincide with their symmetrically opposite low-energy regions [10]. Both approaches can result in almost 90% loss of the initial beam energy and thus require laser sources of sufficiently high output energies. Recently, Nd:YAG lasers with approximately uniform energy distributions in the central part of the beam were developed, which thus avoid most of the losses associated with beam homogenization and allow the use of more compact laser sources and power supplies.

More recently, ''ultrafast'' laser sources with pulse duration in a range 150–300 fs (femtosecond lasers) have also been introduced [14, 15]. The most common type is the titanium-doped sapphire laser (Ti:sapphire), operating at a fundamental wavelength around 800 nm. Owing to the low energy available from the femtosecond laser, the pulse needs to be amplified using a so-called chirped pulse amplifier to generate laser pulses with sufficient energy density to allow ablation of a solid. UV wavelengths can be obtained after frequency tripling (≈266 nm) and quadrupling (≈200 nm) [16, 17], that is, similar to the wavelengths supplied by the Nd:YAG or the excimer lasers. The radial energy distribution is approximately Gaussian.

To adjust the size of the laser beam at the sample surface, it is usually directed onto a mask holding interchangeable apertures of various sizes and eventually different (circular or rectangular) geometries [9, 10]. An image of this aperture is then projected to the sample surface using an objective lens. Together with the aperture size, the demagnification provided through the objective determines the crater size, when the sample surface is placed at the respective image position. The energy density available for ablation is determined by the laser energy transmitted through the aperture and the crater size used. Additional loss of energy occurs by absorption by the optical elements in the beam path such as mirrors, the objective, and the cell window, as well as oxygen in the ambient air, especially for UV wavelengths. The optical elements within the beam path are usually coated specifically to ensure maximum transmission or reflectivity respectively at the wavelength used. Prolonged operation can lead to deposition of ablated material at the cell window, which not only affects the transmission of the incident light locally but may also lead to damage of the window's coating. It is thus critical to position the sample surface as far from the window as possible.

Sample observation is critical, especially when ablation shall be carried out at specific points of interest, which may be only several micrometers in size. Because of this, a LA unit is usually equipped with adjustable illumination and a digital observation system consisting of a charge-coupled device (CCD) camera and zoom optics, which may be supplemented by a microscope eyepiece for direct sample inspection.

Precise and reproducible positioning of the sample under the laser beam can be done using a motorized x–y–z-stage that is controlled by the instrument software. This stage can be used to either move to a specific position and keep that position during the entire ablation process (the so-called single-spot ablation) or to continuously traverse the sample along a predefined path, which may be a straight line or follow specific features at the sample surface (so-called scanning or raster mode ablation). Usually all three axes can be moved simultaneously, allowing the matching of the surface topography with the image point of the laser beam.

Aerosol transport from the ablation cell to the inductively coupled plasma (ICP) is achieved by the continuous flow of a carrier gas. Initially, argon was used for this purpose as it is commonly used in ICPMS instruments for sample introduction. In the late 1990s, however, helium was found to be better suited owing to higher analyte sensitivity and also reduced problems arising from elemental fractionation [9, 18], making it the preferred carrier gas today. The pressure inside the ablation cell may be considered atmospheric, as there should be little restriction of the flow after the ablation cell exit. The carrier gas is typically regulated by a mass flow controller, which may be available at the ICPMS or integrated in the LA unit and adjusted via the instrument software. The aerosol is then carried toward the ICP via flexible tubing. When helium is used as carrier gas, argon is admixed to the aerosol stream downstream the ablation cell to ensure stable operation of the ICP ion source.

The ICP shall transform the laser-generated aerosol into elemental ions, the currents of which can be registered using a mass spectrometer. Several competing processes inside the ICP, the vacuum interface, and ion optics, can greatly affect the sensitivity obtained in LA-ICPMS. In general, the processes are similar to those occurring in conventional ICPMS with solution nebulization but the absence of a solvent and the considerable amount of helium often used can change conditions inside the ICP substantially. The range of particle sizes generated during LA most likely imposes the greatest challenge on the optimization of the ICP ion source [19]. Ion extraction via the vacuum interface of the MS occurs at a fixed point in space and from a limited volume of the ICP. Thus, the ion density needs to be maximized at this position to attain the highest possible analyte sensitivity. The efficiency of particle vaporization depends mainly on gas temperature (T_{gas}) inside the central channel of the ICP and the residence time of the particles before reaching the sampler cone of the vacuum interface. Optimization of the ICP therefore has to balance T_{gas} and residence time between maximum vaporization of the laser-generated aerosol and potential analyte loss by diffusion out of the plasma volume sampled through the vacuum interface.

Extraction of the plasma via the vacuum interface should be governed by similar processes as in conventional ICPMS. The use of helium as a carrier gas, however, usually leads to higher interface pressure, and collisions during the transfer toward the high vacuum of the MS become more frequent. The absence of a solvent, on the other hand, reduces the abundance of molecular ions, formed in collisions during the extraction, significantly.

The transfer of the ions from the vacuum interface to the mass spectrometer is affected in a similar way. Since T_{gas} may be slightly higher when helium is used [20, 21], the ion kinetic energies may span over a greater range for different m/z after the supersonic expansion [22], and thus, focusing of the entire m/z range within the ion optics may become less efficient.

MS separation and detection should be least affected if LA is used in comparison to conventional nebulization. Owing to rapid changes in the ion densities created by the pulsed sample introduction, the scan duration of the MS should be as short as possible in order to maximize the correlation of the ion signals.

In the following chapters, more detailed descriptions of the respective components involved in LA-ICPMS and their effects on the analytical performance are given.

17.2
Fundamental Aspects of Laser Ablation

LA occurs when a material is irradiated by a laser pulse of sufficiently high energy density or fluence (expressed in joules per square centimeters). It results in a rapid heating of the sample material and ultimately evaporation of parts of the irradiated volume. In addition, within 50–200 nanoseconds after the laser pulse a plasma forms above the irradiated area [23]. The mass removal associated with these processes is utilized in many fields of technology (e.g., microfabrication, thin film production, and laser cutting) and also medicine (eye surgery). In spectrochemical analysis, LA is also used as a sampling and excitation tool for a variety of techniques. In laser-induced breakdown spectroscopy (LIBS, sometimes termed laser-induced plasma spectroscopy: LIPS), the material removed from the sample is excited either during ablation or within a localized plasma forming above the ablation crater [24–26]. By means of an optical spectrometer, it is thus possible to record the emission spectrum from the transient plasma. On the basis of this emission, elements present in the vaporized material can be identified and quantified using a calibration curve. A second – less common – application is laser ablation mass spectrometry (LAMS) [27, 28], where the ions formed during the ablation process are directly transferred into a mass spectrometer for analysis. Both former approaches are somewhat limited for quantitative analysis of samples, where matrix-matched calibration standards are not readily available [29–31]. Matrix-assisted laser desorption and ionization (MALDI) [32] may be considered an approach similar to LAMS. A major difference here is that a laser beam of comparably low energy density and large crater sizes are used, which results in the release of nondissociated molecules and molecular ions for analysis by MS. This technique has gained significant attention in the analysis of macromolecules, especially proteins and peptides, but analysis for the elemental composition of the sample is not easily achieved.

In elemental analysis using LA with ICP-based detection methods such as LA-ICPOES (laser ablation inductively coupled plasma optical emission spectroscopy) [33] and predominantly LA-ICPMS, the sampling process is completely separated from the excitation or ionization, which offers the opportunity to optimize both processes independently. This is most likely the key reason why especially LA-ICPMS has gained such significant attention in recent years.

The ultimate goal in LA for ICPMS detection is to create an aerosol that can be transformed into a mass spectrum representing the composition of the ablated material. This cannot be fulfilled in many practical applications because of the variability of the different processes that occur during the generation of the aerosol and the detection in the ICPMS. Elemental fractionation due to preferential vaporization during the ablation can change the composition in the aerosol formed during ablation and in the solid and also alter the thermodynamic properties of the sample material before the next laser shot occurs. On the other hand, vaporization and ionization of aerosols showing different particle size distributions inside the ICP ion source may further change the relative response of the elements when different materials are sampled.

17.2.1
Aerosol Generation and Transport

The aerosol analyzed finally with the ICPMS may be considered a result of various processes resulting from the different mechanisms of the laser–material interaction. These mechanisms change with respect to the sample material and the laser properties such as energy density, pulse duration, and wavelength. This chapter briefly introduces basic concepts of LA leading to aerosol formation from a solid with respect to experimental conditions.

17.2.1.1 Ablation Process

Initially, the laser beam will lead to excitation of electrons inside the solid. A fraction of these electrons may leave the surface by photoionization. The remaining excited electrons will subsequently transfer the energy to the lattice and heat the material. If the energy of the laser beam is above the ablation threshold, the near-surface temperature will rapidly rise above the respective point of vaporization and the vapor is ejected from the sample surface at a velocity in the range of $10^3 – 10^4$ m s^{-1} [34]. As ablation is carried out in an ambient gas at atmospheric pressure, a shock wave forms at the boundary between the expanding material and the background gas [35]. Moreover, ionization of the gas and the vapor released creates a plasma above the ablation crater. When the temperature in the vapor plume has fallen below the condensation temperature of its components, particles start to form [36]. The particles generated in these processes are typically in a range of several tens of nanometers and their overall composition should represent the ablated material unless the material contained species that can form volatile compounds at room temperature (e.g., CO_2 from carbonates). It is not well described yet whether the nucleation and condensation of these aerosol particles occur in a statistical manner or is driven by the thermodynamic properties of the vapor. Principally, an earlier onset of condensation of components with higher boiling temperatures has to be expected. This would ultimately result in a significant variability of the particle composition, size, and thermodynamic properties. In the presence of a considerable amount of melt within the ablation crater, particles can also be generated through splashing of droplets by the recoil pressure inside the expanding plume [37]. The size of these droplets depends to a large extent on the physical properties of the melt such as viscosity, thickness, and temperature and also on the aspect ratio of the ablation crater. Particles of several micrometers diameter were observed for shallow craters and thick molten layers, while their abundance decreases significantly for deeper craters [19]. The splashing of material is typically accompanied by the formation of a chimney-like structure at the top to the ablation crater.

The more rapidly the laser energy is converted into vaporization, the smaller is the degree of material melting, which is considered to represent an important source of elemental fractionation. The amount of energy density deposited within a specific sample volume depends on the fluence of the laser beam, the absorption of the respective wavelength, and the material-specific energy loss processes. A substantial fraction of the laser energy may be lost by reflection of the incident beam at the surface and the so-called ‘‘plasma shielding.’’ Both effects are difficult to estimate in their magnitude as optical reflectivity at the respective temperature is usually not known and because the extent of plasma formation above the laser crater depends to some extent on the ablation process (degree of photoionization, etc.). The latter, however, was estimated to cause as much as 50% loss of the incident beam, mainly due to inverse Bremsstrahlung [38]. Inside the material, the laser energy may further be lost as a result of the thermal conductivity of the material and by radiation [39]. The total energy available for vaporization is finally determined by the heat capacity of the material and its respective latent heat of melting. Especially, for natural samples with complex composition these are often difficult to determine making it difficult to estimate the relevance of the respective processes. Thus, prediction of the evaporation rates and vapor/melt ratios remain difficult for the majority of samples analyzed by LA-ICPMS. The optimization of the ablation process should thus ensure minimizing the extent of melting and maximizing the conversion of the laser energy into vaporization of the sample.

17.2.1.2 **Laser Pulse Energy**

The energy of the laser pulse ultimately determines how much of the solid material can be transferred into the vapor phase to subsequently form an aerosol. Ablation is only occurring if the energy density or fluence is sufficiently high. Depending on the type of material, the laser wavelength, and pulse duration, the ablation threshold lies in the order of some hundreds of millijoules per square centimeter up to several tens of joules per square centimeter. Such energy densities are obtained by focusing the original laser beam (output energy of several millijoules) to a size of typically 5–200 μm in diameter. A total beam energy of only 0.2 mJ output energy, concentrated in a crater size of 50 μm, is then sufficient to achieve an energy density of about 10 J cm^{-2}. Above the ablation threshold, the ablation rate usually increases over a wide range in proportion to the energy density [40] until at very high energy densities the ablation regime changes into a process termed *phase explosion* with significantly greater ablation rates [41].

When an aperture is illuminated by a homogenized beam and imaged onto the sample surface, the energy density remains constant for different crater sizes. Energy homogenization furthermore minimizes variations in the respective ablation processes that occur at different energy densities. In this case, the ablation crater is usually characterized by a regular and flat bottom. If, on the other hand, a focused Gaussian beam is used, the energy density and crater size depend on the focal position of the beam relative to the sample surface and its output energy. The respective energy density and ablation rate decrease along the radius of the beam.

17.2.1.3 **Laser Wavelength**

The absorption coefficient at the laser wavelength mainly influences the amount of energy that can be deposited within a given volume of the sample material. High absorption leads to smaller penetration depth and thus a higher temperature within the material. This is especially critical for transparent materials where the use of deep UV wavelengths (193 and 213 nm) was found to significantly improve the crater morphology and to reduce elemental fractionation during ICPMS detection [8, 13]. The higher the absorbance of the material at the laser wavelength, the more energy is concentrated in a volume at the surface. This leads to a higher vapor/melt ratio [36], which ultimately reduces the abundance of micrometer-sized particles in the aerosol. Deep UV wavelengths also benefit from smaller variability of the absorption for different materials.

17.2.1.4 **Crater Size**

Laser irradiation causes a part of the sample to undergo phase transitions including melting and evaporation. Apart from the area directly irradiated by the laser beam, a much larger volume is heated because of the thermal conductivity of the material (‘‘heat affected zone’’). The larger this volume, the greater is the corresponding amount of laser energy that cannot be converted into evaporation of the material, resulting in a smaller vapor/melt ratio. To avoid elemental fractionation, it is thus desirable to reduce the corresponding energy loss. For a constant fluence, however, the volume of the heat-affected zone relative to the ablation crater will decrease with increasing diameter of the laser beam. Furthermore, larger crater sizes reduce the aspect ratio of the ablation crater developing upon progressive ablation. Deep and narrow craters (high aspect ratio) have been found to enhance elemental fractionation in LA-ICPMS. Low-fluence irradiation at slightly tilted crater walls may cause preferential release of volatile components [42], which may further be enhanced by heating through the laser-induced plasma. Furthermore, transfer of larger particles into the carrier gas is probably less efficient for craters with a high aspect ratio. Finally, there is also the chance that vaporized material is deposited at the crater walls after the ablation event. Thus, especially when attempting to sample at high spatial resolution, the occurrence of elemental fractionation due to the formation of deep craters needs to be monitored. For glass samples and LA using 193 nm, for example, it was found that elemental fractionation is significant when an aspect ratio of six is exceeded, independent of the crater size used.

17.2.1.5 **Laser Pulse Duration**

The ablation of a solid is characterized by different processes occurring at different timescales [43]. In the subpicosecond (10^{-12} s) regime, photon–electron interactions dominate, leading to a rapid rise of the electron temperature inside the material with an instantaneous emission of electrons. The plasma is formed after several hundred femtoseconds (10^{-15} s) and at the same time the excited electrons transfer the energy into the lattice, thereby heating the material to the respective melting and boiling temperatures. Within a few nanoseconds (10^{-9} s) after the pulse, evaporation of the material starts. Currently, LA is most frequently carried out by nanosecond lasers, where the duration of the laser irradiation is sufficiently long to interact with all transformation stages of the material during the heating process and also with the laser-induced plasma above the ablation crater. Therefore, a significant fraction of the incident beam is shielded from the sample surface by heating the electrons in the plasma (inverse Bremsstrahlung) while heat conduction causes the energy deposited inside the ablation crater to be readily dissipated into the sample body. This ultimately limits the energy available for evaporation of the material and leads to a relatively large volume of molten material that may be splashed from the ablation crater [37]. When the pulse duration is reduced to the subpicosecond regime by using femtosecond lasers, energy loss by plasma shielding can be eliminated, and the laser energy is deposited inside the irradiated volume before relaxation of the electron energies into the lattice and thermal diffusion becomes significant. Owing to these major differences, femtosecond lasers are expected to improve the ablation characteristics for LA-ICPMS. First results indicate that especially ablation of metallic samples is significantly improved when femtosecond lasers are employed [17, 44–46]. Despite the typically lower fluencies available from femtosecond lasers, significantly higher ion signal intensities are observed in LA-ICPMS of metal samples, when compared to nanosecond lasers. For the ablation of dielectric materials such as glass, on the other hand, the use of femtosecond lasers may result in lower signal intensities [47]. This latter is attributed to the lower fluence supplied by current femtosecond-LA systems. Dielectric materials typically have significantly smaller thermal conductivity, which mitigates the energy loss by thermal diffusion, and the advantage of the shorter pulse duration diminishes to some extent. The higher fluence obtained from the nanosecond laser in this case results in greater ablation rates and correspondingly higher ion signal intensities.

17.2.1.6 Gas Environment

LA for sampling into the ICPMS has to be carried out in an inert gas, usually at atmospheric pressure. Argon is the common carrier gas for ICPMS operation and was thus initially also used in LA-ICPMS for aerosol transport [6]. Experiments using helium as the ambient gas during ablation, added to an argon flow for stable operation of the ICP, led to significant improvements with respect to analyte sensitivity, reduced the amount of material deposited near the ablation crater and showed smaller elemental fractionation effects [9, 18]. Both are ascribed to the change in the particle size distribution of the ablated material, which occurs when changing from argon to helium under otherwise similar ablation conditions [48]. Helium has an approximately 10-fold higher thermal conductivity and lower density than argon, resulting in a more rapid cooling of the evaporated material and greater dilution due to a wider expansion of the vapor plume. In addition, the shock applied to the molten surface of the sample during the expansion of the plasma is less pronounced in the less dense gas. These processes can explain the reduced abundance of micrometer-sized particles and solidified droplets in the sample aerosol when helium is used as carrier gas in LA-ICPMS.

17.2.1.7 Ablation Cell and Aerosol Transport System

The ablation cell provides a gas-tight enclosure of the ablation region connected via flexible tubing to the sample inlet of the ICPMS. It is continuously flushed by the carrier gas at flow rates between 0.3 and 1.1 $\mathrm{l\,min^{-1}}$. Ablation cells are often cylindrical in shape and equipped with a top window for observation, illumination, and delivery of the laser beam [6, 49]. The dependency of transport efficiency and signal dispersion on the volume and the shape of the ablation cell as well as differences in turbulent and laminar gas flow is still subject of intense research and also numerical modeling [46, 50]. It was observed, however, that the amount of mass transported from the ablation cell to the ICP is largely independent of the cell geometry or carrier gas flow rate if unrestricted flow to the ICP is attained [51]. Another important characteristic of the transport system is the aerosol dispersion. It may cause the aerosol generated from a single laser pulse to occur as a very sharp signal inside the ICPMS or stretched to a duration of several seconds. The dispersion of the aerosol is affected by the internal volume of the ablation cell and its geometry, and by the carrier gas flow rate and occurrence of laminar or turbulent flow regimes [52]. The effect of cell volume on signal dispersion is shown exemplarily in Figure 17.2. For a laser pulse repetition rate of 2 Hz, both ablation cells show distinct oscillations of the ion signals. The amplitude, however, is dramatically greater for the cell with only 0.25 $\mathrm{cm^3}$ internal volume compared to the 63 $\mathrm{cm^3}$ ablation cell. In addition, the smaller cell leads to a pronounced oscillation of the peak intensities at a frequency of approximately 0.3 Hz. This

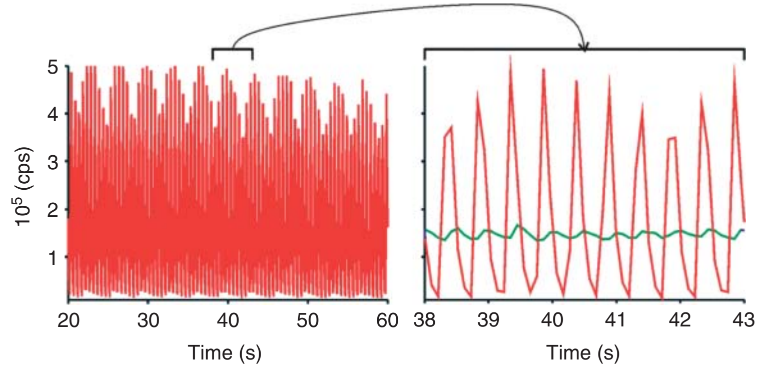

Figure 17.2 Influence of ablation cell volume on signal dispersion. Laser ablation carried out with 2 Hz pulse repetition rate. Red line: 0.25 cm^3 internal volume; green line: 63 cm^3 internal volume (not shown in the left panel). Average ion signals 158 kcps (0.25 cm^3) and 134 kcps (63 cm^3).

beat is originating in the rapid intensity change at 2 Hz and the data acquisition frequency of ≈9.71 Hz (103 ms scan duration of the MS). Averaged ion signal intensities obtained are fairly similar for both ablation cells. The smaller cell shows about 20% higher overall ion signal intensities, which is attributed to reduced deposition inside the cell due to flow dynamics.

High aerosol dispersion leads to tailing signals that can last for seconds and results in lower peak intensities from a single laser pulse. It is most pronounced for large cell volumes, low carrier gas flow rates, and especially when turbulent flow conditions prevail inside the ablation cell [46]. The volume of tube connections to the ICP was found not to have a major influence on the signal dispersion unless it becomes comparable to that of the ablation cell [52]. An advantage of higher dispersion, however, lies in smoother ion signal intensities that can be obtained. Therefore, additional pulse mixing devices have been employed in LA-ICPMS, which can be realized through volume holding baffle plates inserted between ablation cell and the ICP [9, 53]. Turbulences and abrupt changes in the flow direction, however, may lead to particle size dependent transport efficiency or changes in the respective transport times. Smaller particles tend to follow the gas flow more closely, while larger particles may be lost upon collisions with the tube walls. Vortexes in the transport system, on the other hand, may cause temporal trapping of smaller particles [50].

17.2.2
Requirements for Quantification

Elemental analysis using LA-ICPMS requires the transformation of the solid material into an aerosol that either resembles the composition of the analyzed volume or allows to asses and compensate for deviations in the aerosol composition by using a matrix matched material for calibration that shows identical effects.

In addition, the transient variation of the aerosol density in the carrier gas flow, caused by the use of pulsed lasers, in combination with aerosol dispersion affects the spatial resolution attainable owing to the mixing of aerosols generated by subsequent laser pulses. The pronounced variability of the dominating ablation mechanisms, which depends on the sample composition, can impose a challenge for the quantification of unknown samples. All processes involved can lead to varying ablation rates as well as sample- and time-dependent aerosol composition and particle size distributions. To minimize these effects with respect to quantitative analysis by LA-ICPMS, a few general remarks may be made.

- *When matrix-matched calibration standards are available*, the processes occurring during LA mainly affect the sensitivity of the method in general. As changes in the ablation rates, particle size distributions, and composition of the aerosol should be identical for the calibration standards and the unknown samples, the major limiting factors should cancel out in the calibration. It should be ensured, however, that the data acquisition for quantification is carried out for identical ablation conditions, that is, during the same ablation period when the ablation rates vary with time or crater depth.
- *When matrix matched calibration standards are not available*, it needs to be ensured that the stoichiometry of the aerosol is representative for the composition of the calibration standards and unknown samples respectively. In the case of dielectrics such as glasses, minerals, or ceramics, this appears to be mainly dependent on the wavelength used and the fluence applied. Deeper UV wavelengths and higher fluence were found to allow accurate quantification of these materials in a wide variety of applications. Elemental fractionation may, however, still be pronounced, especially when comparing volatile and refractory elements, but the extent is greatly reduced. For the analysis of metals, on the other hand, the duration of the laser pulse is more important. The use of femtosecond lasers was found to reduce elemental fractionation to a great extent in these materials. Currently, however, these systems still lack sufficient fluence in the deep UV to provide ablation rates in dielectric materials that are comparable to nanosecond lasers.

17.3
ICPMS Detection

Since the fundamental aspects and operating principles of ICPMS have been described in a previous section (Chapter 16), this chapter only discusses aspects that are considered important for LA sampling.

17.3.1
Instrumentation

In principle, the configuration of ICPMS for LA sampling is identical to solution-based sample introduction methods. Fundamental differences occur mainly in the composition of the carrier gas, which usually does not contain a solvent but a significant fraction of helium. The change in its composition, however, may affect the characteristics of the ICP with respect to sample vaporization and ionization to some extent. It will also alter the pressure in the vacuum interface and ion optics of the ICPMS as helium is less efficiently pumped by the vacuum system. Helium is typically supplied via mass flow controllers that may be incorporated in the ICPMS system or from an external unit fitted to the LA unit. The addition of argon to the carrier gas is typically performed using the nebulizer supply of the ICPMS.

17.3.1.1 **The ICP Source**

The laser-generated aerosol needs to be vaporized, atomized, and ionized before detection by the MS is possible. The abundance of the analyte ions in the ICP further needs to be maximized within the limited volume that is extracted via the sampler cone into the vacuum interface of the MS [54]. The residence time of the aerosol inside the ICP is limited to a few milliseconds only [55]. This will cause significant variations of particle evaporation when the laser-generated aerosol is characterized by a wide size distribution [21] and ultimately affect the efficiency of the sampling process. Figure 17.3 shows distribution of Rb^+, representing elements with higher volatility, and Y^+, representing more refractory elements inside the ICP when different LA configurations are employed.

The radial and axial distribution of analyte ions can be highly variable and dependent on the conditions used for LA sampling and inside the ICP. Generally, the distribution gets wider in the axial direction when argon is used as the carrier gas. At the same time, the volatility of the element has a significant influence on the distribution. Because of this, the more refractory Y^+ ions show a wider radial spread when the aerosol contains a significant amount of large particles (266 nm with argon as carrier gas) compared to Rb^+ ions. Changing to helium as carrier

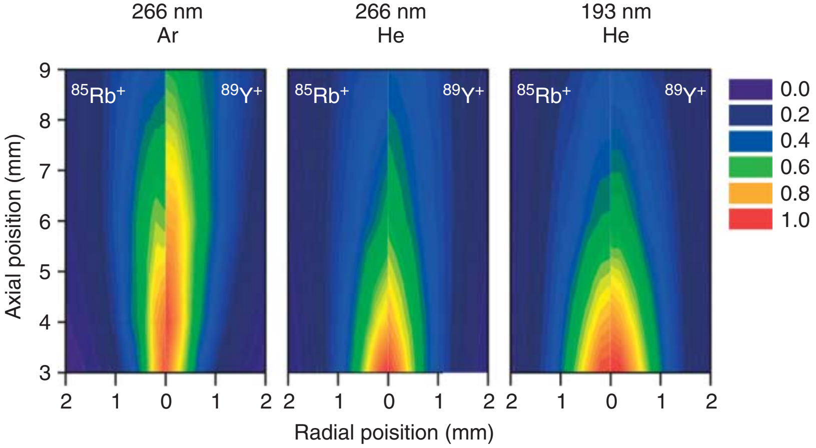

Figure 17.3 Radial and axial distribution of ion density in the ICP (normalized to the maximum signal) for aerosols from silicate glass, generated by different configurations of laser ablation (266 or 193 nm) and carrier gas (argon or helium). (Data according to [21].)

gas reduces the axial spread but leads to slightly wider radial distributions for both elements. When the laser-generated aerosol consists mainly of particles of around 100 nm (193 nm helium as carrier gas), the axial distributions of the elements are almost equal. The radial distribution then depends almost exclusively on the isotope mass and increases with decreasing isotope mass [21]. This would correspond to the higher diffusion rates for lighter isotopes and may therefore add to the mass dependency in the detection efficiency of the ICPMS (see also Figure 17.4).

An aerosol containing a significant fraction of large particles is thus disadvantageous, as the point where complete evaporation is achieved will vary substantially with particle size. Particles exceeding a certain limit may furthermore not be vaporized at a timescale of a few milliseconds, which is the typical transit time through the ICP [58]. The maximum particle size that can be vaporized in the ICP for MS detection will depend on its composition and is estimated to be in the order of 100 nm for silicate glass [59]. For comparison with solution nebulization, the mass of this particle would be equivalent to the dissolved fraction of only 20 mg l^{-1} in a droplet of 5 μm diameter.

Adjusting the ICP operating conditions to increase the residence time or the gas temperature within the plasma would allow for more efficient vaporization of larger particles. It will, however, also lead to more pronounced radial diffusion of the vaporized material and thus cause greater analyte losses due to incomplete ion sampling through the vacuum interface [56]. It is thus desirable that the aerosol predominantly consists of smaller particles to ensure complete vaporization of the entire aerosol in a narrow region to maximize sensitivity.

The extent to which the absence of the solvent in LA-ICPMS changes the plasma properties is not very well understood until today in detail. The gas temperature in the central channel of the ICP may increase because of the absence of the solvent

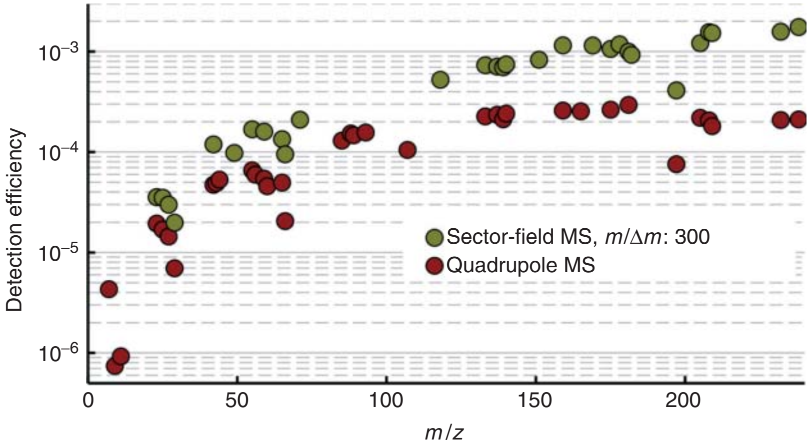

Figure 17.4 Typical detection efficiencies for LA-ICPMS when using quadrupole MS (Data from [56].) or sector field MS (Data from [57].) for isotope detection. (Data from [56].) and sector-field ICPMS (Data from [57].) for LA-ICPMS of silicate glass.

and thus the onset of particle vaporization may shift further upstream inside the ICP. In a similar manner, the presence of helium in the carrier gas can increase the gas temperature [20] because of its higher thermal conductivity. It may also lead to a higher evaporation rate due to faster diffusion of vapor away from the particle surface. Ionization, on the other hand, should not be affected to a remarkable degree by the presence of helium as its first ionization potential exceeds that of argon significantly. The relative degree of ionization thus should be similar to that observed in conventional ICPMS using solution nebulization.

17.3.1.2 **The Vacuum Interface and Ion Optics**

The use of helium as carrier gas can also affect the plasma expansion inside the vacuum interface and the ion optics. Helium is less efficiently evacuated by the vacuum pumps and thus the interface pressure is typically higher when it is present in the carrier gas. The plasma temperature on the other hand may be higher for the dry plasma, which can, to some extent, compensate for this effect. The influence on the respective transmission efficiencies is thus difficult to estimate. Only a few studies have tried to further optimize the vacuum interface for dry sampling by LA specifically [60, 61]. It was found that reducing the sampler cone aperture size or increasing the pump speed at the interface can, to some extent, improve transmission, especially for ions of high m/z. This is most likely a result of fewer collisions of the analyte ions with the background gas due to a lower interface and ion optics pressure. The fact that no improvement or even lower sensitivity was observed for low m/z ions indicates that a greater fraction of the lighter ions is lost owing to incomplete sampling of the ions from the ICP or because of greater diffusion in the vacuum interface at reduced pressure. Transmission through the ion optics may similarly become affected by increasing collision rates when helium is used as carrier gas. This may increase the magnitude of the mass bias observed to some extent. A greater influence on ion transmission, however, may result from variations in the total ion density due to varying sample mass introduced into the ICP. While the excess of solvent in conventional solution-based methods may act as a temperature buffer in the ICP, variations in the abundance of the dominating Ar^+ ions are reduced in most cases. In a dry plasma, on the other hand, varying amounts of the sample aerosol may induce larger variations of the abundance of Ar^+, which in turn would influence the magnitude of space charge effects to a greater degree.

The ion optics' mode of operation can further affect the abundance of background ions because of memory effects to some extent. Instruments utilizing extraction optics with highly negative potentials relative to the ion source such as sector field MS [62] typically provide higher analyte sensitivity when compared to instruments where only moderate extraction voltages or even positive potentials [63, 64] are applied. Highly negative potentials on the other hand are more prone to collect and transfer ions that can be sputtered from upstream surfaces and ionized. This can lead to increased background signals, especially for volatile species with low ionization energies such as the alkaline elements. Because the sputtered ions carry much smaller initial kinetic energies [65], ion optics with only moderate extraction or positive bias more efficiently discriminate against such background ions, which results in lower memory effects and improves the background equivalent concentrations.

17.3.1.3 Mass Spectrometers

The different mass spectrometers used for current ICPMS instruments have specific characteristics, which influence the performance for LA sampling in a similar way as with conventional solution nebulization. Because of the transient nature of the aerosol generation by the pulsed laser, however, the correlation of the individual ion signals depends on the scan frequency that can be achieved with the mass spectrometer.

Especially when the laser is operated at frequencies of <10 Hz or when the aerosol dispersion in the sample introduction system is small, the ion signals can exhibit a distinct oscillation at the laser pulse frequency (Figure 17.2). Depending on frequency and aerosol dispersion, the amplitude of this oscillation may span over more than an order of magnitude. Correlated ion signals are, however, important to allow correction for variations in the ablated mass with time and in between individual samples. Owing to the sequential nature of the signal acquisition in quadrupole and single-collector sector field mass spectrometers, the attainable correlation is limited by the duration for a mass scan covering all isotopes of interest. Therefore, the integration time (or dwell time) as well as the settling time need to be adjusted in order to maximize the correlation while still yielding sufficient reproducibility and accuracy of mass adjustment and ion signal acquisition. In most configurations, the dispersion of the aerosol is sufficient to minimize signal oscillations when pulse repetition rates >5 Hz are applied. In these cases, a scan duration of <1 s is usually appropriate to achieve sufficient signal correlation for quantitative analysis. Care should, however, be taken to adjust the scan duration not to be close or equal to a multiple integer of the time period between individual laser pulses, especially when the laser is fired at low repetition rates or the dispersion of the signal is low. Many applications with quadrupole instruments use a dwell time in the range of 10 ms, which, together with typical settling times between 1 and 3 ms, allows recording ion signals for more than 50 isotopes within 1 s. Sector field instruments may exhibit longer scan durations when wide m/z ranges are analyzed, where the magnet needs to be scanned. The dynamic range of the detection system for current instrumentation allows acquisition of ion signals over a range of 9 orders of magnitude by parallel read-out of pulse counting and analog signals at the secondary electron multiplier (SEM). This is sufficient to analyze for elements present at weight percentage concentrations to microgram/kilogram levels in a single mass scan. Recent developments also employ fast switching between an SEM and Faraday-cup for detection of even higher ion signal intensities [66]. If the analyte signals are acquired in different detector modes for different samples it needs to be ensured that the corresponding cross calibration is updated frequently in order to make pulse counting and analog signals comparable. Some instruments additionally allow attenuation of ion transmission for specific isotopes by dynamic adjustment of the mass resolution. This can further be used to include isotopes of the matrix elements into the acquisition, which would otherwise exceed the upper detector range in applications where large crater sizes and high laser fluence are used to increase sensitivity for trace and ultra-trace elements.

The mass resolution ($m/\Delta m$ at 10% peak height) achieved with sector field instruments is typically adjustable between $\approx$300 and $\approx$12 000 [62], allowing the separation of various spectral interferences from the analyte isotopes. In quadrupole instruments, on the other hand, the mass resolution is usually adjusted with m/z analyzed to obtain a peak width of 0.7–0.8 m/z at 10% of the peak height. Quadrupole ICPMS currently achieves detection efficiencies between 10^{-7} and 10^{-4} ions per atom present in the ablated volume. Sector field instruments can provide higher detection efficiency, most pronounced at high m/z (Figure 17.4). Limits of detection are additionally affected by the instrumental background and are thus much lower at high m/z where nanograms per gram detection limits can routinely be achieved at a lateral resolution of several tens of micrometers (Figure 17.13).

Time of flight mass spectrometer (TOFMS) acquires all isotope signals quasi-simultaneously at a rate of several 10^4 spectra per second [67]. This principally allows for a better ion signal correlation for rapidly changing ion signal intensities [68]. Even though this feature would make them ideally suited for LA sampling, the number of applications using these instruments has remained comparably small in comparison to quadrupole or sector field instruments. This may mostly be a result of their limited sensitivity due to a lower duty cycle and more pronounced space charge effects in the drift region. In addition, the dynamic range of current instruments is often limited to about 6 orders of magnitude because of the demands for high signal acquisition speed.

Sector field instruments with multiple detectors arranged at the focal plane of the MS (multi collector inductively coupled plasma mass spectrometry, MC-ICPMS) allow parallel detection of ion signals for more than 15 isotopes. An increasing number of applications use these instruments with LA for *in situ* isotope ratio measurements [16, 69–72]. Even though isotope ratio measurements with a precision in the sub permil range can be achieved, the accuracy is usually inferior to that with solution-based methods because of difficult-to-compensate-for variations in mass discrimination and spectral interferences from isobars and molecular ions. Elemental fractionation may further limit the applicability in application where decay products shall be analyzed simultaneously with the precursor elements, for example, in U/Pb dating. Because of the fact that the highest precision and accuracy is obtained by determination of the respective ion current using Faraday cups, the elements of interest have to be present at relatively high concentrations in the range of about 10–100 mg kg^{-1}. Low abundance isotopes can also be determined using ion counting detectors, whose precision though is limited because of greater drift of the detector gain (i.e., variation in the detector output for constant ion current) and poorer counting statistics.

The benefit of MC-ICPMS instruments by recording the ion signals simultaneously can be utilized for larger m/z ranges by using miniaturized, chip-based detectors in combination with a Mattauch–Herzog mass spectrometer [73]. The ongoing advances in chip technology and electronics design may lead to unique instrumentation that can avoid the limitations of the aforementioned instruments with respect to temporal correlation (sequential MS), duty cycle (TOFMS), or elemental coverage (MC). A potential limitation of this instrument type may arise from the unamplified analog ion current detection [74], which is typically affected by a greater detector noise, affecting the attainable limit of detection. The higher sensitivity of sector field instruments compared to a quadrupole or TOF-based system, however, may at least partially compensate for this [74].

17.3.2
Spectral Interferences

One of the advantages of LA sampling is the absence of a solvent in the sample aerosol, which dramatically reduces the abundance of the corresponding molecular ions in the mass spectrum. The abundance of polyatomic species containing oxygen, for example, is by at least an order of magnitude lower than in conventional solution-based methods. For optimized ICP operating conditions, the $\mathrm{ThO^+/Th^+}$ intensity ratio observed is typically <0.3%, $\mathrm{Th^+}$ being an elemental ion with a very high affinity to oxygen.

Owing to the limited resolution of quadrupole mass spectrometers, spectral interferences usually cannot be resolved. Sector field instruments can provide sufficient mass resolution for separating a range of potential analytes from these interferences albeit at the expense of sensitivity. Furthermore, a large number of polyatomic ions' m/z is still too close to the analyte ions to be resolved (Figure 17.5).

Identification of spectral interferences is usually possible by comparing the isotopic signature of an element with its natural distribution and relating the deviation to potential polyatomic ions on the basis of the composition of the sample. In the case of monoisotopic elements, however, this can only be achieved when

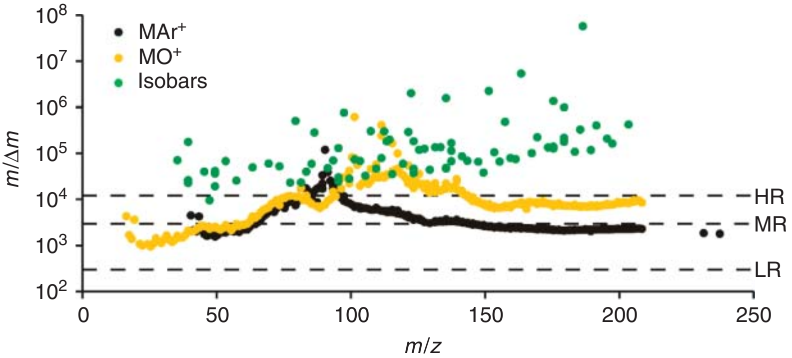

Figure 17.5 Representation of the mass resolution required to separate analyte and interference signals of equal height at the respective m/z for isobaric interferences and molecular ions containing oxygen or argon. Dashed lines indicate the resolution available from sector field instruments at typical instrumental settings of $m/\Delta m$: 300 (LR), 3000 (MR), and 12 000 (HR).

other elements in the same mass region show noticeable deviation from their natural pattern. It is thus generally advisable to know as much as possible about the approximate composition of the sample to allow estimating the occurrence of potential spectral interferences.

17.3.2.1 **Origin of Spectral Interferences**

All elements present in the ICP can principally form polyatomic ions, giving rise to spectral interferences. The magnitude of the interference depends on its respective abundance in the plasma and many possible species presumably occur at levels that do not contribute significantly to the measured ion signal intensities. The most abundant polyatomic ions are species consisting of argon, nitrogen, oxygen, and elements present at higher abundance in the sample aerosol. Furthermore, interferences from doubly charged ions occur at levels comparable to or slightly above those for solution-based methods owing to the potentially higher plasma temperature. Isobaric ions cannot be resolved by current instrumentation because of restricted mass resolution (one exception could be the overlap of $^{48}Ca^+$ and $^{48}Ti^+$, where the mass resolution of sector field instruments may just be sufficient). Nonetheless, all elements except for indium have at least one isotope free from isobaric overlap. Plasma background species are dominated by Ar, O, N, C, and several combinations of these elements, which are most abundant in the mass range between m/z 12 and 80 (Figure 17.6). Other components of the plasma gas as trace amounts of Kr and Xe are also present at detectable levels.

17.3.2.2 **Coping with Spectral Interferences**

Because it is difficult to modify the composition of the aerosol reaching the ICP with LA sampling, there are limited ways to remove an element causing spectral interference. One possibility, recently introduced, that may be useful for selected applications is thermal aerosol treatment, where ion signals of volatile elements could be selectively suppressed [75]. Passing the laser-generated aerosol through a graphite tube electrically heated to 2000 °C, for example, allowed attenuation of Rb by almost 2 orders of magnitude while not affecting the ion signal for Sr and thereby significantly reducing the spectral interference on ^{87}Sr. Apart from the rather complex setup, the approach is yet only applicable when the analyte and the interferent show sufficient difference in their respective volatility. The simplest approach to account for spectral interferences is thus to select an appropriate isotope for analysis, where spectral interferences do not occur at a significant level, instead of using the isotope yielding highest sensitivity. As an example, it would be more reasonable to determine copper using $^{65}Cu^+$ instead of the more abundant $^{63}Cu^+$ in samples with a high concentration of sodium to avoid interference from $^{23}Na^{40}Ar^+$. In many cases, however, an analyte isotope free from spectral interferences may not be available and other methods have to be employed.

Instrumental approaches to minimize spectral interferences include increasing the mass resolution with sector field instruments or the use of ion–neutral interactions in collision or reaction cell instruments. Both methods are yet limited in the general applicability.

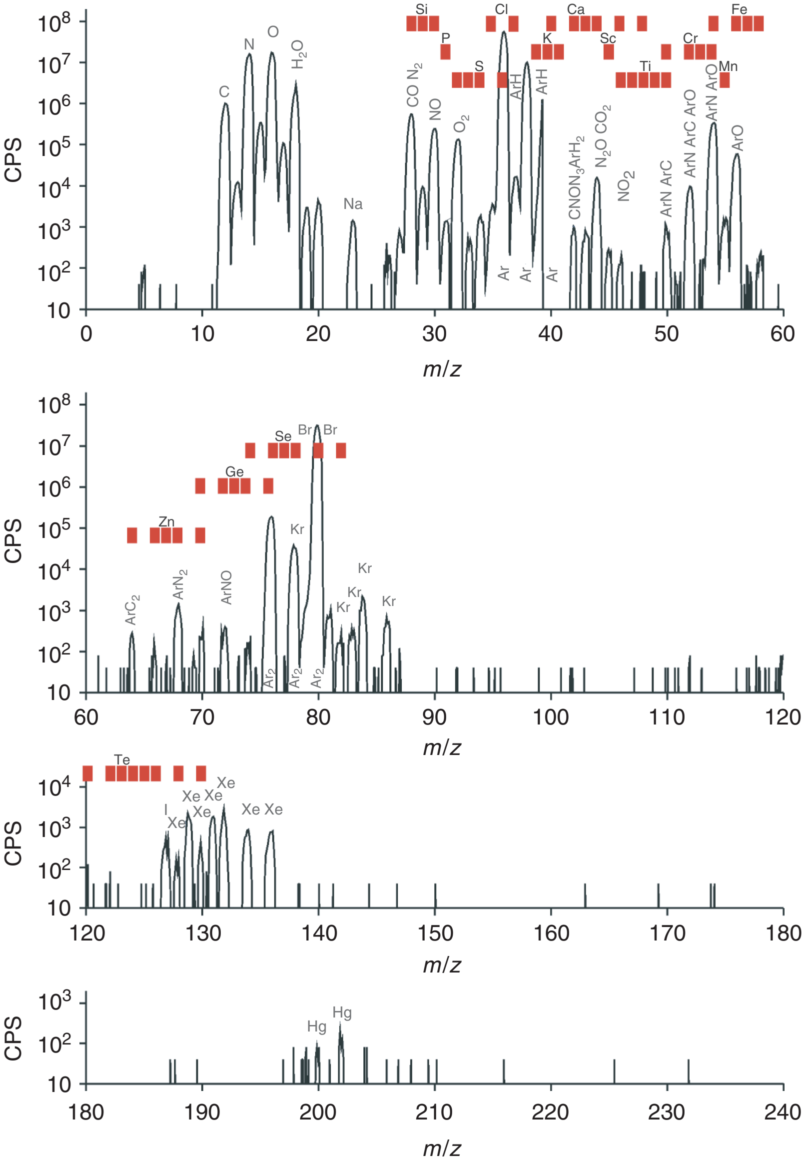

Figure 17.6 Example of a typical instrumental background or gas blank spectrum in LA-ICPMS (*m*/*z* 40 and 41 omitted). Tentative assignments for the background species are printed in blue. Red bars indicate the *m*/*z* of isotopes, where elements are affected by instrumental background signals. Several random signals of 40 cps result from single detector counts. Acquisition by quadrupole ICPMS using an integration time of 25 ms per point and 10 points per *m*/*z*.

Sector field instruments can resolve a wide variety of spectral interferences irrespective of their chemical composition. The mass resolution can typically be chosen depending on the requirements of the application and may reach values for $m/\Delta m$ of up to 12 000. Intermediate settings (usually around $m/\Delta m$ of 3000) are often sufficient to separate abundant spectral interferences from elemental ions (Figure 17.5). This reduces the loss in ion transmission and is less demanding with respect to a rapid and accurate adjustment of the magnetic field. Changing between mass resolution settings, however, requires adjustment of the entrance slit of the MS, which cannot be carried out on a timescale of milliseconds. In order to ensure a sufficiently high data acquisition speed, the instrument thus needs to operate at fixed mass resolution settings for all analytes of interest, which in turn reduces the sensitivity when measuring noninterfered isotopes. A variety of spectral interferences would also require much higher resolution values than 12 000 in order to avoid interference with analyte ions (Figure 17.5). Molecular ions with oxygen that occur in the range between m/z 100 and 140, SrO^+ or MoO^+ for example, cannot be resolved by current instrumentation.

Collision or reaction cell instruments utilize ion–neutral interactions (often termed *ion–molecule reactions*) to facilitate interference suppression in different ways [76]. The interaction of the gas with the ion beam from the ICP is facilitated by directing the ion beam through a chamber filled with the neutral gas at a pressure in the low millibar range [77]. A multipole ion guide is place inside the chamber to minimize transmission losses due to scattering processes with the background gas [78]. Reactive gases can be used, for example, to initiate charge transfer reactions, usually aiming at neutralization of the interfering species. Reactive gases can also be applied in atom transfer reactions, where the interference is resolved, for example, by transforming the analyte ion into a polyatomic ion of different m/z, where interference-free detection is possible [79, 80]. In a corresponding process, the interference may also be transformed into another species of a different m/z [81]. In LA applications, hydrogen may be useful for the removal of polyatomic ions containing argon because it is less reactive with other elemental ions and does not form adduct ions to a large extent [82]. Other highly reactive gases as ammonia or methane, however, are prone to induce undesired side reactions leading to the formation of unwanted molecular and cluster ions that may interfere with other isotopes of interest and reduce the sensitivity of the reaction partners [83]. In this view, it may be considered problematic to use these gases for multielement applications in complex matrices. Current instruments equipped with collision or reaction cells typically utilize either a dynamic bandpass filter [84] or kinetic energy discrimination (KED) [85] to minimize the abundance of cell-generated polyatomic ions in the mass spectrum. A bandpass filter is realized through a quadrupole ion guide, which transmits a range of m/z (bandpass). The bandpass can be adjusted dynamically with the m/z of the analyte isotopes. It is set to allow the analyte ions to pass through, while precursor ions of potential cell-generated ions are excluded. This approach is most efficient for large differences of the m/z of precursor and analyte ions because a very narrow bandpass also reduces transmission of the latter. KED on the other hand is making use of the higher collision frequency of the larger polyatomic ions with the background gas. Accordingly, they lose kinetic energy more rapidly than elemental ions. An electrostatic potential barrier before the MS can thus be adjusted to just allow the elemental ions with higher kinetic energy to pass through but to exclude the polyatomic ions from the MS. Both approaches can be fairly efficient, especially for interferences occurring at low to intermediate m/z. Nonetheless, they also reduce the sensitivity for elemental analyte ions, especially when a high degree of suppression is required and for ions at high m/z, where the relative energy or mass difference between the analyte and the interference is small [83].

When instrumental methods cannot be applied to resolve spectral interferences because of lack of mass resolution, or collision or reaction cell approaches are not feasible, mathematical correction of the measured ion signal intensities may be a last resort to account for spectral interferences. On the basis of known relative abundances of the isotopes of the interfering species it is, in many cases, possible to determine the respective contribution of the interference and the analyte to the measured ion signal intensities. The correction is then carried out by determining the contribution of the interference based on the measurement of another isotope that can be detected interference free and including the mass discrimination of the ICPMS:

$$I^{A}_{\text{isotope}} = I^{A}_{\text{raw}} - I^{B}_{\text{correction}} \cdot K\left(\frac{A}{B}\right)$$

where I represents ion signal intensities; isotope indicates the net signal for the isotope of interest (m/z: A); raw represents background-corrected ion signal (m/z: A); correction is the net ion signal intensity for the isotope used for correction (m/z: B); and $K(A/B)$ is the correction factor. $K(A/B)$ has to be determined from the intensity ratio of the interfering species, measured under identical conditions in a sample without the analyte isotope or calculated using mass bias approximations and the relative abundance of the isotopes of the interference (Section 17.5.3)

This process can principally be iterated a number of times to include potential interferences on ion signals used for correction or to include multiple interferences on one analyte isotope [86, 87]. The accuracy of this approach will, however, depend on the quality of the correction factors. The presence and variability of instrumental mass discrimination makes it impossible to simply use correction factors based on the isotopes' natural abundance. The correction factors thus need to be calibrated and eventually updated frequently and in dependence on the sample composition. This ultimately increases the uncertainty in the corrected signal intensities and the corresponding analytical results. Even greater uncertainties arise when corrections based on the abundance ratio of molecular ions relative to an elemental ion shall be employed. As an example, one may estimate the contribution from $^{181}\text{Ta}^{16}\text{O}^+$ on $^{197}\text{Au}^+$ (both almost monoisotopic) by assuming that the abundance ratio TaO^+/Ta^+ is constant and can be determined using any gold-free sample containing tantalum. Such abundance ratios, however, depend significantly on the operating conditions of the ICPMS and may show pronounced variability with time [88] and sample composition. Furthermore, the mass difference between the isotope used for correction and the analyte is comparably large and variations in mass discrimination can lead to significant bias.

17.3.3
Non-Spectral Interferences

Just as with solution nebulization methods, ICPMS with LA sampling is susceptible to non-spectral interferences or matrix effects [89]. They manifest in changes in the sensitivity ratios for different elements depending on the sample matrix or the ablation process in general. The origin of these interferences is manifold and related to a variety of processes that occur during the LA process and detection in the ICPMS.

- *Elemental fractionation occurring during LA*. This term was originally introduced to describe time-dependent sensitivity changes during a single spot ablation, caused by preferential vaporization of more volatile elements as the depth of the ablation crater increases [90]. A so-called ''fractionation index'' was derived by Fryer *et al*. [91] by splitting the measurement period in two halves and dividing intensity ratios obtained in the second half by those obtained in the first half. Any deviation from one would indicate elemental fractionation. When using calcium as reference element, several other elements showed fractionation indices greater than 1, indicating their relative enrichment in the aerosol as the ablation proceeded. Later, Mank and Mason [42] showed that, for the ablation of glass, this effect was largely independent of the crater size used but more closely related to the aspect ratio of the developing crater. Very recently, however, it was shown that the fractionation index is not showing the same trend in the entire ablation period but may actually reverse when calculated during the early ablation period [89] (see also Figure 17.7 and Figure 17.8).

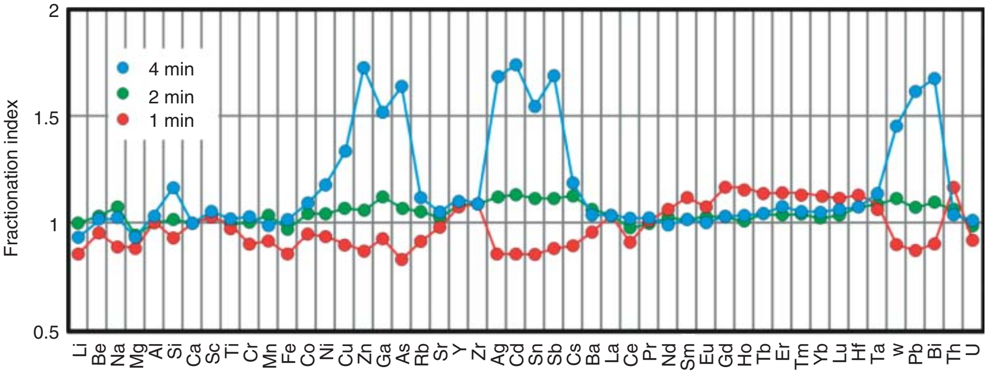

Figure 17.7 Fractionation indices of laser ablation of silicate glass (NIST SRM 610, 266 nm LA), calculated according to Fryer *et al*. [91] for different durations of the ablation. Short measurements show largely opposite trends compared with long ablation periods, while intermediate periods seem to exhibit no significant fractionation. (Reproduced from [89].)

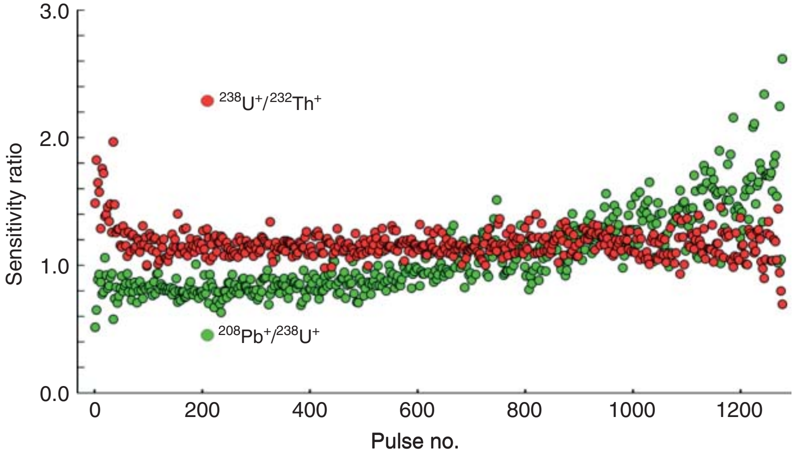

Figure 17.8 Representation of two distinctly different expressions of elemental fractionation occurring in single-spot LA-ICPMS measurements for silicate glasses. In the initial ablation pulses, the occurrence of large particles causes incomplete vaporization of Th, leading to high U^+/Th^+ sensitivity ratios. While the ablation proceeds, large particles are becoming less abundant and the sensitivity ratio remains stable. Pb^+/U^+ shows most pronounced deviation from their concentration ratio when the crater has deepened, which indicates that the more volatile elements are released preferentially.

- *Elemental fractionation occurring in the ICPMS*. The ICPMS may also cause elemental fractionation due to the dependence of vaporization, ionization, and ion transmission on the composition and size distribution of the particles in the laser-generated aerosol. Larger particles or particles that consist of a highly refractory matrix require longer residence time within the ICP or higher gas temperatures for complete vaporization [58, 92]. This can introduce a bias in the sensitivity ratios if the evaporation of the particles in the ICP is incongruent or if the composition of an aerosol particle varies with size [93]. Furthermore, the temperature inside the ICP will to some extent depend on the amount of aerosol present [94]. Thus, for highly variable mass loads in the ICP, the sensitivities of different elements may not change proportionally even when the particle size distributions are similar.

It will remain difficult to discriminate between elemental fractionation occurring during the ablation process and within the ICP as potential changes in the composition of the aerosol due to preferential vaporization during LA are usually accompanied by changes in the particle size distribution [59], which can cause fractionation within the ICP. Figure 17.8 demonstrates the different effects of elemental fractionation in LA-ICPMS that were frequently observed, for example, in Pb/U dating. In this measurement, the $^{238}U^+/^{208}Pb^+$ sensitivity ratio remains constant and close to 1 during the initial ablation period but continuously increases as the crater depth (or aspect ratio) exceeds a critical value (after ~500 laser pulses in this case). This would indicate that elemental fractionation is least significant at the beginning of the ablation, where only a slight but constant offset is observed, which is merely resulting from mass discrimination of the ICPMS. Pb appears to be preferentially released while the more refractory U remains as the ablation crater gets deeper. The sensitivities of $^{238}U^+$ and $^{232}Th^+$ on the other hand differ most significantly at the onset of ablation, where a significant fraction of micrometer-sized particles is present in the aerosol [19]. The relative depletion of Th^+ at this stage is thus considered to result predominantly from less efficient vaporization of Th relative to U within the ICP. The occurrence of preferential vaporization within the ICP is further supported by the fact that the change in the U/Th sensitivity ratio is significantly affected by the ICP operating conditions. Reducing gas temperature or residence time of the aerosol within the ICP usually leads to greater deviations of the corresponding sensitivities [95].

In general, elemental fractionation needs to be considered a phenomenon that is ultimately determined by the laser–sample interaction. The processes involved in the generation of the aerosol determine the composition and particle size distribution of the aerosol. The particle size distribution, however, can induce fractionation within the ICP even when the composition aerosol resembles the stoichiometry of the sample material. When elemental fractionation occurs, it may thus result in variations of measured sensitivity ratios for a sample upon prolonged ablation on the one hand and also in constant but biased sensitivity ratios for individual samples of different composition on the other.

17.3.4
Instrument Drift

Instrument drift can result from a variety of processes. It becomes notable by changing absolute intensities in the repetitive analysis of a homogeneous sample with time, using identical operating conditions. In many cases, drift is related to the thermal equilibration of the LA unit and/or the ICPMS. On the laser side, the output energy often depends on the actual temperature of the laser and optical components, for example, for generation of higher harmonics. In addition, there may be temporal changes in the absorption of UV radiation within the optical path owing to the formation of ozone when the laser is fired. Similarly, components of the ICPMS are sensitive to temperature (e.g., vacuum interface, electronics, and drift region), which can affect transmission efficiency. Apart from instrumental aspects, the composition of the carrier gas can drift over time after the ablation cell has been closed because of the washout of residual ambient air. The change in the concentration of molecular ions, however, was found to affect not only the abundance of molecular ions but also the sensitivities obtained with the ICPMS in an element-dependent manner [88]. Most processes described above equilibrate on timescales of several minutes, which is easily diagnosed by repetitive analyses of a reference sample. Ozone buildup and thermal equilibration of the laser head, however, may occur only within the duration of the measurement unless the laser is continuously fired against a shutter in between individual analyses.

17.4
Sampling Strategies

The ability to perform LA on practically any material at a lateral scale in the micrometer range and at ablation rates of 10 to several hundred nanometers per laser pulse allow for a wide range of sampling strategies. By using large crater sizes, extended ablation periods, and repetitive analyses, bulk concentrations can be assessed. Spatially resolved analysis can be carried out using finely focused laser beams or by analyzing individual layers in depth. The following chapters shall provide an overview about typical sampling strategies in the respective cases.

17.4.1
Bulk Analysis

The sample mass that is consumed during LA experiments is typically not more than some nanograms per laser pulse. Taking also into account that solid samples can a priori not be considered homogeneous on a scale of the laser beam diameter, determination of bulk concentration values by LA-ICPMS should be approached with some care. Typically, milligram amounts of a sample are analyzed for quantification of a sample when established techniques such as solution-based methods after sample digestion or X-ray fluorescence are used, for example. LA-ICPMS would thus require applying several million laser pulses to sample a comparable mass, which, at 10 Hz pulse repetition rate, would require several hours of measurement! In this sense, any ''bulk'' analysis carried out by LA under typical acquisition protocols should rather be considered an estimate for the true concentration – in many cases a good one however. Nonetheless, the degree to which the elemental concentrations vary needs to be verified by analyzing different regions of an unknown sample. Whether these regions are chosen randomly or using a pre-defined pattern (Figure 17.9) is not of importance. If a sample is suspected to contain concentration gradients, for example, due to the production process, it may be reasonable to follow such gradients if their orientation can be identified by other methods, for example, optical inspection in the simplest case.

The analysis can be carried out by multiple single spot ablations, line scans, or arbitrarily defined tracks of the laser beam across the sample surface (Figure 17.9), which generally does not affect the analytical results as long as representative amounts of the material are analyzed. Any type of scan, however, is much more affected by potential surface contamination and unfavorable particle size distributions in the laser-generated aerosol [19]. Single spot ablation, on the other hand, may suffer from laser-induced elemental fractionation when a large number of shots is applied because of the thermal effects in the vicinity of the ablation crater and the increasing degree of elemental fractionation when ablating from deeper cavities. Generally, approaching the ''true'' concentration value with uncertainties close to those obtained by solution nebulization methods requires comparably long measurement times, which may limit the cost-effectiveness of LA-ICPMS.

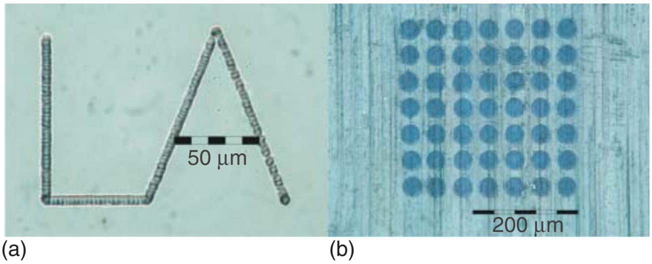

Figure 17.9 Laser ablation sampling. (a) Example for a line scan in a silicate glass with a beam diameter of 6 and a groove depth of 6 µm. The trench consists of four individually programmed segments ablated within a single scan. Thirty pulses were applied on each position. (b) Example for a single point raster on anodized aluminum using a beam diameter of 36 µm. One pulse applied at each position. A homogenized 193 nm laser ablation system with fluence of 15 J cm^{-2} was used in both experiments.

17.4.2
Depth Profiling

Depth profiling for layer thickness determination is typically performed by ablating the sample surface layer by layer and by comparing the number of pluses applied with the ablation rate of the material. Low-energy pulses increase the depth resolution but reduce the measurement sensitivity because less material is removed per laser pulse. The ion signals acquired by the ICPMS are then used to determine the penetration of the layer as indicated by the appearance of the substrate elements in the mass spectrum or from the decrease in the layer material [96–98]. The depth resolution of such an approach is ultimately dependent on the ablation rate per pulse and the energy distribution of the laser beam. The concave crater bottom obtained with near Gaussian energy distributions of the laser beam leads to ablation of material from all depths between the crater bottom and the sample surface, which limits the attainable resolution substantially. A homogenized beam, on the other hand, yields a constant ablation rate across the entire crater and a geometry that is close to cylindrical unless the aspect ratio of the crater is exceedingly large. Removal of material from the crater wall still occurs, but to a much lower extent, improving the resolution.

Compositional depth profiling, on the other hand, requires removing the surface layer by layer in a representative way while simultaneously registering ion signals for all isotopes of interest. To achieve a high definition of the depth profile in this case, mixing of the aerosols generated by successive laser pulses should be avoided as much as possible. Therefore, low laser pulse frequencies are most often employed. In addition, the aerosol transport system should be designed in order to minimize dispersion for increased peak signal intensities and to reduce the total measurement time. The depth profile can then be obtained by plotting ion signal intensities against the number of pulses or the crater depth if the ablation rate is known. When suitable calibration standards are available, the respective concentrations can be calculated as well. The theoretical depth resolution that can be obtained is again dependent on the ablation rate and can thus be adjusted over some range by the laser pulse energy. In practice, however, a certain degree of mixing of individual layers will always occur within the molten phase at the crater bottom and by removal of material from the crater wall. A further limitation for the characterization of very thick layers may occur through the laser-induced elemental fractionation, observed when the crater depth exceeds a critical value [42]. This will become most important when layers of a thickness of several hundred micrometers shall be analyzed. It may be more reasonable in this case to cut the sample and analyze the layers sideways.

At energy densities close to the ablation threshold for the respective laser used, ablation rates in the range of several tens of nanometers can be obtained. The depth resolution obtained in recent applications, however, ranges from about 100 nm to several micrometers [99], depending on the configuration and the sample material under investigation.

17.4.3
Lateral Profiling

Lateral profiling or elemental imaging refers to the analysis of element distributions in a surface layer of several micrometers or in thin sections of a solid sample. The sampling strategies for elemental profiling are generally similar to bulk analytical methods. The aim is, however, to identify and differentiate specific regions in the sample with respect to their elemental composition. Thus, in contrast to bulk analyses, variations of the respective ion signal intensities shall be explicitly determined in relation to the sampling position. The temporal correlation of the ion signal intensities should thus be as high as possible in order to be able to distinguish between real concentration changes and artifacts caused by the dispersion of the aerosol.

One or two dimensional profiles or images of the elemental distribution can be obtained in quasi-continuous approaches, when the sample is scanned by continuous line scans, and ion signal acquisition is carried out at high frequency. Alternatively, individual discrete positions can be analyzed using single-spot ablations distributed over the sample. Single-spot approaches ultimately provide the highest level of confidence in accurately assigning the measured ion signal intensities or element concentrations to a specific position at the sample surface. When the sample is continuously scanned under the laser beam, the dispersion of the transport system will lead to mixing of the aerosol generated from different positions. The temporal profile of the ion signal intensities in comparison with the actual concentration in the sample is therefore always blurred [100, 101]. In general, using a laser pulse repetition rate that ensures the occurrence of the aerosol in the ICP only after the previous cloud has diminished would reduce this effect but lead to exceedingly long analysis times when large samples need to be analyzed. Most applications therefore are carried out by using higher laser frequencies (typically between 5 and 10 Hz) and operate at low to moderate translation speed (between 5 and 50 $\mu m\, s^{-1}$) of the sample under the laser beam [102, 103]. This leads to greater overlap of the individual laser shots and deeper grooves. As more material is removed from each position, higher signal intensities are achieved as well but the aerosol always contains a mixture of material released from different depths. This may complicate an unambiguous assignment of the respective ion signal intensity or element concentration with a specific position in the sample, when the elemental composition varies substantially with depth [100]. In order to separate contributions from individual laser pulses or spatial positions of the sample in the sample aerosol, mathematical models may be employed.

An additional potential complication in spatially resolved analysis arises when sequential mass spectrometers are employed because of the discontinuous acquisition of the individual ion signal intensities. Every isotope will, in this case, be measured within a different time period relative to the arrival of the aerosol, generated by one specific laser pulse, in the ICP [104]. The smaller the dispersion of the aerosol transport system and the longer the duration of the mass scan, the larger is the deviation of the measured ion signal intensity ratios from those that would reflect the true concentration ratios within the entire aerosol cloud. The influence of this effect on the correlation between the measured intensity ratios and the respective concentrations in the sample can be minimized when many laser pulses are applied during each mass scan and when there is a substantial overlap of the individual ablation craters. In this case, the amplitude of the oscillation of the aerosol density is reduced and each laser pulse contains a significant fraction of material from the region ablated by the previous pulse. The depth of a groove generated by line scans will depend on the number of pulses applied on each position and the ablation rate of the material at the respective laser fluence. In order to estimate the influence of the individual operating parameters, the following expressions may be useful.

The number of pulses (N_{p}) applied on each position within the line is given by

$$N_{\mathrm{p}} = \frac{f}{v} \cdot D$$

where D is the diameter of a circular ablation crater or length of the side parallel to the translation direction for rectangular craters (µm), v is the translation speed of the sample under the laser beam ($\mu\mathrm{m\,s^{-1}}$), and f is the laser pulse repetition rate (Hz).

The number of pulses applied during one mass scan (N_{scan}) is given by

$$N_{\mathrm{scan}} = T \cdot f$$

where T is the mass scan duration (s); see Section 17.3.1.3.

In order to acquire ion signals for more than one laser pulse at each position of the sample, N_{p} has to be greater than N_{scan} or

$$\frac{D}{v} > T$$

The aspect ratio of the resulting scan line can be estimated if the ablation rate is known, using

$$\frac{d}{D} = \frac{N_\mathrm{p} \cdot R}{D} = \frac{f \cdot R}{v}$$

where d is the depth of the scan line (μm) and R is the ablation rate per laser pulse (μm pulse^{-1}).

It may be interesting to note that the aspect ratio resulting for a given combination of laser pulse repetition rate and translation speed is not dependent on the crater diameter when the ablation rate is constant.

The overlap of the areas for successive circular (O_c) or rectangular (O_r) ablation craters can be calculated according to

$$O_\mathrm{r} = \left[1 - \frac{1}{N_\mathrm{p}}\right] \times 100\%$$

$$O_\mathrm{c} = \frac{2}{\pi}\left[\arccos\left(\frac{1}{N_\mathrm{p}}\right) - \frac{\sqrt{N_\mathrm{p}{}^2 - 1}}{N_\mathrm{p}^2}\right] \times 100\%$$

Their dependencies on N_p are shown in Figure 17.10. There is little difference for the geometries for $N_\mathrm{p} > 10$ where the overlap is close or equal to 90% in both cases. More than 50% overlap is obtained in both cases for an N_p of 3.

It may further be interesting to compare the coverage of the trench obtained from circular crater geometries to that of a quadratic crater of identical D. When the sample is moved under the laser beam, a circular crater omits a fraction of the trench depending on N_p. If the length of the trench is much longer than the diameter of the ablation crater, the fraction omitted is always <2% if N_p is >2 and

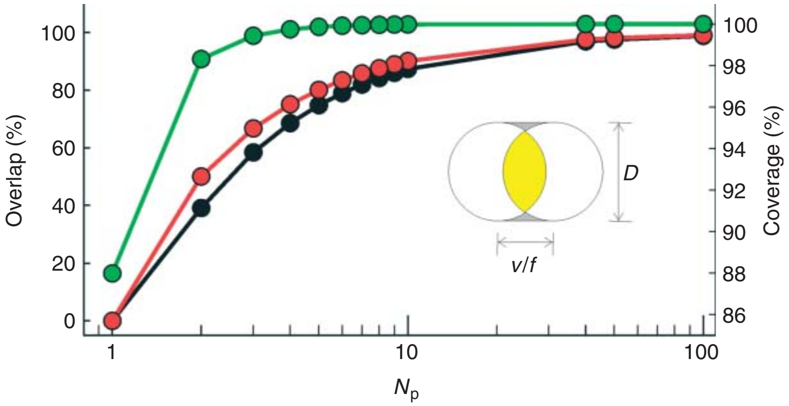

Figure 17.10 Overlap and coverage of successive laser craters for line scan ablation using circular or rectangular ablation craters. The overlap for a circular crater shape (black circles, yellow region in the inset) is only slightly smaller than for when a rectangular shape (red circles) is used. For a circular laser beam, the deviation of the coverage (green circles) from 100% is a result of omitting the gray area shown in the inset.

$<0.02\%$ for $N_p > 10$. One may thus consider the mass removed using a circular crater to closely represent that of a quadratic ablation crater.

If we consider a LA experiment with $D = 50\,\mu\text{m}$, $f = 10\,\text{Hz}$, $v = 10\,\mu\text{m}\,\text{s}^{-1}$, and $T = 0.52\,\text{s}$ (40 isotopes analyzed using 10 ms dwell time and 3 ms settling time) as an example, the resulting parameters will be

$N_p = 50$, $N_{\text{scan}} = 5.2$, $O_c = 97\%$, $O_r = 98\%$ and an aspect ratio equal to the value of R.

Increasing v to $50\,\mu\text{m}\,\text{s}^{-1}$ results in

$$N_p = 5,\ N_{\text{scan}} = 5.2,\ O_c = 75\%,\ O_r = 80\% \text{ and an aspect ratio equal to 0.1 R.}$$

The higher translation speed in the second set may be problematic because only one pulse will be applied at each position of the sample during acquisition of all isotopes within the duration of a mass scan. It will therefore be difficult to describe the respective element distributions, unless the dispersion of the aerosol transport system leads to a decay period of the ion signals from a single laser pulse that is much greater than the scan duration. This will lead to substantial mixing of the aerosol from successive laser shots and make an unambiguous assignment of the ion signals to a specific location at the sample difficult.

When line scans are used, repetitive parallel scans can be used to construct a two-dimensional image [102]. When the depth of the ablation crater or scan line is smaller or comparable to the crater sizes used, the images obtained by this approach represent the elemental distribution within the material reasonably well. The quality of such images with respect to spatial resolution is significantly affected by the instrumental conditions of the sampling process, aerosol dispersion, and detection by the ICPMS. Larger crater sizes will lead to coarser images but increase the measurement sensitivity of the ICPMS when trace element patterns are of interest.

17.4.4
Inclusion Analysis

Analysis of fluid or melt inclusions may be considered a specific case of lateral and depth profiling of solids. Melt inclusions of a size of several micrometers for solids, or fluid inclusions of some tens of micrometers may be characterized by ‘‘drilling’’ out the respective volume holding the inclusion in a single-spot ablation [105]. Homogeneous melt inclusions are often analyzed by polishing the sample material to bring the inclusion close to the sample surface. The laser beam diameter may then be chosen to limit ablation to the inclusion material without analyzing the grain boundary and avoid mixing with the host material. When the entire inclusion needs to be analyzed or, in the case of fluid inclusions where sampling the entire inclusion can only be accomplished by removal of surrounding material, discriminating between the contributions from the inclusion and the host material may become a challenge for the quantification [106]. Opening inclusions, present in a material that is prone to cracking, is commonly achieved by opening the inclusion with a small beam diameter and stepwise increasing the crater size until the entire inclusion is removed [107].

17.5
Data Treatment

Solid sampling by LA-ICPMS is inherently affected by potential variations of the aerosol composition due to concentration changes in the sample analyzed. It is thus recommended to acquire ion signal intensities in time-resolved mode and at high frequency [108]. This approach allows evaluation of the intensity profiles in retrospect and to identify peculiarities in the transient signal. Figure 17.11 shows an example of the transient signals obtained from ablation of a silicate glass reference material (NIST (National Institute of Standards and Technology) SRM (Standard Reference Material) 610). The laser is started about 40 s after the data acquisition to record the instrumental background. Afterwards, the laser is fired for 70 s and

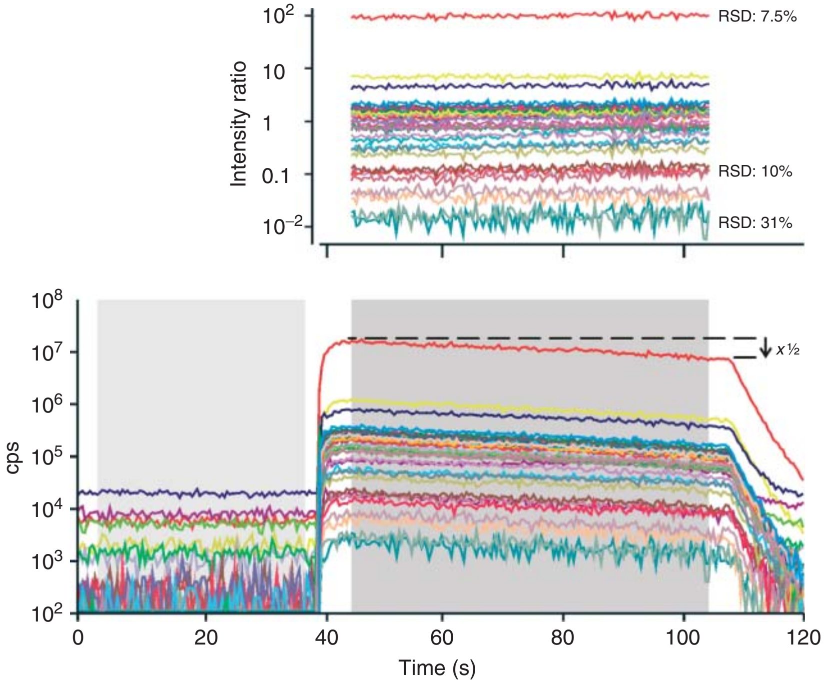

Figure 17.11 Time-resolved data acquired for single-spot ablation of a homogeneous sample (NIST 610 glass, 193 nm helium as carrier gas, quadrupole MS with 10 ms dwell time, 50 isotopes measured). Shaded areas indicate the integration period for instrumental background before ablation and the evaluated laser ablation signal. Top panel shows background-corrected ion signal intensities during the ablation period normalized to an internal standard (Ca).

the ion signal intensities (plus instrumental background) are registered. The raw ion signals exhibit a clear downward trend during the single-spot ablation, due to the increasing crater depth. While the ion signal intensities drop by 50%, the ratios of the background-corrected ion signal intensities, remain stable during the entire ablation period. The relative standard deviations (RSD) of the intensity ratios obtained depends mostly on the sensitivity of the isotope registered. For high-abundance isotopes, the intensity ratio is in the range of 7–10%, while isotopes of low abundance show a higher RSD of ≈30%.

Depending on the type of analysis, concentrations or intensity ratios may be calculated from the average ion signals measured, for example, for bulk analysis or single-spot ablation. Alternatively, when concentration profiles shall be obtained, a point-by-point evaluation is carried out, which can be transformed into the respective lateral or depth distribution. An example for ablation of an inhomogeneous synthetic sample is presented in Figure 17.12. In this case, element-specific profiles were obtained even for the chemically similar rare earth elements. Eu and Dy show high correlation to the internal standard cerium with relative standard deviations of 2%. Other rare earth elements show variations on the micrometer scale (Tm, Ho, Tb, and Pr) while especially Er exhibits a significantly different profile over the depth of the crater.

A remaining limitation before calculation of the ion signal intensities of a measurement is the lack of suitable blank samples that would allow determination of the true background signal intensities. Currently, most often only the instrumental background or gas blank is subtracted from the measured ion signal intensities. This approach is reasonably accurate as most isotopes of interest are not affected by

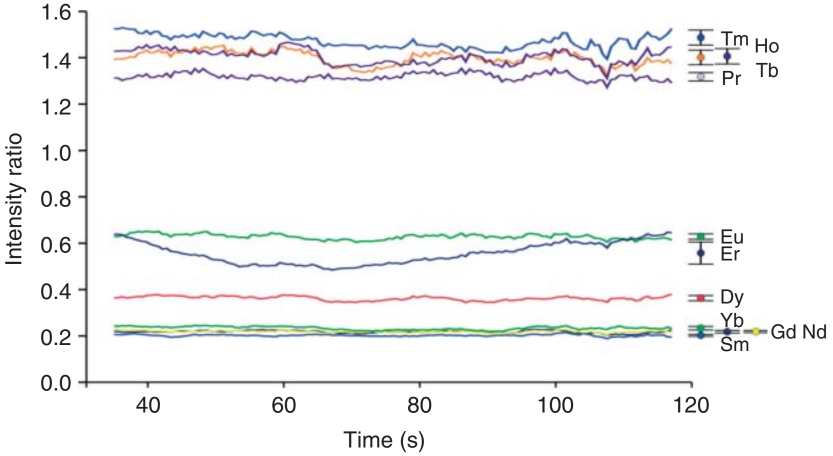

Figure 17.12 Intensity ratios of rare earth elements obtained from single-spot ablation, normalized to $^{140}Ce^+$. Average values of the intensity ratios are indicated by symbols with error bars representing one standard deviation of the measurement. Laser ablation was carried out using a crater diameter of 60 μm and reached a depth of ∼140 μm depth after 90 s.

spectral interferences from the instrument background or memory effects (Figure 17.6). Whenever such interferences occur, however, their abundance in the spectrum may differ from the gas blank when the laser-generated aerosol is introduced into the ICP [94]. This may especially impair the evaluation of Si, P, S, Cl, K, Ca, Cr, Mn, and Fe, where background intensities are significant on all major isotopes (Figure 17.6).

Data analysis in LA-ICPMS is most often carried out using off-line methods by importing raw analysis data into specific software or spreadsheet programs [109]. These allow setting specific integration periods covering the gas blank and the ablation signals. The average background signal intensity is then subtracted either from the raw ion signals of each data point or from the average signal intensity of the integrated ablation signal respectively. Average concentration values or concentration profiles can be directly obtained when the sensitivity ratios are available after a corresponding calibration.

To determine the limit of detection in LA-ICPMS one needs to take into account that the sample mass analyzed in each acquisition cycle of the ICPMS may change, for example, due to temporal variation of the ablation rate, leading to changes in element sensitivity during the analysis. In addition, when the transient signals shall be evaluated on a point-by-point analysis, the uncertainty of a single measurement is different from that represented by an average of a large number of measurements. To assess the low limit of ion signal intensities that can be determined above the instrumental background the following equation can be used [108]:

$$\mathrm{LOD} = 3 \times \mathrm{SD}_{\mathrm{BG}} \times \sqrt{\frac{1}{N_{\mathrm{BG}}} + \frac{1}{N_{\mathrm{Signal}}}}$$

where LOD is the limit of detection, expressed in ion signal intensities; $\mathrm{SD}_{\mathrm{BG}}$ is the standard deviation of the instrumental background measurements; N_{BG} is the number of data points acquired for the instrumental background, and N_{Signal} is the number of data points used for calculating the ion signal intensity.

As a consequence of this treatment, the average ion signal intensities that can be detected above the instrumental limit of detection depend on the mode of analysis. Point-by-point evaluation can lead to lower average signal intensity because a greater number of data points are excluded from the calculation of the average value when the ion signal intensities are close to the LOD of the individual measurement.

Because background signals often exhibit very low intensities, calculation of the standard deviation based on a normal distribution may not be adequate in all cases [110]. A normal distribution may be considered only if the background signal is >70 counts per acquisition on average. Until today, however LOD*s* are typically calculated by assuming a normal distribution for the background signals. It should be noted that this will typically underestimate the actual value, especially when the background signal intensities are close to zero.

17.5.1
Qualitative Analysis

Qualitative analysis in the context of *LA-ICPMS* refers to the evaluation of ion signal intensity ratios for different elements without calculation of absolute concentrations. This approach is most often applied when no suitable internal standard is available for quantification and when specific ‘‘fingerprints’’ of the intensity ratios are sufficient to discriminate individual samples by means of statistical analysis. Forensic [111–113] and authenticity testing [114, 115] are prominent fields of application where such fingerprinting is frequently used. The intensity ratios may be calculated from average ion signals, resembling the mean local concentration ratios or as a profile across a sample or in depth. Averaging an increasing number of data points will improve the uncertainty of the respective intensity ratios and thus the discriminating power of the approach. For lateral or depth profiles, the number of data points to be averaged needs to be balanced with respect to the desired spatial resolution.

17.5.2
Quantitative Analysis

When quantitative concentration values are to be calculated, the use of LA-ICPMS relies on the availability of one or more internal standard(s). This internal standard needs to compensate for matrix-dependent ablation rates, instrument drift, and potential variations in sensitivity, caused by the ICPMS. When the concentration of such an internal standard is known a priori or can be deduced from the chemical composition of the sample, the intensity ratios measured can be related to the sensitivity ratios, according to a calibration standard, to calculate the element concentration:

$$C_{\mathrm{E}}^{\mathrm{S}} = I_{\mathrm{E}}^{\mathrm{S}} \cdot \frac{C_{\mathrm{IS}}^{\mathrm{S}}}{I_{\mathrm{IS}}^{\mathrm{S}}} \cdot \frac{C_{\mathrm{E}}^{\mathrm{Cal}}}{I_{\mathrm{E}}^{\mathrm{Cal}}} \cdot \frac{I_{\mathrm{IS}}^{\mathrm{Cal}}}{C_{\mathrm{IS}}^{\mathrm{Cal}}}$$

where C *is the* concentration, I is the ion signal intensity (background corrected), S is the unknown sample, Cal is the calibration standard, E is the analyte element, and IS is the internal standard element.

This approach assumes that no non-spectral interferences are leading to changes of the relative sensitivities of the analyte element and the internal standard during the analysis or that the magnitude of these effects is identical for calibration standard and unknown sample. Furthermore, the ion signal intensities need to be acquired interference free or appropriate corrections have to be applied [108]. As mentioned earlier, true blank samples are usually not available for solid materials, which limit the effectiveness of the blank correction, by simply assuming that the abundance of background ions in the gas blank is not affected by the presence of the aerosol inside the ICP.

In an ideal case, matrix-matched calibration standards can be used to establish the sensitivity ratios necessary for quantification. The broad range of compositions of solids, however, renders this highly difficult for all materials under investigation. Unfortunately, the availability of calibration standards that contain a wide range of elements at concentration levels suitable for LA-ICPMS is still limited. Furthermore many of these materials are actually not certified for elemental concentrations at trace and ultratrace levels or even major and minor constituents. Nonetheless, LA-ICPMS has been employed for quantitative analysis in a wide range of applications. Many of these are related to geochemical investigations where reference materials of similar composition are available for a wide range of matrices. The NIST glass standard reference materials 612 and 610 are fairly frequently used because they contain most elements of the periodic table at concentration levels readily detectable by LA-ICPMS. In addition, a variety of vitrified natural geological samples are being used (e.g., BCR-2G), which have been characterized for a wide range of elements. Glasses are particularly attractive as calibration standards because they can be produced most homogeneously. Moreover, there is a wide range of metallic reference materials available, which have been characterized by a variety of methods and thus should be suitable as calibration standards for related applications. For many other materials, such as polymers or tissue, for example, calibration standards may be very difficult to obtain. In this case, quantification may be carried out after calibration with materials of similar matrix composition, which have been characterized by independent methods. The calibration standard's homogeneity with respect to the elements of interest, however, is often not explicitly known and needs to be tested before the material can be used.

Provided that the calibration material is long-term stable with respect to composition and that the element concentrations are well established, a single reference sample may be used to establish the sensitivity ratios for calibration. When this cannot be assumed, various reference materials have to be considered to estimate the respective uncertainty of the sensitivity ratios and this uncertainty ultimately needs to be included in the quantification.

A few reports have proposed the use of isotope dilution (ID) as an alternative to external calibration also for LA-ICPMS. ID, however, requires the chemical equilibration of an isotopically enriched spike with the sample matrix, which is more difficult to ensure when solid samples are under investigation. The only approach that may ensure the equilibration is fusion of the material with the spike into glasses that can be analyzed with LA [116]. Several other approaches have applied addition of dissolved spike solutions to a powdered sample and pressing the thoroughly mixed, dried powder into pellets before analysis [117–119]. The accuracy obtained in these analyses was satisfactory but not in all cases was better than when using external calibration methods. This may be partly because the ablation of pressed powders often results in ''noisy'' ion signal intensities, caused by the release of large particulates from the pressed pellets. In addition, it may be questioned whether chemical equilibration of the isotope spike is actually always ensured in this approach. Equilibration can only be ensured when no preferential evaporation of the spike from the surface of the powder particles occurs and when the entire aerosol reaching the ICP is formed by condensation of a well-mixed vapor phase after the ablation. Both conditions may not be assumed to be fulfilled in general, and any deviation will induce some bias in the analytical results. However, even though ID can only be applied for elements where at least two isotopes can be detected interference free by ICPMS, it may be a viable way for the characterization of materials, where calibration standards of similar matrix are not accessible at all.

In specific cases also, external calibration using nebulized solutions may be applied. Here, the aerosol generated by LA is mixed with an aerosol from solution nebulization before entering the ICP. Calibration curves can then be obtained from synthetic solutions that contain the analyte elements and the internal standard without firing the laser [120–122]. During analysis by LA a blank solution is nebulized to achieve comparable ICP operating conditions. Despite the flexibility of this approach, drawbacks may occur through increased abundance of polyatomic ions from the solvent, potentially higher blank signal intensities due to contamination, and, most importantly, differences in the sensitivity ratios of analyte and internal standard due to different vaporization efficiencies for droplets and laser-generated particles.

17.5.2.1 **Internal Standardization**

The internal standard for LA-ICPMS measurements mainly compensates for instrumental drift and changes in the ablation rate of the sample and between samples and calibration standards. In most cases, a matrix element is therefore used, whose concentration can be determined by an independent method such as X-ray fluorescence or electron probe microanalysis (EPMA). It needs to be present in calibration standards and samples and should be sufficiently abundant to ensure reproducible measurements and to mitigate influence from potential spectral interferences. When elemental fractionation occurs and no calibration standard of very similar composition is available, individual elements may be classified in accordance to their fractionation trend [90] and more than one internal standard needs to be employed for quantitative analysis.

As an alternative to single element internal standardization, matrix or 100% normalization has been applied [123, 124]. In this case, initially the sensitivity ratios of the elements to one reference element are determined by relating the sensitivity ratios to those of an external standard. After calculating the concentration ratios for all elements, each concentration ratio can be normalized to the sum of all ratios, resulting in the respective mass fractions present in the analyzed sample:

$$C_{\mathrm{E}}^{\mathrm{S}} = \frac{\frac{I_{\mathrm{E}}^{\mathrm{S}}}{I_{\mathrm{IS}}^{\mathrm{S}}} \cdot \frac{C_{\mathrm{E}}^{\mathrm{Cal}}}{I_{\mathrm{E}}^{\mathrm{Cal}}} \cdot \frac{I_{\mathrm{R}}^{\mathrm{Cal}}}{C_{\mathrm{R}}^{\mathrm{Cal}}}}{\sum \frac{I_{\mathrm{E}}^{\mathrm{S}}}{I_{\mathrm{IS}}^{\mathrm{S}}} \cdot \frac{C_{\mathrm{E}}^{\mathrm{Cal}}}{I_{\mathrm{E}}^{\mathrm{R}}} \cdot \frac{I_{\mathrm{R}}^{\mathrm{Cal}}}{C_{\mathrm{R}}^{\mathrm{Cal}}}} \times 100\%$$

where C is the concentration, I is the ion signal intensity (background corrected), S is the unknown sample, Cal is the calibration standard, E is the analyte element, R is the reference element, and IS is the internal standard element.

In order to make use of this approach, however, all elements contained in the sample would have to be detectable by the ICPMS. In the presence of elements that cannot be detected by ICPMS such as H, N, O, or F, this procedure can still be used when the stoichiometry of each element is known. For silicate glasses, for example, one may assume that the elements are present in the form of oxides whose stoichiometry is known. In this case, all concentration ratios can be transformed into the respective element–oxide concentration ratios, which can be normalized in the same way. When compounds are present where none of the elements can be determined by ICPMS such as crystal water, for example, the normalization factor (100%) may be adjusted to the fraction of the detectable elements if the difference can be estimated or determined by another method.

17.5.3
Isotope Ratio Determination

A steadily increasing number of applications utilize LA-ICPMS for *in situ* isotope ratio measurements. It is particularly attractive when sample specimens are very small; spatially resolved profiles of isotope ratios within a sample shall be acquired or if the samples are difficult to digest for analysis by conventional ICPMS methods [125, 126]. In most cases, MC-ICPMS are used for such applications because the parallel detection of the isotope signals substantially improves the isotope ratio precision compared to single collector instruments [69]. Furthermore, sector field MC-ICPMS provides very high sensitivities, allowing detection of isotopes with very low abundance. Typical applications include age determinations based on parent/daughter decay series such as U/Pb [126], U/Th [127], or Sr isotopes [128]. Other investigations study isotope fractionation by natural processes (e.g., S, Fe, and Os) [16, 129, 130] or for discriminating sample populations based on the isotope signature of characteristic elements (e.g., Sr in teeth and bones) [131, 132].

As in MC-ICPMS, with conventional nebulization, an important aspect in the accuracy of the measured isotope ratios is the correction for mass discrimination [133]. In addition, isobaric and polyatomic interferences become a greater problem because separation of the elements of interest from the sample is not possible with LA sampling [131]. Furthermore, it has been demonstrated that isotope fractionation may occur during the ablation process [134, 135]. The precision of the isotope ratios determined with LA sampling is thus by about an order of magnitude inferior to those achievable with conventional methods for comparable ion signal intensities.

As in conventional solution-based methods, the accuracy of the isotope ratio measurement depends to large extent on the quality of the correction for mass discrimination. Standard sample bracketing requires availability of a solid sample with well-known isotope abundance to establish the mass discrimination correction of the instrument before and after analysis of the unknown sample. This approach is most effective when the bracketing standard is of very similar composition as the unknown sample and when only a small drift occurs on the timescale of the measurements. Also, internal normalization is possible when the element has at last two isotopes whose abundance ratio is known a priori. In this case, the mass discrimination can be assessed from the measured ratio of the invariant isotope pair using mathematical approximations [136]. The most frequently used approximations of mass discrimination make use of the power law

$$r = R \cdot g^{(m_1 - m_2)}$$

or the exponential law

$$r = R \cdot \left(\frac{m_1}{m_2}\right)^{\beta}$$

where r is the measured isotope ratio, R is the true isotope ratio, m_1 is the mass of the heavier isotope, m_2 is the mass of the lighter isotope, and g, β are the mass discrimination coefficients.

Both methods are successfully used to improve the accuracy of isotope ratio determinations. One should keep in mind however that these correction formulae have been derived empirically and do not necessarily describe the relative ion transmission in the ICPMS accurately. In a similar manner, heteroelement normalization can be used, where the mass discrimination coefficient is determined from the measured isotope ratio of another element with known isotope abundance [137]. This element is either present in the sample at detectable levels or added to the laser-generated aerosol, for example, by continuous solution nebulization. Minute differences in the mass bias coefficients of different elements, however, will lead to greater inaccuracies and uncertainty of the result. Correction for spectral interferences is also usually carried out by using a single mass discrimination coefficient for analyte and interference isotopes. Thus, unless the contribution of the interference is comparably small, the deviation in the actual mass discrimination from the assumed value may introduce an additional bias.

17.6
Summary and Outlook

LA-ICPMS has grown into a mature technique for direct elemental analysis of solid samples in many applications. The technique has several advantages based on the conceptual simplicity of combining an atmospheric pressure ion source with a sampling system that allows spatially resolved analysis at the micrometer scale. Depending on the spatial and depth resolution, high elemental sensitivity can be obtained, providing limits of detection in the low milligram/kilogram or even microgram/kilogram range (Figure 17.13). LA-ICPMS furthermore offers the possibility to optimize the sampling and detection process individually, which helps reduce the matrix dependence of analyte sensitivities. Thus, non-matrix-matched calibration can be performed in many applications, significantly relaxing the requirements with respect to the composition of the calibration standards, compared to other direct solid analytical techniques.

Prevailing shortcomings predominantly lie in the still limited detection efficiency, especially for ions of low m/z and the occurrence of elemental fractionation effects in specific samples. Ongoing developments of ICPMS and LA instruments, especially the availability of femtosecond-lasers, are nonetheless expected to further improve the general applicability of the technique.

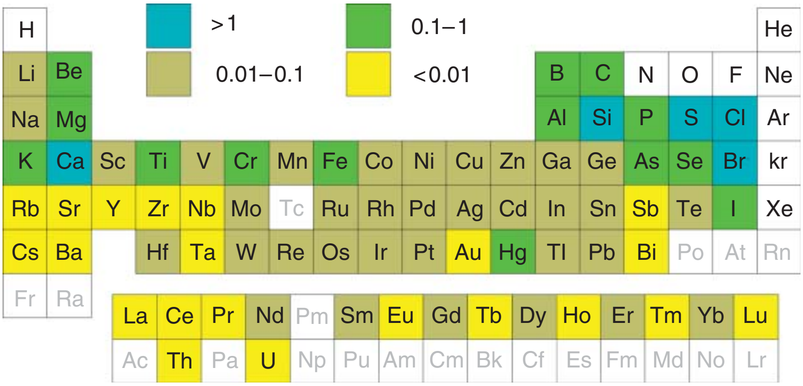

Figure 17.13 Approximate limits of detection in milligram/kilogram for elements in silicate glass using LA-ICPMS, determined using a 193 nm excimer laser, 40 µm crater diameter, 10 Hz pulse repetition rate, 20 J cm^{-2} fluence and helium as carrier gas coupled to a quadrupole ICPMS.

The roots of the technique are in geochemical research, where the distinct advantages of the technique were realized first, and LA-ICPMS is expected to remain an important analytical tool in this context. The distinct improvements in the past 20 years, however, have led to a significantly broader range of applications, which is expected to further increase in the near future.

In comparison with other techniques for spatially resolved solid sample analysis, LA-ICPMS may be positioned between EPMA and secondary ion mass spectrometry (SIMS), in terms of detection capabilities. Avoidance of high vacuum at the sampling site, on the other hand, increases the spectrum of applications significantly.

Future developments with respect to the ICPMS may include the development of more robust ion sources, to reduce fractionation effects caused by preferential vaporization. Furthermore, higher detection efficiencies may be realized to allow analysis from even smaller sample quantities and eventually approach the sub-micrometer range in spatial resolution. On the side of LA, more powerful femtosecond lasers may become available, which would achieve higher ablation rates for transparent materials and reduce elemental fractionation during the sampling process. Broader use as a routine technique will depend on the availability of integrated data acquisition schemes that allow unattended operation and automated data reduction for a large set of samples.

17.6.1
Characteristics, Figures of Merit, Applications

LA instrumentation used in commercially available systems and laboratory prototypes for LA-ICPMS are given below.

Laser type	**Wavelength (nm)**	**Pulse duration**	**Beam profile**	**Output energy (mJ)**	**Pulse repetition rate (Hz)**
Nd:YAG	266 (λ/4) 213 (λ/5)	5–10 ns	Flat top	≈5	≤20
ArF-Ecximer	193	5–20 ns	Homogenized	≈5	≤100
Ti:sapphire	≈800	≈150 fs	Gaussian	<5	≤10 000
	≈265 (λ/3)			<0.5	
	≈200 (λ/4)			<0.05	

Mass spectrometer configurations and their characteristics with respect to LA sampling are as follows:

Type	**Mass resolution ($m/\Delta m$)**	**Scan frequency**[a]	**Detection efficiency**[b]	**Detector range**
Quadrupole	<350	2–500 Hz	10^{-7} to 10^{-4}	10^9 SEM
Sector field	300	2–500 Hz	$10^{-6}$to 10^{-3}	10^9 (10^{12} with FC)
	3000		$10^{-7}$to 10^{-4}	
	12 000		10^{-8} to 10^{-5}	
Multicollector	300 (<10 000)[c]	N.a.	10^{-6} to 10^{-3}	10^3 (FC), 10^6 (SEM)
Time of flight	<3000	20–30 kHz	10^{-8} to 10^{-5}	10^6 SEM

FC, Faraday cup; SEM, secondary electron multiplier.

[a] Depends on number of isotopes, dwell time, and settling time of the MS.

[b] Typical values for analyses of silicate glass. Depends on particle size distribution and composition of the laser-generated aerosol.

[c] Mass resolving power in "pseudo high resolution" mode.

Figures of merit for LA-ICPMS instrumentation are as follows:

Beam diameter/lateral resolution	4–200 µm
Ablation rate	0.01–0.3 µm/pulse
Typical analysis time	120 s/sample (single-spot analysis)
Reproducibility	5–30% RSD ($C > 10 \times$ LOD)
Isotopes/analysis	2–50[a]
Elements detectable	68[b]

[a] Principally, more than 50 isotopes can be analyzed in LA-ICPMS but correlation of ion signal intensity degrades when acquired by sequential MS.

[b] Only considering naturally occurring elements. Radiogenic or synthetic isotopes are principally also detectable when not affected by spectral interferences.

Applications are as follows:

Geochemistry	Bulk element composition of mineral grains [138] Partition coefficients of elements among different phases [139, 140] Analysis of melt and fluid inclusion [105, 141–143] Isotope ratio measurements for age determination [144–146] Tracer studies
Materials science	Bulk element composition of difficult-to-digest materials [147] Elemental distribution Characterization of composition and thickness of layers [97, 148] Impurities and contamination from the production process Characterization of inclusions Trace element determination in plastics [149]
Forensic science	Elemental fingerprints of specimens from scenes of crime, investigation of authenticity, or origin [112]
Bioscience	Metal, sulfur, or phosphorus determination in macromolecules after separation using gel electrophoresis in one or two dimensions [150, 151]
Gemology	Authenticity of gemstones [152, 153] Identification of gemstones that were synthetically enhanced by trace element doping
Medicine	Trace element distribution in thin sections of tissue, bone, hair, and nails [154, 155]

Section VI
Methods 5: Surface Analysis

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

Introduction

Surface analysis uses different means of the *probe* techniques of the surface leading to a *response*, an *analytical signal* serving as a source of *analytical information*. The probe/response combinations used in surface analysis are very bright, including electrons, ions, photons, neutrals, heat, and electric field. Practically all combinations may form the basis of techniques used in surface analysis and so their list is rather long and should by no means be considered to be complete. This is also due to fact that very subtle variations of a technique sometimes become known by their own name and acronym. Some of these acronyms along with the references to the text are listed in the Appendix.

There are several ways of classifying the surface analysis techniques [1, 2].

According to the used probe, we have:

1) *photon probe techniques*, divided further according to fundamental process to:
   a. scattering techniques (Raman spectroscopy),
   b. absorption techniques (infrared spectroscopy, extended X-ray absorption fine structure (EXAFS), surface extended X-ray absorption fine structure (SEXAFS), and near-edge X-ray absorption fine structure (NEXAFS)),
   c. emission techniques (ultraviolet photoelectron spectroscopy (UPS), X-ray photoelectron spectroscopy (XPS), laser micro mass spectrometry (LAMMS)).
2) *electron probe techniques*, based on:
   a. elastic scattering processes (transmission electron microscopy (TEM), reflection electron microscopy (REM), low-energy electron microscopy (LEEM), backscattered electron imaging (BSE), transmission high-energy electron diffraction (THEED), low-energy electron diffraction (LEED), reflection high-energy electron diffraction (RHEED)),
   b. inelastic processes (reflection electron energy loss spectroscopy (REELS), transmission electron energy loss spectroscopy (TEELS), electron probe X-ray microanalysis (EPXMA), Auger electron spectroscopy (AES), and scanning electron microscopy (SEM)).
3) *ion probe techniques*, based on
   a. elastic scattering processes (Rutherford backscattering spectrometry (RBS), medium energy ion scattering (MEIS), ion scattering spectroscopy (ISS), and elastic recoil detection (ERD)),

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

   b. inelastic processes (nuclear reaction analysis (NRA), charged particle activation analysis (CPAA), secondary ion mass spectrometry (SIMS), and sputtered neutral mass spectrometry (SNMS)).
4) *field probe techniques* (scanning tunneling microscopy (STM)).

International Union of Pure and Applied Chemistry (IUPAC) Compendium of Analytical Nomenclature, Definitive Rules 1997 [2] recommends following schema:

1) *the electron, photoelectron, and related spectroscopies*
   a. The photoelectron emission spectroscopies (UPS/UPES, XPS/XEPS, DSPES (depth-selective photoelectron spectroscopy), synchrotron radiation photoelectron spectroscopy (SRPES), scanning electron spectroscopy for chemical analysis (SECSA), photoelectron diffraction (PED), angle-resolved photoelectron spectroscopy (ARPS/ARPES)),
   b. Electron impact spectroscopies (high-resolution electron energy loss spectroscopy/high electron energy loss spectroscopy (HREELS/HEELS), electron energy loss spectroscopy (EELS), electron energy loss fine structure/extended electron energy loss fine structure (EELFS/EXELFS), ionization spectroscopy (IS), and electron transmission spectroscopy (ETS)),
   c. Electron-induced photon emission spectroscopies (inverse photoemission spectroscopy (IPS), Bremsstrahlung isochromat spectroscopy (BIS), and Bremsstrahlung spectroscopy (BS)),
   d. Appearance potential spectroscopies (soft X-ray appearance potential spectroscopy (SXAPS), Auger electron appearance potential spectroscopy (AEAPS), disappearance potential spectroscopy (DAPS), total current spectroscopy (TCS), X-ray excited electron appearance potential spectroscopy (XEAPS), extended (electron) appearance potential fine structure analysis (EAPFS), and inelastic electron tunneling spectroscopy (IETS)),
   e. Auger electron spectroscopies (electron-excited Auger electron spectroscopy (EAES), scanning Auger microscopy (SAM), angle-resolved Auger electron spectroscopy (ARAES), spin-polarized Auger electron spectroscopy (SPAES), ion-excited Auger electron spectroscopy (IAES), and Auger electron (emission) spectroscopy (AEES)),
   f. The electron coincidence spectroscopies.
2) the photon spectroscopies resulting from the use of electromagnetic radiation (total reflection X-ray fluorescence (TXRF)),
3) neutron and ion scattering
   a. Ion scattering (ISS, RBS),
   b. Inelastic neutron scattering (INS),
   c. Ion neutralization spectroscopy (INS).
4) mass spectroscopy
   a. Secondary ion mass spectrometry (SIMS),
   b. Fast-atom bombardment mass spectroscopy (FAB MS),
   c. Field-ion mass spectroscopy (FIMS).
5) other spectroscopic techniques
   a. Metastable desorption spectroscopy (MDS),

    b. Inverse photoelectron spectroscopy (IPES/BIS).
6) desorption and related techniques
    a. Thermal desorption spectroscopy (TPD),
    b. Temperature-programmed reaction spectroscopy (TPRS).
7) spectroscopy/diffraction hybrids
    a. X-ray photoelectron diffraction (XPD),
    b. Extended X-ray absorption fine structure,
    c. Surface extended X-ray absorption fine structure (SEXAPS),
    d. Near-edge X-ray absorption fine structure/X-ray absorption near-edge structure (NEXAFS/XANES).

For practical purposes, a discrimination of the methods can be done according to information obtained on:

- surface elemental composition
- chemical bonding and molecular composition
- surface electronic structure.

In this section, an attempt is made to present the fundamentals of some of the spectroscopic methods used for characterization of surfaces. As shown, the spectroscopic methods represent a very important part of the arsenal used for characterization of surfaces, but in many cases it is difficult to separate the spectroscopic principals of a particular method from those of closely related techniques. Also, the usage of the term *spectroscopy* is sometimes confusing. A broader definition of spectroscopy will be accepted here, embracing not only an interaction of matter with electromagnetic radiation/photons but also the interactions with particles (electrons, ions, and molecules). Diffraction, desorption, microscopic, and imaging methods have been excluded from the discussion, but we are not quite rigorous in some cases where these methods are very closely connected with related spectroscopic methods.

Definition of the Surface

Surface is a poorly defined term. The IUPAC recommendation is to distinguish three terms: surface in general, physical surface, and experimental surface [2–4].

Surface (general) is the ‘‘outer portion’’ of a sample of undefined depth. This term is to be used in general discussions of the outside regions of the sample.

Physical surface is the outermost atomic layer of a sample (this is the layer that would be in direct contact with the vacuum if the sample were placed in a vacuum).

Experimental surface is that portion of the sample with which there is significant interaction with the particles or radiation used for excitation. It is the volume of sample required for analysis, or the volume corresponding to the escape of emitted radiation or particles, whichever is larger.

A typical problem of surface analysis is a study of a material deposited or adhered to a substrate. Coverage of a substrate by one atomic or molecular layer of a species is called *monolayer*. The term *multilayer* designates that more than one layer of a species covers the substrate. In contrast to the monolayer, in this case not all elementary units of the layer are in contact with the surface layer of the substrate. *Surface coverage* for both monolayer and multilayer coverage is defined as the ratio of the amount of substance covering the surface to the monolayer capacity. Coverage equals unity for one complete monolayer on the substrate. The *film* is a material which has been deposited or adhered to a substrate and has a uniform thickness within 20% of its average thickness, which is $<10\,\mu m$.

A major problem of all surface methods is their sensitivity. Among the surface techniques, only a limited number of atoms must be detected. Contained in a $1\,cm^3$ bulk sample is about 10^{22} molecules, in one $1\,cm^2$ of the surface only about 10^{15}, and when following a component present at the 1% level, a technique sensitive to about 10^{13} atoms is needed. A *surface-sensitive technique* is more sensitive to the atoms located near the surface than to the atoms in the bulk. A *surface-specific technique* gives signals due to atoms of the physical surface only. The mass fraction of the component in the experimental surface divided by its total amount in the volume of interest is often called *surface concentration*. It can be given in terms of atoms (particles) (ppm) or in terms of mass ($\mu g\,g^{-1}$).

Selection of Method

There are many criteria according to which the method can be selected [5]. A detailed discussion of the decision steps has been described in detail elsewhere. A survey of the method is given in the Reference data table along with some characteristics (Table 1). This table allows one to select the method according to information needed and its parameters. Some tentative figures are also given, allowing an estimate of the price and availability of a suitable laboratory to be made.

At present, the most popular techniques for chemical surface characterization are XPS, AES, SIMS, and also infrared (IR) techniques, which bring different and complementary information.

The critical point of surface analysis is to prevent any changes to the surface before or during the experiment; because of this, most methods do not allow one to carry out the technique *in situ*, as ultrahigh vacuum(UHV)isneeded.

UHV is required for most surface analysis techniques for several reasons:

- to have sufficient mean free path of the probe and detected particles (electron, ions, and atoms),
- to eliminate the signal from interaction of the probe particle with the molecules in the gas phase,
- to preserve a reproducibly clean surface during all measurement.

Even though the first two requirements allow work at pressures better than 10^{-2} Pa, contamination of the surfaces occurs in <1 s at this pressure. It means that for maintenance of a clean surface, pressures lower than 10^{-7} Pa are needed. These pressures are now routinely obtainable.

Another problem is connected with sputtering and heating of the surface.

Table 1 Reference data table.

Technique[a]	Sample[b]		Conditions[b]	Surface specificity		Resolution		Time needed for analysis

[a] Data for techniques in the normal fonts are taken from Ref. [5] and have been compiled from a questionnaire action; data given in italics are only an estimate of the authors of this chapter.

[b] s, solid; l, liquid; cr, crystal; c, (solid), conductor; V, vacuum; UHV, ultra high vacuum; ML, monolayer; th, thin film.

[c] Diameter or area.

Surfaces in UHV are initially covered in ‘‘crud’’ that is associated with prior exposure to atmosphere. This normally consists of several monolayers of oxide and adsorbed hydrocarbons that need to be cleaned away by argon ion bombardment to permit analysis of the sample by a surface-sensitive technique. This process of sputter cleaning can change the surface composition and/or structure, and is not always successful at removing all contamination.

Interaction of the highly energetic particles with the sample may also result in heating of the targeted parts (especially for thermally nonconductive samples) and additional cooling may be required to minimize this effect.

For some methods, erosion of the surface is inherent. This is typical for dynamic SIMS, where the sputtered particles are analyzed.

A survey of the individual techniques will be given in three chapters, divided up according to whether the excitation source used is electrons (Chapter 18), ions or neutrals (Chapter 19), or photons (Chapter 20). Owing to limited space, only selected techniques are discussed in detail and characterized by its underlying principle, instrumentation, sample requirements, characteristic spectral features, extractable analytical information, performance criteria, and main areas of application.

Acknowledgments

The authors thank Graham Beamson, RUSTI, Daresbury Laboratory, Warrington, UK, for the permission to use data from the Scienta X-ray Photoelectron Spectrometer and to Jiri Homola, Institute of Radioengineering and Electronics, Academy of Sciences of the Czech Republic and University of Washington, Department of Electrical Engineering, Seattle, USA, for cooperation on some parts of this chapter.

18
Electron Probe Techniques

Christopher George Havelock Walker

Excitation of surfaces with electrons is accompanied by the release and detection of secondary electrons or photons and only a limited number of techniques use detection of neutrals or ions, for example, electron-stimulated desorption. To the first group, detecting secondary electrons, belongs Auger electron spectroscopy (AES) that is the workhorse technique for characterizing the elemental constituents of a surface. Another popular technique is electron energy loss spectroscopy (EELS) that can provide information regarding the electronic and optical dielectric properties of a surface. As for photon excitation, energy dispersive X-ray spectroscopy (EDXS) is in common use, although the volume to which it is sensitive is typically a micron or more below the surface and so not as surface sensitive as many techniques. More recently, developed techniques such as scanning tunneling spectroscopy can provide details of the electronic structure at very high spatial resolution. Certain techniques can use a spin-polarized source beam or detect spin-polarized emission. These techniques often find uses in the analysis of magnetic samples.

Individual techniques are presented in alphanumerical order.

18.1
Appearance Energy Spectroscopy

18.1.1
Introduction

Also known as Appearance Potential Spectroscopy. The energy of an incident ionizing radiation (usually electrons) is gradually increased such that the energy passes over the ionization threshold of a core level of an atom in the surface being studied [1]. This is the basis of the appearance potential spectroscopies. In the case of disappearance potential spectroscopy (DAPS), the onset of ionization is detected by a reduction in the intensity of the elastically scattered beam. For Auger electron appearance potential spectroscopy (AEAPS), the Auger electron current is measured as the incident beam energy is increased. For soft X-ray appearance potential spectroscopy (SXAPS), it is the appearance of X-ray emission

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

that is detected. If the incident radiation is X-rays, then the methods are more generally known as extended X-ray absorption fine structure (EXAFS) and related techniques. It should be noted that the term *appearance potential* is deprecated. However, alternative names for the various appearance potential spectroscopies have not been decided upon.

18.1.2
Instrumentation

The measurement is carried out in an ultrahigh vacuum (UHV) chamber. Electrons from an electron gun in the energy range 50–2000 eV are directed onto the sample. The incident electron energy is gradually increased. In the case of DAPS, the elastically scattered primary electrons are detected using a retarding field analyzer (RFA). As the energy of the incident beam passes through an ionization edge, the number of elastically scattered electrons drops slightly.

In the case of AEAPS, it is not necessary to detect individual Auger peaks, as the total secondary electron yield can be measured instead. The electron cascade within the material can act as an electron multiplier increasing the AEAPS signal. Hence, an RFA could be used or an electron detector of a type used in a scanning electron microscope (SEM).

For SXAPS, the instrumentation is very simple. A filament is used as a source of electrons and is mounted close to the sample. The electrons from the filament are accelerated toward the sample. A screening mesh in front of the detector allows X-rays to pass into the detector, but not electrons. The X-rays cause photoelectrons to be emitted from the wall of the detector and these photoelectrons are collected on a thin wire. The detector has a superficial similarity to a Geiger–Muller tube. UHV is not needed for the instrumentation (this is especially true for SXAPS), but a clean surface is necessary for reliable data.

18.1.3
Sample

Conducting samples that survive well in UHV are normally studied. Insulating or biological samples will usually degrade in the beam.

18.1.4
Analytical Information

The elemental composition within the surface may be determined, but quantification is difficult. In addition, information regarding the empty density of states (DOSs) can be revealed. Therefore, it supplies complementary information to inverse photoelectron spectroscopy (IPES) and scanning tunneling spectroscopy (STS).

18.1.5
Performance Criteria

Typically, a content of ~5 at% in the surface region can be determined or alternatively ~20% of one monolayer covering the surface. These estimates are very much dependent on the material as there are large variations in sensitivity depending on the density of empty states within the sample.

The change in the elastically scattered yield when the primary beam energy passes through an ionization threshold is typically 0.1%. Hence, electronic differentiation is used to enhance the weak signal. AEAPS is ~10 times more sensitive than DAPS. SXAPS is ~10 000 times less sensitive than DAPS and hence is the least used despite its simple instrumentation.

18.1.6
Applications

Appearance potential spectroscopy (APS) is used to determine the empty DOSs and elemental composition of conducting materials. Currently, a little used technique.

18.1.7
Other Techniques

Total (or target) current spectroscopy (TCS) is similar to DAPS, but it is a very low-energy technique (0–15 eV) and all the secondary electrons originate from the valence band.

18.2
Auger Electron Spectroscopy

18.2.1
Introduction

An incident-exciting beam (normally electrons) is directed at a surface [2–8]. The atoms in the surface enter an excited state and can relax by the emission of an Auger electron, which has a characteristic energy. The energy spectrum of Auger electrons (20–2000 eV) emitted following the primary ionization of a core energy level can reveal the chemical composition of the surface layers.

18.2.2
Instrumentation

The measurement is carried out in an UHV chamber. Fixed energy electrons from an electron gun in the energy range 100 eV to 10 keV are directed on to the sample (beam diameter 3 nm to 1 mm). The electrons from this primary beam excite electrons from the surface (known as *secondary electrons*) and some of the primary electrons are scattered from the nuclei of the surface atoms to create backscattered primary electrons. The primary beam of electrons can also cause atoms in the surface to emit Auger electrons, which have energies characteristic of the element that emitted them. Some of the electrons emitted from the surface pass through an aperture and into an electron energy analyzer, which selects electrons over a narrow range of energies, and these electrons are then detected. A spectrum is obtained as the first or second derivative of the secondary electron current by changing the voltages on the electron energy analyzer such that the energy of electrons that passes through the analyzer is gradually changed. Spectra can also be acquired by pulse counting the electrons that passes through the analyzer with the aid of a channeltron or microchannel plate. The hyperbolic field analyzer can acquire spectra in few seconds. However, this device is not in common use.

18.2.3
Sample

Conducting samples that survive well in UHV are normally studied. Insulating or biological samples degrade in the beam.

18.2.4
Analytical Information

The first or second derivative of secondary electron current, with respect to the analyzer energy is measured (Figure 18.1). The secondary electron current can also be measured by electron counting techniques. The resultant electron spectrum reveals a series of peaks at different electron energies. The energy of the peaks is characteristic of the element that produced the electrons. The electrons rapidly lose energy within the solid and 1–10 nm they will no longer have the same energy with which they started. Therefore, the elements composing only the top few monolayers of the surface can be determined. Depth profiles can be obtained by sputtering the surface with Ar ions and simultaneously acquiring an Auger spectrum. Chemical bonding information can be determined from the line shape of the Auger spectra. In addition, whether the element is only on the top surface layer, or subsurface can be determined by examining the shape of the peaks and the near background. Estimates of the composition of the surface layers can be made by comparison with pure element standards. An accuracy of ∼3–10 at% is achievable.

18.2.5
Performance Criteria

Energy resolution is normally in the range of 0.5–2 eV.

Typically, a concentration of ∼0.5 at% in the surface region can be determined or alternatively ∼2% of one monolayer covering the surface. This depends on the intensity of Auger emission for the element concerned. Typically, Auger electron

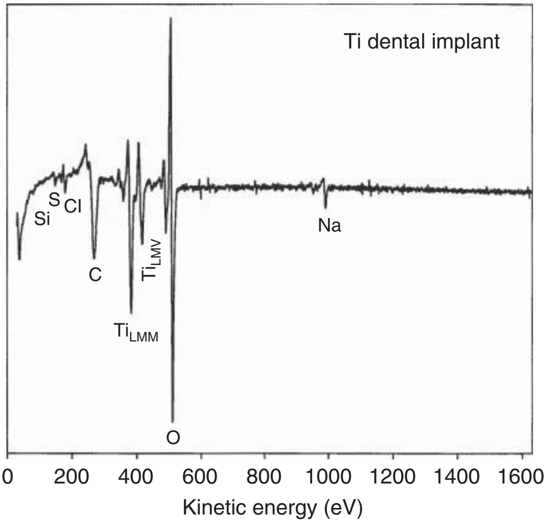

Figure 18.1 Auger electron survey spectrum from a titanium dental implant surface, showing that the surface consists of a titanium surface oxide, with a carbon contamination overlayer and some trace impurities (3 keV primary electrons, 250 nA primary beam current). (Reprinted with permission from Ref. [2].)

emission is high for low atomic number elements and gradually drops as the atomic number increases.

Auger electrons are not emitted by hydrogen and helium.

18.2.6
Applications

This method is a workhorse technique for surface science experiments in UHV. Typically, it is used to determine surface cleanliness prior to the main experiment. The usual contaminants are carbon and oxygen. It is also used in metallurgy, microelectronics, catalysis, and corrosion science.

18.2.7
Other Techniques

If the primary beam consists of ions, then the technique is known as *ion-excited Auger electron spectroscopy* or (IAES). This offers no major advantages in sensitivity of the technique, but simultaneous Auger emission and depth profiling can be carried out. By varying the take off angle of the detected electrons, some information regarding the depth profile of the elements under study can be obtained. This technique is known as *angle-resolved Auger electron spectroscopy* (ARAES). Owing to the longer path length, angle-resolved X-ray photoelectron spectroscopy (ARXPS) is a better method in this regard. Spin-polarized AES is possible by using a Mott detector as with other spin-polarized techniques. This can provide information regarding the spin-resolved DOSs for different elements. The low detection rate of the Mott detector makes data collection very slow for SPAES.

18.3
Cathodoluminescence Spectroscopy

18.3.1
Introduction

Cathodoluminescence (CL) occurs when a beam of high-energy electrons (typically 1–20 keV) strikes the surface of a luminescent material causing light emission [9]. It is used as the source of light in cathode-ray tube televisions. It can be used to study minerals, semiconductors, insulators, and so on (but not metals). Electrons within the valence band are excited into the conduction band. A hole remains within the valence band and when recombination of the excited electron and the hole occurs, light is emitted. Direct bandgap semiconductors such as GaAs and ZnS tend to emit more CL than indirect bandgap semiconductors such as Si as a phonon is required in the light emission for the latter. There is a sharp increase in the photoabsorption with light frequency, which corresponds to the bandgap. At low temperatures, the electrons and holes can form bound pairs known as *excitons*. This can lead to sharp emission lines below the edge emission frequency.

CL can also be used to study organic substances, where the excitation and subsequent emission occurs within a single molecule. Electrons from a ground state are excited to other singlet states, which then decay using a combination of radiationless and radiative transitions.

18.3.2
Instrumentation

This technique requires vacuum conditions. A tightly focused beam of high-energy electrons (2–100 keV or higher) strikes the surface of the sample. Cathodoluminescence studies are normally carried out in a SEM. The light emission can be detected using a photodetector. However, in order to carry out spectroscopy on the light emission, a spectrometer is required. The light can be collected by an elliptical mirror and passed down through an optical fiber. The light spectrum is then detected with the aid of a monochromator.

18.3.3
Sample

Vacuum compatible semiconducting or insulating solids.

18.3.4
Analytical Information

Variation in the bandgap can be determined in semiconductor compounds such as $Ga_xAl_{1-x}As$, which can then be used to determine the composition in hetereostructures or graded layers. The concentration of donors or acceptors may be revealed.

18.3.5
Performance Criteria

Exposure to intense electron beams may cause damage to the sample. This is especially the case for organic molecules.

18.3.6
Applications

SEM is one of the most widely used analytical techniques across all fields of science, technology, and industry. Cathodoluminescence can be used to image dislocations on Si and to identify defects on Si wafers. By strobing the beam source, estimates of the lifetime of the luminescence can be obtained. Dislocations can influence the lifetime and intensity of CL.

18.4
Electron Momentum Spectroscopy

18.4.1
Introduction

Electron momentum spectroscopy (EMS) measures the electronic structure of materials whereby an incoming electron with known energy and momentum scatters from an electron in a solid, transferring some of its energy; hence, this electron is also ejected from the solid [10]. If the energy and momentum of both the ejected and scattered electrons are measured in coincidence then it is possible to calculate, using the elemental laws of energy and momentum conservation, the energy and momentum of the ejected electron before the collision.

18.4.2
Instrumentation

In some experiments, the primary electrons have energies of ~50 keV. The two electrons after the collision have energies of 25 keV and are decelerated after emerging from the sample. They pass through electron energy analyzers to ensure that each electron has precisely the right energy. If there are simultaneous events on both detectors, the event is counted. Such high-energy electrons result in poor surface sensitivity. In other coincidence experiments, much lower (10–100 eV) electrons are used and this results in much higher surface sensitivity.

18.4.3
Sample

Metals, insulators, semiconductors, and gases.

18.4.4
Analytical Information

By using high-energy primary electrons, this technique provides information concerning the energy and momentum of electrons within the sample. By using low-energy electrons, the technique provides information on the spin–orbit coupling and exchange coupling in magnetic materials.

18.4.5
Performance Criteria

The technique is sensitive to the surface for low-energy primary electrons.

High voltages are needed. High vacuum or UHV is required if lower energy electrons are used.

18.4.6
Applications

EMS is used to determine electron momenta and energies within solids and (for the low-energy primary electrons) to shed light on the role of exchange coupling and spin–orbit coupling in the dynamic interaction of low-energy electrons in the valence band of solids.

18.5
Electron Probe Microanalysis

18.5.1
Introduction

Energy Dispersive X-ray Spectroscopy (EDS or EDX or XEDS) also goes under the name of Electron Probe Microanalysis (EPMA) [11–14]. An electron beam is made to strike a surface using an electron gun from a SEM. The X-rays generated by the electrons striking the surface contain elemental composition information from the sample surface down to a depth of $\sim 2\,\mu m$. This depth is sufficient to make it representative of the bulk rather than a surface sensitive technique. The X-ray energy range of operation lies from 1 to 20 keV.

18.5.2
Instrumentation

Electrons from a primary beam are made to strike a surface and the resulting X-ray emission from that surface is detected. The X-rays can be detected using a solid-state detector, which gives rise to the energy dispersive X-ray (EDS) technique. Alternatively, the X-rays can be dispersed by a crystal and then detected, which gives rise to the wavelength dispersive X-ray spectroscopy (WDS) technique. In EDS, the detector is normally a lithium-drifted silicon detector called *Si(Li) detector*, which needs to be kept at a low temperature using liquid nitrogen. However, a recent development is the silicon drift detector (SDD) that allows a much greater flux of X-rays to be detected. X-rays that strike the detector generate electron–hole pairs and the larger the energy of the X-ray, the more electron–hole pairs that are generated. The electron–hole pairs are prevented from recombining by application of a large electric field within the Si(Li) detector. The electrons and the holes travel to opposite ends of the detector where they generate an electric pulse. The larger the pulse, the higher the energy of the X-ray. Hence, an X-ray spectrum can be acquired with all X-ray energies in parallel, with each pulse being assigned to a different bin in a histogram. This can be performed with the aid of a multichannel analyzer. A higher energy resolution than the Si(Li) detector can be achieved using a microcalorimeter (also parallel acquisition). In this case, the detector has to be cooled to a much greater degree.

An alternative approach to obtaining higher energy resolution is to use WDS. The X-rays strike a crystal and the diffracted beams strike a detector. Different crystals may be used (e.g., quartz or lithium fluoride) that provide sensitivity to different X-ray energies. Several different crystals are normally available on a single SEM. By rotating the crystals, different energy X-rays can be made to strike the detector. The WDS spectrum acquisition is serial, whereas the EDS approach is parallel making EDS much faster than WDS. However, the much higher energy resolution of the WDS (and microcalorimeter) method provides a much greater sensitivity to lower concentration elements.

18.5.3
Sample

Conducting samples are usually studied. Some samples degrade under electron bombardment.

18.5.4
Analytical Information

For EDS, the Si(Li) detector is capable of detecting X-rays down to ∼200 eV, which implies that all elements from beryllium upwards can be detected. The sensitivity rises as the X-ray energy increases as a result of the fluorescence yield, which increases with atomic number. The elements composing the top ∼2 μm of the surface are determined from analyzing the X-ray spectrum. It is sensitive to ~0.5 at%, depending on the particular peak and possible peak overlaps, and so on.

With regard to WDS, it is sensitive to all elements mentioned earlier and including Boron. It can be sensitive to parts per million levels and if the elements concerned are solely on the surface and not in the bulk, then it can have high surface sensitivity.

In both approaches, the beam can be scanned across the surface to create images of each element in the scanned area (Section 18.13).

18.5.5
Performance Criteria

Spatial resolution is normally in the region of ~2 μm. For EDS, the energy resolution varies with X-ray energy, but typically varies from 50 eV at an X-ray energy of 1.5 keV to 200 eV at an X-ray energy of 6 keV. For WDS, the energy resolution depends on the crystal used in the diffracting geometry, but 5–10 eV can be achieved.

The electron beam spreads out as the primary electrons strike the surface. This means that the spatial resolution is limited based on the beam spreading within the material (~2 μm). The probability of X-ray emission reduces with atomic number; hence, elements with low atomic number are difficult to detect and helium and hydrogen have never been detected using EDS. The depth of penetration of the electron beam into the material is ~2 μm. This means that EDS is not a truly surface sensitive technique, but is more sensitive to the bulk.

18.5.6
Applications

EPMA is typically used in metallurgy, microelectronics, and corrosion science.

18.6
Electron-Stimulated Desorption

18.6.1
Introduction

Low-energy electrons are directed at the surface and can cause an atom or molecule on the surface to be desorbed [1, 15–17]. Electron-stimulated desorption usually occurs by electronic energy transfer and not by direct momentum transfer. Other processes include conversion of one binding energy state to another and desorption of atomic and molecular species, which may be charged (positive or negative) or neutral (ground state or excited). This technique also has a more specialized form called electron-stimulated desorption ion angular distributions (ESDIAD) (see later). Incident electron energy is typically <500 eV for electron-stimulated desorption (ESD).

18.6.2
Instrumentation

An electron beam strikes the surface of a single crystal at glancing incidence, and a small fraction of the ions ejected from the surface are collected using a mass spectrometer. The detection of positively charged ions is generally favored over negatively charged ions as a voltage can suppress interference from the primary electrons in the detection system. A quadrupole system cannot measure total desorption cross sections. For this purpose, a series of concentric grids can be used similar to a low-energy electron diffraction (LEED) system.

18.6.3
Sample

Samples that can be studied include metals, highly ionic oxides, alkali-halide solids, and semiconductors among others, usually with an adsorbed layer of gas or other atom/molecule.

18.6.4
Analytical Information

The incident electron energy is varied and the ejected ion current is measured. The experiments can be carried out at different temperatures. The resultant spectra provide information on intermolecular forces and bonding length of defect surface structure. By comparison with computer models, thermal dynamics of adsorbed species can be obtained. Desorption of an adsorbed molecular species can occur by the breaking of an intramolecular bond or the breaking of a molecule–surface bond.

18.6.5
Performance Criteria

The desorption cross section varies considerably depending on substrate and adsorbed species. As such the performance varies considerably on the system being studied. Different desorbing species can be selected using a mass spectrometer. This technique requires a good vacuum. Most of the desorption may originate from minority states and desorption cross sections vary enormously from species to species. The cross sections for metallic adsorbates (e.g., Cs on W or Th on W) are low. The information provided by ESD is semiquantitative.

18.6.6
Applications

Used for the study of adsorbates on metals or semiconductors.

18.7
Electron-Stimulated Desorption Ion Angular Distributions

18.7.1
Introduction

Low-energy electrons are directed at the surface and can cause an atom or molecule on the surface to be desorbed [1, 15–17]. By measuring the intensity of the desorbed species as a function of take off angle information regarding how the molecule is oriented on the surface can be determined (i.e., bond directionality). ESD usually occurs by electronic energy transfer and not by direct momentum transfer.

Range of operation is 0–3 eV.

18.7.2
Instrumentation

An electron beam strikes the surface of a single crystal at glancing incidence, and a small fraction of the ions ejected from the surface are collected by a channeltron mounted on a motor driven, computer-controlled goniometer. The detector can traverse a spherical surface and map out ESD ion intensity as a function of angle. Digital data is displayed in three-dimensional form, and digital background subtraction can be utilized to enhance the appearance of ESDIAD patterns.

An alternative approach is to arrange for the particles that are ejected to encounter a four-grid electrostatic lens array. All positive ion and neutral ESD species pass through the grid system, striking the first of two microchannel plates (MCPs), which produce ∼1 million electrons for each positive ion (or excited state neutral). This electron pulse is accelerated into a resistive anode, causing an expanding ring of charge, centered at the pulse arrival point, to propagate across the thin conductive film. The position analysis computer translates it into a three-dimensional image.

18.7.3
Sample

Samples that can be studied include metals, highly ionic oxides, alkali-halide solids, and semiconductors among others.

18.7.4
Analytical Information

A map of ion intensity versus the direction of take off is acquired. By comparison with model structures a number of characteristics can be determined, such as the bonding geometry of surface species from adsorbates on single crystal surfaces, intermolecular forces, bonding length, and orientations of defect surface structures. This leads to an understanding of the thermal dynamics of adsorbed species.

18.7.5
Performance Criteria

The performance criteria are similar to ESD. Different desorbing species can be selected using a mass spectrometer. This technique requires single crystals and a good vacuum. Most of the desorption may originate from minority states and desorption cross sections vary enormously from species to species. The information provided is semiquantitative.

18.7.6
Applications

It is used for the study of adsorption site symmetry of molecules on single crystal surfaces such as in the production and observation of synthetic catalytic intermediate species at high coverage. There are overlaps with techniques such as LEED and surface extended X-ray absorption fine structure (SEXAFS).

18.8
Extended Energy Loss Fine Structure

18.8.1
Introduction

Extended energy loss fine structure (EXELFS) is generally carried out in a conventional transmission electron microscope (TEM) [1, 18]. The electron beam loses energy through various mechanisms, but includes characteristic energy losses by the excitation of an electron from a core state. This results in a sudden rise in the number of loss events at certain energy below that of the primary beam energy corresponding to an absorption edge of an element contained within the sample. The excited core electron has a certain probability of being backscattered to the emitting atom. This can in turn affect the initial probability of ionization by the incident beam. This gives rise to oscillations in the ionization probability with electron energy loss (better known as *X-ray absorption fine structure*, oscillations).

Hence, information regarding the local structure around the atom whose absorption edge is acquired can be obtained. A much higher spatial resolution can be obtained with EXELFS than with EXAFS.

Range of operation: incident electron energy is typically hundreds of kiloelectron volt.

18.8.2
Instrumentation

A conventional TEM is required, as well as an electron energy analyzer, to measure the electron energy loss spectra. The EXELFS signal is very weak, and thus direct electron detection using a photodiode array for parallel detection is preferable.

18.8.3
Analytical Information

EXELFS spectra provide information regarding the local environment surrounding the atom whose absorption edge is studied. The specific local information includes the atom type of neighboring atomic shells, the distance of those shells from the central (absorbing) atom, and the static or dynamic disorder. The latter is given by the Debye–Waller value. The two-electron final state can make the interpretation of EXELFS spectra more complicated than EXAFS. Normally, EXELFS would be regarded as a bulk sensitive technique. However, by the use of grazing incidence electrons, it is possible to probe the near-surface region.

18.8.4
Performance Criteria

Primary electron energy is 100–500 keV.

The sample should be able to withstand the intense incident electron beam. As in EXAFS, it can be difficult to distinguish elements in the shells surrounding the central atom if they are close in atomic number and it can also be difficult to distinguish static from dynamic disorder.

18.8.5
Applications

EXELFS is used in many applications where local state information is required such as materials analysis (for example, structure of amorphous materials). It can be used where the amount of material is too small for conventional EXAFS experiments, or where a high spatial resolution of the local structure is required.

18.8.6
Other Techniques

Parallel electron energy loss spectroscopy (PEELS) is a method whereby electron energy loss spectra can be acquired in a TEM with great rapidity. This is accomplished by the use of a multielement solid-state detector. Typically, PEELS is used to determine the composition of the sample under study and does not have sufficient energy resolution to provide EXELFS data. Improvements in detector technology may change this.

18.9
High-Resolution Electron Energy Loss Spectroscopy

18.9.1
Introduction

A highly monochromated primary electron beam (energy 1–50 eV) impinges on a sample [1, 2, 19]. Many electrons are elastically scattered directly from the surface, whereas others undergo inelastic scattering by exciting a vibrational state of atoms in the surface layers. The scattered electrons reflected back from the surface are collected and their energies are analyzed.

18.9.2
Instrumentation

The electron beam from an electron gun is passed through a monochromator that results in a highly monochromatic electron beam with an energy spread <10 meV at a typical primary beam energy between 1 and 10 eV. The electrons are often made to strike the surface at grazing angles of incidence. The reflected electrons pass through an electron energy analyzer before being detected.

18.9.3
Sample

Samples should have flat surfaces and should preferably be conducting.

18.9.4
Analytical Information

The source of information is a dependence of electron current on electron energy loss.

There are three important scattering mechanisms in high-resolution electron energy loss spectroscopy (HREELS) – dipole scattering, impact scattering, and negative ion resonance scattering.

For dipole scattering, the electron is scattered to a long distance from the sample (~10 nm) and generates surface phonons. Only vibrational modes that are perpendicular to the surface are normally excited in dipole scattering and the low-energy losses result only in a small angle of deflection from the original direction.

For impact scattering, electrons scatter at much shorter range (~0.3 nm) and over a much wider angle than dipole scattering. Impact scattering has a much lower probability than dipole scattering and can be distinguished from dipole scattering by moving the analyzer away from the specular direction.

18.9.5
Performance Criteria

HREELS probes vibrational features from ~0 to >4000 cm^{-1} with resolution of <1 meV (8 cm^{-1}). It has a much more limited resolution in comparison with the infrared (IR)-based methods.

The method is sensitive to all elements, but only to the top few atomic layers for metals or to fractions of a monolayer (much <1%) for bands with large dipole moment changes. It can be possible to detect vibrational (<0.5 eV) and electronic losses (1–50 eV) in the same instrument.

It is possible to monitor vibrational modes below 1000 cm^{-1}, where reflection–absorption infrared spectroscopy (RAIRS) has problems with sufficient intensity of the infrared (IR) source.

HREELS has poor spatial resolution (1–5 mm) and it requires an UHV chamber with very good magnetic shielding. Stray charges may build up in the spectrometer, which then requires frequent baking. HREELS is difficult to quantify. It is best for small, nonmagnetic single crystals. HREELS is not very sensitive to insulating materials, as surface charging makes the analyzes difficult. It has poor sensitivity for rough surfaces and is difficult to use with depth profiling.

HREELS equipment is expensive (minimum $80 000) and there are a few number of commercial suppliers. HREELS instruments are very complex and bulky, and it is difficult to optimize the electron optics for the primary beam.

18.9.6
Applications

HREELS is used to investigate vibrational scattering mechanisms on surfaces. It helps to provide molecular orientation information for molecules on surfaces as well as bond strengths, adsorption geometry and surface acoustic, and optical phonon information.

18.9.7
Other Techniques

Reflection electron energy loss spectroscopy (REELS, energy loss spectroscopy (ELS)), and extended electron energy loss fine structure (EXELFS) work with a higher fixed energy of the primary electrons (50–200 eV and 10–80 keV, respectively) and higher energy losses of the scattered primary electrons ranging from 0.005 eV to several hundreds and from 200 to 4000 eV, respectively.

REELS provides information concerning higher energy loss mechanisms than HREELS, such as plasmons, interband transitions, and characteristic energy losses. EXELFS is a technique used in TEM. It provides information similar to EXAFS (i.e., data regarding the immediate neighborhood of atoms of certain elements in the sample). EXELFS is bulk sensitive.

Transmission electron energy loss spectroscopy (TEELS) is another technique that is used in a TEM. The electron energy loss is much higher than in EXELFS and characteristic energy losses can be observed. This provides information concerning the elemental composition of the sample. The spectra are detected using a multi-element solid-state semiconductor detector that results in spectra being acquired in parallel. Hence, it is known as parallel electron energy loss spectroscopy (PEELS).

18.10
Inelastic Electron Tunneling Spectroscopy

18.10.1
Introduction

Electrons (0–1 eV) are caused to tunnel between two conducting substrates through an insulating layer, which has a film of material deposited on it [20–22]. Electrons can tunnel through the insulating layer and attached film without losing any energy (i.e., an elastic process) or some energy may be lost (i.e., an inelastic process). Hence, the technique is sensitive to the empty states, vibrational molecular states, phonons, and magnons.

Range of operation is 0–3 V

18.10.2
Instrumentation

The current–voltage ($I-V$) characteristic of the metal-insulator-film-metal (M–I–x–M) junction is measured. AC modulation of the voltage can be used with lock-in amplifiers to obtain a plot of the $\mathrm{d}^2I/\mathrm{d}V^2$ against ΔV (i.e., against electron energy). Liquid helium temperatures are typically required for inelastic electron tunneling spectroscopy (IETS) experiments.

18.10.3
Sample

The sample is a film placed on a thin insulating substrate and then sandwiched between two metallic plates. Molecules adsorbed on an oxide or oxide-supported metal can be studied in such a way.

18.10.4
Analytical Information

Vibrational modes of the molecules in the film are displayed as sharp peaks on the plot of d^2I/dV^2 against ΔV. Even though both Raman and IR active modes are also active in IETS, only modes perpendicular to the surface are observed (as is also the case in reflection-spectroscopy-based techniques).

18.10.5
Performance Criteria

Resolution of the order $10\,\text{cm}^{-1}$ is reached. IETS has ultrahigh sensitivity; $<10^{13}$ molecules are needed for a spectrum. Overtone and combination bands are very weak. Optically forbidden transitions may be observed. The fact that the layer being studied is buried has made it difficult for other surface science techniques to be used in combination with IETS.

18.10.6
Applications

IETS is applied to the study of films such as self-organized monolayers. Adsorption experiments are limited by the low temperature required for the experiment.

18.10.7
Other Techniques

IETS provides information complementary to vibrational spectroscopies, such as Raman, IR, or HREELS. In addition, the technique has gained a new lease of life, in recent years, because of its use in association with scanning tunneling microscopy (STM). This has given rise to the technique known as *STM–IETS*.

18.11
Inverse Photoelectron Spectroscopy

18.11.1
Introduction

A beam of low-energy electrons with a fixed energy (5–50 eV) and momentum illuminates the sample where they couple with the unoccupied bands above the

Fermi energy [23, 24]. The electrons lose energy by emitting a photon and dropping down into another unoccupied band at a lower energy. The initial energy of the electron is known; hence, by measuring the energy of the photon that is emitted the remaining energy of the final state can be determined to produce a spectrum that is representative of the unoccupied DOSs above the Fermi level.

18.11.2
Instrumentation

This technique requires UHV conditions. An electron gun is used to direct a beam of low-energy electrons onto the sample. The electrons couple with unoccupied states above the Fermi level from which they decay into lower unoccupied states by emission of a photon. This photon hits a diffraction grating and is diffracted (at an angle that is dependent on its energy) onto a position (and hence energy) sensitive photon detector such as a charge-coupled device (CCD). As the initial energy of the electron is known, and the energy of the photon has been measured, the energy of the final unoccupied band can then be determined. Hence, a spectrum that is representative of the unoccupied DOSs above the Fermi level can be produced. Alternatively, photons of a fixed energy can be measured while the energy of the electron beam is scanned to produce the spectrum, a mode known as Bremsstrahlung isochromat spectroscopy (BIS).

By varying the angle of incidence of the electrons their momentum (*k*) can be varied to produce ‘‘band maps’’ of the unoccupied states as a function of momentum that are analogous to those of the occupied states produced in angle-resolved ultraviolet photoelectron spectroscopy (ARUPS). This is known as *k*-resolved inverse photoemission spectroscopy (KRIPES) or angle-resolved inverse photoemission spectroscopy (ARIPES).

If a spin-polarized electron gun is used then separate spectra of the unoccupied ‘‘spin-up’’ and ‘‘spin-down’’ DOSs can be produced that are analogous to the ‘‘spin-up’’ and ‘‘spin-down’’ spectra of the occupied states produced by spin-resolved ultraviolet photoemission spectroscopy (SRUPS). This is known as spin-resolved inverse photoelectron spectroscopy (SPIPES).

18.11.3
Sample

- UHV compatible conductors for IPES/BIS.
- Single crystal UHV compatible conductors for ARIPES/KRIPES.
- Magnetic UHV compatible conductors for SPIPES.
- Owing to the low count rates obtained in all variations of IPES the sample must be stable under intense electron beams in UHV for prolonged periods.

18.11.4
Analytical Information

This technique determines the density of unoccupied states above the Fermi level. Hence, IPES is complementary to ultraviolet photoelectron spectroscopy (UPS) that measures the density of occupied states below the Fermi level. As in UPS, angle- or spin-resolved variants on the technique can be used to perform band mapping of single crystals or to produce spin-resolved spectra of magnetic samples.

18.11.5
Performance Criteria

The inverse photoemission process is much less efficient than the photoemission process (by some five orders of magnitude). This can be offset somewhat because electron beams can generally be made more intense than X-ray beams. However, count rates are still much lower, and acquisition times much longer than in UPS.

The energy range of IPES is typically 5–50 eV, the energy resolution is generally ∼0.2 eV and the spatial resolution is generally ∼1 mm. Surface sensitivity is similar to UPS, that is, limited primarily to the top five atomic layers.

UHV is required for this technique. High surface sensitivity combined with long acquisition time means that IPES is limited to samples that will remain stable and clean in vacuum for many hours under the electron beam.

The low energies of the electrons involved means that the technique can be vulnerable to stray magnetic fields and magnetic shielding may be required. Spectra can be influenced by the particular crystal structure of the sample's top few atomic layers, which may not be completely representative of the bulk material. IPES is generally not suitable for insulating materials.

18.11.6
Applications

The empty states immediately above the Fermi level play a vital role in surface chemistry, optical properties, and the electrical conduction of semiconductors and so IPES and its variants can reveal vital information about these properties that is complementary to the information on the occupied DOSs obtained from UPS.

18.12
Reflection Electron Energy Loss Spectroscopy

18.12.1
Introduction

A primary electron beam (energy typically 100–2000 eV) impinges on a sample [15, 25]. The electrons are elastically and inelastically scattered back from the surface. Those electrons that undergo inelastic scattering typically do so by exciting a plasmon or interband/intraband transition in the surface layers. The energies of the reflected electrons are analyzed to produce an energy loss spectrum. This loss spectrum consists of a series of loss peaks at different energies and intensities. The technique is normally available on instrumentation designed primarily for AES (or X-ray photoelectron spectroscopy (XPS)) where an electron gun has been fitted) and thus provides useful extra information on the sample surface under study.

18.12.2
Instrumentation

The electron beam from a simple electron gun is directed at the sample surface. The beam normally has an energy spread of ~1–2 eV at typically primary beam energy between 100 and 2000 eV. The reflected electrons pass through an electron energy analyzer before being detected.

18.12.3
Sample

Samples should have reasonably flat surfaces and preferably be conducting.

18.12.4
Analytical Information

The source of information is dependent on electron current, primary beam energy and electron energy loss. The plasmon losses are typically of the order of ~10 eV and can provide information on the dielectric function of the material under study. EELS is, thus, complementary to optical reflectivity techniques. Interband transitions can be compared with theoretical models of the electronic structure of the material. Estimates of the inelastic mean free path (IMFP) can be determined from the dielectric function.

18.12.5
Performance Criteria

The method is sensitive to energy losses of greater than ~1 eV. Hence, it cannot detect vibrational losses as in HREELS. The detection volume is limited to the top few atomic layers for metals.

REELS requires an UHV chamber with magnetic shielding; stray charges may build up in the spectrometer, which then requires frequent baking. REELS is difficult to quantify. It is best for small, nonmagnetic single crystals, and has poor sensitivity for rough surfaces. It is not very sensitive for insulating materials as surface charging makes their analysis difficult. REELS equipment is relatively low cost in comparison to HREELS.

18.12.6
Applications

EELS spectra can be used to estimate the dielectric function of the material under investigation, which can in turn be used to derive the IMFP and the energy loss of electrons as they travel through materials. Such information can assist in the quantitative understanding of AES and XPS spectra.

18.12.7
Other Techniques

Scanning low-energy electron loss microscopy (SLEELM) can provide a map of electron energy loss peaks across a surface.

Extended electron energy loss fine structure (EELFS, EXELFS) works with higher fixed energy of primary electrons (10–80 keV) and higher energy losses of the scattered primary electrons ranging from 200 to 4000 eV. EXELFS is a technique used in TEMs. It provides information similar to Extended X-ray absorption fine structure (EXAFS), that is, data regarding the immediate neighborhood of atoms of certain elements in the sample. EXELFS is bulk sensitive. Transmission electron energy loss spectroscopy (TEELS) is another technique that is used in a TEM. The electron energy loss is much higher than in EXELFS and characteristic energy losses can be observed. This provides information concerning the elemental composition of the sample. The spectra are detected using a multielement solid-state semiconductor detector, which results in a spectrum being acquired in parallel. Hence, it is known as *PEELS*.

18.13
Scanning Electron Microscopy

18.13.1
Introduction

A tightly focused beam of high-energy electrons (typically 10 keV) is rastered back and forth across the surface of the sample [2, 9]. The impact of the high-energy electrons ejects low-energy secondary electrons from the sample, which are collected by a detector to produce a real-time magnified image of the sample.

18.13.2
Instrumentation

This technique requires vacuum conditions. A tightly focused beam of high-energy electrons (2–100 keV or higher) is rastered across the surface of the sample. This generates a number of effects including emission of low-energy secondary and Auger electrons from the surface, generation of X-rays from within the sample and the backscattering of the primary electrons. The analysis of these different forms of emission reveals complementary information about the sample. The output from an electron or X-ray detector within the instrument is sent to a display that is synchronized to the raster frequency of the beam to produce a real-time magnified image of the sample. The magnification is changed by keeping the size of the image constant while increasing or decreasing the size of the area of the sample being scanned by the electron beam. Hence, electron microscopy does not require the use of multiple sets of focusing optics for different magnifications as would be the case in optical microscopy.

The emission of secondary electrons is very sensitive to surface topography and so the collection of these electrons allows a topographic image of the sample to be obtained that has a much greater depth of field and a much higher ultimate magnification that would be possible with conventional optical microscopy techniques. Secondary electron microscopy also has a high surface sensitivity of a few tens of angstroms.

When secondary electrons are emitted from a magnetic material they become polarized and so by using a polarization sensitive detector such as a Mott detector to collect the secondary electrons an image can be obtained that has magnetic contrast, allowing magnetic domain structures to be studied. This technique is known as scanning electron microscopy with polarization analysis (SEMPA).

Images with elemental contrast can be obtained by detecting the high-energy backscattered electrons whose intensity is a function of the atomic number of the elements in the sample; these electrons also have a greater penetration depth than secondary electrons and so can be used for studying buried structures.

Quantitative information about the elemental distribution and concentration can be obtained by analyzing the energies of the X-rays emitted, which are characteristic of the elements involved. This is known as *energy dispersive X-ray analysis* or electron probe microanalysis (EPMA). It is essentially a bulk technique that reveals composition down to a depth of several microns.

Quantitative information regarding the surface (~1 nm depth) elemental distribution and concentration can be obtained by analyzing the energies of the Auger electrons emitted, which are also characteristic of the elements involved. This is known as scanning Auger microscopy (SAM). The instrumentation involved in detecting the Auger electrons is the same as in AES and the reader should refer to that technique to learn more. UHV is required for SAM.

18.13.3
Sample

Vacuum compatible conducting solids–nonconductors such as biological samples are generally coated with a thin layer of gold to render than conductive. Biological or insulating sample may also degrade under electron bombardment.

18.13.4
Analytical Information

Secondary electron mode – real-time magnified topographic contrast images.

Backscattering mode – real-time magnified elemental contrast images.

EDS mode – quantitative analysis of elemental composition and distribution at particular points of interest in the secondary or backscattered images. In addition, magnified elemental contrast images.

SEMPA – magnified magnetic contrast images of domain structures.

SAM – quantitative analysis of surface (~1 nm depth) elemental composition and distribution at particular points of interest in the secondary or backscattered images. In addition, magnified elemental contrast images.

18.13.5
Performance Criteria

Magnifications ranging from ×3 to ×500 000 are possible depending on the instrument. Spatial resolution may be as good as 20 Å.

One of the major strengths of SEM is that the depth of field is very large (generally 10–60% of the width of the field), ranging from 1 μm at high magnifications up to several millimeters at low magnifications. This is much larger (by some ×300) than the depth of field obtainable in conventional optical microscopy at equivalent magnifications. Hence, SEM allows realistic looking images of highly three-dimensional samples, such as biological structures, to be obtained.

Depth sensitivity depends on the analysis mode and energy range used. SEM with low-energy secondary electrons can result in a surface sensitivity of 20 Å, while EDS reveals information about the top few microns of the sample. Depth sensitivity for backscattered electrons is greatly dependent upon the electron beam energy and the elemental composition of the sample, but is generally hundreds of nanometers.

Elemental sensitivity in EDS mode is 0.1% depending on the elements in question with an accuracy of 1–3% achievable. The elemental sensitivity for the SAM mode is ~1% with an accuracy of ~5% achievable.

EDS is not sensitive to elements lighter than carbon in the periodic table and has only limited sensitivity for elements lighter than sodium. SAM is not sensitive to H or He, but has better sensitivity to lower atomic number elements.

EDS is not able to produce the sort of information on chemical states than can be obtained in XPS as the obtainable resolution is only some 3 eV. SAM can produce some information regarding chemical state.

Quantitative EDS and SAM are most effective on flat-polished samples.

Count rates in EDS are generally much lower than in backscattering or secondary electron mode and so it is often used for quantitative analysis of particular points of interest within a backscattered or secondary electron image, although EDS images can also be acquired if necessary. The same is true of SAM.

Mott scattering is a very inefficient means of electron detection and so magnetic contrast SEMPA images will require much longer acquisition times.

Exposure to intense electron beams may cause damage to the sample.

18.13.6
Applications

SEM is one of the most widely used analytical techniques across all fields of science, technology, and industry. Applications include imaging of highly three-dimensional biological structures, imaging and microanalysis of semiconductor structures, magnetic domain imaging for data storage applications, and imaging of fracture surfaces in component failure analysis.

18.14
Scanning Tunneling Spectroscopy

18.14.1
Introduction

Scanning tunneling spectroscopy is a technique that is carried out using a STM [6, 26, 27]. The STM is one of a family of scanned probe techniques that can provide atomic level (or near atomic level) resolution. A sharp conducting tip is brought within a tenth of nanometers from a surface such that an electric current can flow by quantum tunneling between the tip and sample. By rastering the tip across the surface a map of the surface defined by the tunneling current can be acquired. In the case of STS, the voltage (V) at each point can be varied and the corresponding variation in the current (I) can be measured. The resulting $I-V$ curve is characteristic of the electronic structure at the particular tip position. Hence, images of the electronic structure can be acquired at atomic resolution.

18.14.2
Instrumentation

A STM is the principal piece of equipment. The microscope should be placed in an UHV chamber in order to ensure clean surfaces. A lock-in-amplifier can be used to acquire $\mathrm{d}I/\mathrm{d}V$ or $\mathrm{d}I/\mathrm{d}z$ (where z is the height of the tip above the surface) curves. However, simple numerical differentiation of the $I-V$ curve usually suffices. The experiments are often carried out at cryogenic temperatures.

18.14.3
Sample

Samples should have reasonably flat surfaces and preferably be metallic or semiconducting. However, it has been shown that very thin films of insulators can also be analyzed.

18.14.4
Analytical Information

The electrons tunnel from filled states to empty states. The filled states can be in the tip or sample. Hence, by varying the sample tip voltage both filled and empty states in the sample can be probed. In such a way, STS provides information similar to UPS and IPES. STS is a much more local probe, but cannot achieve the angular resolution of UPS or IPES. The value of $\mathrm{d}I/\mathrm{d}V$ is proportional to the surface local DOSs, but contains an exponential dependence of the transmission probability on the tip-sample bias. The data is often displayed in the form $(\mathrm{d}I/\mathrm{d}V)/(I/V)$ that is known as the *normalized conductance*, which removes the voltage dependence and provides an improved approximation to the local DOSs of the sample. A good understanding of the electronic structure of the tip is also necessary to understand the data.

18.14.5
Performance Criteria

The technique is sensitive to surface contamination. The nature of the tip can affect both the spatial resolution and the I/V curves of the acquired STS data.

18.14.6
Applications

STS spectra are used to acquire information regarding the electronic structure at atomic resolution. For example, in the study of chemical reactions on a Si (111) surface it is possible to image reacted and unreacted sites or establishing the whether dimers on a Si surface are symmetric or asymmetric. Superconductors have been studied in order to determine the local energy gap in both conventional and high-temperature superconductors.

18.14.7
Other Techniques

Current imaging tunneling spectroscopy (CITS) is a technique whereby an STS spectrum is acquired at each point in an image. Multivariate techniques such as principal component analysis (PCA) can then be applied. Electrons injected from an STM tip can give rise to photon emission from the sample-probe area from both semiconductors and metals. The STS technique can be carried out at a solid–liquid interface (e.g., in an electrochemical cell). This leads to the technique of electrochemical tunneling spectroscopy (ETS) or voltage tunneling spectroscopy (VTS). This technique is used to analyze electrochemical interfaces at the nanometric scale. It is influenced by the presence of oxygen in the electrolyte, speed of the measurement, and unisolated areas of the tip and sample that are exposed to the electrolyte.

Another related technique is ballistic electron emission spectroscopy (BEES) that is the spectroscopic version of ballistic electron emission microscopy (BEEM). With BEES and BEEM, a semiconductor is coated with a metal film and an STM tip is brought close to the surface. A voltage is applied to the tip relative to the sample. Current flows from the tip to the metal film. However, only the current from the substrate semiconductor is measured to create the BEEM image or BEES spectrum. Only when the electrons from the tip have sufficient energy to overcome the Schottky barrier can the current be measured. Hence, only ballistic electrons contribute to the current measurements. By varying the voltage on the tip, the Schottky barrier height can be determined.

The technique of atomic force spectroscopy (AFS) uses an AFM to measure the mechanics of individual molecules on a surface. The tip adheres to a molecule and then is pulled from the surface. The resultant ''spectrum'' is a force distance curve and therefore AFS is not a spectroscopy in the strictest sense. AFS has been used to study polymers, proteins, and DNA/RNA molecules.

The scanning near-field optical microscopy (SNOFM) method can also provide standard far field optical spectroscopy techniques, but at resolutions down to a few nanometers.

18.15
Scanning Tunneling Microscopy – Inelastic Electron Tunneling Spectroscopy

18.15.1
Introduction

STM–IETS is one of a family of spectroscopies based on the STM (STM) (e.g., see STS) [28, 29]. In the case of STM–IETS, the voltage (V) is modulated with an amplitude of $\sim$1 meV and the modulation in the tunneling current is detected. STM–IETS can provide information regarding the vibrational properties of molecules on a surface and at a very high spatial resolution. Indeed, the vibration modes of single molecules can be studied with this technique. Electrons tunneling from the tip can excite a vibrational mode within a molecule lying on the surface.

18.15.2
Instrumentation

A STM is the principal piece of equipment. The microscope should be placed in an UHV chamber in order to ensure clean surfaces. A lock-in-amplifier can be used to acquire d^2I/dV^2 curves. The experiments are often carried out at cryogenic temperatures.

18.15.3
Sample

Samples should have reasonably flat surfaces (at an atomic scale). Typically, the surface will be coated with the molecule(s) of interest.

18.15.4
Analytical Information

STM–IETS experiments provide information regarding the vibrational modes of single molecules on a surface. Resonant states are excited in STM–IETS that is important to take into account when interpreting the spectra.

18.15.5
Performance Criteria

The technique is sensitive to surface contamination. The nature of the tip can affect both the spatial resolution and the $\mathrm{d}^2I/\mathrm{d}V^2$ curves of the acquired STM–IETS data.

18.15.6
Applications

An STM can be used to cleave molecules in a process known as *electron-induced dissociation*. This can be used to modify surfaces and create structures on an atomic scale. This could lead to applications involving lithography.

18.15.7
Other Techniques

STM–IETS is based on a combination of the techniques of STM and IETS. Although the instrumental setup is similar to STS, it provides different information regarding vibrational modes of surface molecules rather than the densities of states. Hence, the technique is similar to HREELS, Raman spectroscopy, and IR spectroscopies in the nature of the data that it provides.

18.16
Secondary Electron Emission Spectroscopy

18.16.1
Introduction

Although the term *secondary electron spectroscopy* could include both AES and REELS, the SEES technique generally refers to a beam of low-energy electrons (typically 20–100 eV) striking a sample [9, 30]. The impact of the primary beam of electrons ejects low-energy secondary electrons from the sample, which are energy analyzed and then collected by a detector. A spectrum is produced by ramping the analysis energy in a similar manner that occurs for AES and REELS except that the main interest is in the structure of the spectrum of secondary electrons at very low energy (0–50 eV). The spectrum shows a low-energy peak between and often has very little structure. However, fine details on the secondary electron background have been observed and it is these that are generally of interest.

An alternative technique that is also referred to as *secondary electron spectroscopy* ramps the primary electron energy while acquiring the entire (<50 eV) secondary electron emission. The ratio of the secondary electron emission to primary electron current is known as the *secondary electron coefficient*.

18.16.2
Instrumentation

This technique requires vacuum (preferably UHV) conditions. A beam of electrons (20–100 eV) is directed at the surface of the sample. This generates emission of low-energy secondary electrons from the surface. The emitted secondary electrons are energy analyzed using an electron energy analyzer such as a cylindrical mirror analyzer (CMA), concentric hemispherical analyzer (CHA) or a RFA. The electrons that pass through the analyzer are amplified using a channeltron or MCP, which are then detected using a charge sensitive preamplifier. It is difficult to amplify very low-energy electrons using a channeltron or MCP, so they may need a small acceleration prior to striking these devices. In the case of the RFA, the current to ground measured from a hemispherical grid is measured to detect the SEES signal. The energy dependence of low-energy electrons can be determined using through the lens detectors on modern SEMs.

18.16.3
Sample

Vacuum compatible conducting solids.

18.16.4
Analytical Information

The emission can be influenced by the DOS (both the filled and empty) below and above the Fermi level as the emitting electrons have such a low energy. These states are in turn influenced by the band structure of the solid. Angle-resolved measurements are thus of interest as the band structure will create a directionality in the emission. Hence, the analysis of the secondary electron emission can reveal information regarding the DOS of filled and empty states and the band structure. However, the data is more difficult to interpret than UPS, ARUPS, or IPES.

Information regarding local surface potential and fine structure caused by plasmon decay is also possible to acquire. The energy dependence of secondary electrons can be influenced by the dopant concentration in semiconductors. This can lead to dopant contrast in SEMs.

Although the IMFP for low-energy electrons is larger than that for most Auger electrons, secondary electron emission spectroscopy still has a high surface sensitivity of a few nanometers. An estimate of the IMFP of the secondary electrons can be made by studying the secondary electron coefficient as a function of primary beam energy.

18.16.5
Performance Criteria

Exposure to intense electron beams may cause damage to the sample.

18.16.6
Applications

SEES is used to study the empty DOSs near the Fermi level, the band structure, local surface potential, and plasmon decay.

18.16.7
Other Techniques

Some SEES experiments provide information regarding the empty DOSs and in this sense gives data complementary to IPES, IETS, and STS.

Ion/Neutral Probe Techniques

Anna Macková and Andrew Pratt

Excitation of surfaces with ions or neutrals gives rise to elastic or inelastic scattering processes or to nuclear reactions. As a result of this processes, a variety of secondary particles, such as electrons, photons, positive or negative ions, or neutrals may be emitted. Numerous combinations of the excitation and emitted particles are used for analytical purposes. From these combinations, some of the most popular spectroscopies are ion Auger electron spectroscopy (IAES) (which is based on electron detection), secondary ion mass spectrometry or secondary neutral mass spectrometry (SIMS or SNMS), Rutherford back-scattering spectroscopy (RBS), low-energy ion scattering (LEIS), elastic recoil detection analysis (ERDA), or nuclear reaction analysis (NRA) (which are all based on ion detection), and glow discharge optical emission spectrometry (GD-OES) or ion beam spectrochemical analysis (IBSA) (which are both based on photon detection) for photon detection.

Individual techniques are presented in alphanumerical order.

19.1
Atom Probe Field Ion Microscopy

19.1.1
Introduction

Atom probe field ion microscopy (APFIM) is a combination of field ion microscopy (FIM) and TOF mass spectrometry [1–3]. Hence, although strictly speaking this technique is not a spectroscopy, it is judged sufficiently close to warrant inclusion in this handbook. In FIM, an atomically sharp metallic tip is kept in an atmosphere of gas and a high electric field is then applied in the region of the sharp tip. Gas atoms on the tip are emitted from it and impinge on a phosphor screen. The very small area of gas emission from the tip can be viewed on the screen giving images of the tip at atomic resolution. With APFIM, a mass spectrometer is added to the instrumental setup. This provides the ability to identify which atoms are being emitted from the surface. A sudden pulse is applied to the tip and this can cause a layer of atoms to be removed from it. The atoms emitted enter a drift

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

tube and the time of arrival of the atoms at the detector enables their mass to be determined. This enables atomic resolution images in three dimensions of the material comprising the tip.

19.1.2
Instrumentation

A ultrahigh vacuum (UHV) chamber containing the sample in the form of a sharp tip is required. A time-of-flight (TOF) mass spectrometer to identify the type of atoms emitted from the surface is also needed.

19.1.3
Analytical Information

APFIM provides information concerning the three-dimensional arrangement of elements within the sample at atomic resolution.

19.1.4
Performance Criteria

The sample should be in the form of a sharp tip and be electrically conducting. The form of the sample is less convenient than for the scanning probe methods, but APFIM does provide extra elemental information.

19.1.5
Applications

APFIM is used where the elemental composition of the material at the very highest spatial resolution is needed.

19.2
Charged Particle Activation Analysis

19.2.1
Introduction

Charged particle activation analysis (CPAA) is an analytical method for determining the elemental concentration of trace elements in the near-surface region. The activated region in CPAA is prescribed by both the penetration range (it is defined as the thickness of appropriate material that stops the charged particle) and the charged particle beam diameter. Activation analysis is a highly sensitive, nondestructive technique for the detection of trace amounts of elements in a variety of matrices. The sample to be analyzed is activated by irradiation with an ion beam of a suitable type and energy. Artificial radioisotopes are created by nuclear reactions with nuclides present in the sample. The half-life of the produced radionuclides and the type and energy of the emitted radiation are used to identify the elements present.

19.2.2
Instrumentation

For CPAA, protons and deuterons have to be accelerated to energies between a few megaelectronvolts and 20–30 MeV and twice as high for helium-3 or -4 particles. An isochronous cyclotron, designed as a variable energy accelerator, covers this energy range. The energy of the beam should be well defined (an accuracy of 0.1 MeV) and reproducible. An important consideration is the beam uniformity for even irradiation of the beam spot area. If the beam energy is higher than that required for sample activation, the energy can be reduced by energy loss in a filter foil of a carefully chosen thickness [1, 4–6].

19.2.3
Sample

CPAA has no special limitations on the type of samples that can be studied. The sample should have a size in the order of centimeters in the usual case of solid samples. The simplest measurement is possible for solid samples with good thermal conductivity, not powdered and available as a foil or sheet with the thickness slightly larger than the range of the charged particles in the material (it means that charged particles should be stopped in the sample). However, CPAA offers a number of possibilities for the determination of trace elements in biological materials also.

19.2.4
Analytical Information

Qualitative analysis is based on the identification of the created radioisotopes, mainly using high-resolution gamma-ray spectroscopy. In CPAA, a related method is mostly used, whereby a sample and a standard are irradiated and the activity from the analyzed element is measured in both the sample and the standard. The concentration in the sample can then in principle be calculated from the concentration in the standard and the ratio of the activities measured in the sample and the standard.

19.2.5
Performance Criteria

For optimum analytical sensitivity, it is desirable to produce the maximum amount of activity in the sample to determine and measure that activity with the maximum efficiency. The measurement of activities with short half-lives should be carried out as soon as possible after the irradiation. It follows from the basic equation of activation analysis that 50% of the maximum activity is obtained after irradiation time equal to one half-life and more then 90% after four half-lives.

Detection limit down to 1 ng g^{-1} can be reached for certain isotopes. The choice of ion type and energy provide versatility for optimizing sensitivity and selectivity to suit particular problems. Proton energies from 5 to 20 MeV are needed to obtain a sufficiently high cross section for good sensitivity in CPAA. CPAA has excellent sensitivity especially for light elements, such as B, C, N, and O. CPAA is unique among activation techniques for determination of H and He with detection limits below 1 μg g^{-1}. CPAA can also be performed after radiochemical separations of products to improve detection limits.

The main disadvantages of CPAA are its complexity and cost, its lower suitability for liquid samples, and heating of the sample during irradiation. Special precautions have to be taken for samples that are not massive and are poor thermal conductors. Samples may need to be mounted on a cooled background to prevent overheating during irradiation. Even then, the temperature of the sample surface may rise by many hundreds of degrees of Celsius with beam currents of the order of 10 μA. A conducting surface layer or foil may be needed when irradiating insulating materials to prevent overheating and consequent sample damage. Cross sections are generally lower than those for neutron activation analysis (NAA). Counting times of 10–120 h are necessary to achieve high sensitivity and this reduces the number of samples that can be analyzed. Ionization energy loss prevents the irradiation of large volumes and so the ion range limits the produced activity.

19.2.6
Application

Activation analysis is primarily a technique used for detection of impurities in bulk materials. CPAA offers a number of interesting possibilities for the determination of trace elements in biological materials. It allows the determination of those elements that are difficult or impossible to determine by neutron activation, such as Al, Si, V, Cr, Ni, Cd, Sn, Tl, and Pb.

It makes CPAA a powerful technique when a sufficiently powerful accelerator is available.

19.2.7
Other Technique

NAA is similar to CPAA, but uses thermal neutrons (typically from a nuclear reactor), to activate the sample rather than charged particles. In general, the detection limits of NAA are in the range of 10^{-8} to 10^{-14} g. There is no intrinsic depth sensitivity in NAA because of activation of the whole sample. Neutron losses in the sample are negligible.

19.2.8
Related Techniques

Neutron depth profiling (NDP).

19.3
Elastic Recoil Detection Analysis

19.3.1
Introduction

ERDA is one of the most useful ion beam analysis techniques for depth profiling of light elements. A beam of energetic ions is directed toward the sample. When the incident ion's mass is bigger than the mass of the target atoms in the sample, a forward scattering geometry can be used to detect the recoiling light atoms, which emerge after colliding with the heavier incident ions. Atoms recoiled from the surface appear at different energies for the different elements (Figure 19.1b; [7]).

19.3.2
Instrumentation

The basic experimental equipment is similar as in RBS, but the glancing geometry with very small incident angles is usually used (Figure 19.1a). ERDA relies on the ability to discriminate between forward scattered incident ions and recoiling light atoms [1, 4–7]. The typical experimental arrangement is Mylar foil placed in front of the detector to block out the scattered incident ions but allow the lighter recoiled atoms, which suffer considerably less energy loss, to pass through toward the detector. Note that 10 μm Mylar foil completely stops 2.6 MeV He^+ ions, but megaelectronvolt recoiled protons go through with low-energy loss. Thus, He^+ ions are used for hydrogen profiling. Heavy ion-ERDA (HIERDA) is able to analyze light and medium elements, so typically heavier probe ions are used, for example, Cl^{n+}, I^{n+} with energy tens of megaelectronvolts [8]. In the case where the system parameters are calibrated, ERDA is standardless, and the analysis is independent of the matrix material. ERDA with heavy projectiles needs an appropriate detection technique to distinguish between a large number of different particles that are recoiled simultaneously. The technique is based either on the simultaneous measurement of the energy and velocity of the detected particles (TOF measurement) to separate a mass of recoils or a gas-filled ionization chamber is used for mass separation. The velocity in TOF measurement is determined by measuring the time elapsed between the detection of a particle in two sequential detectors that are placed at a fixed distance from each other. The full TOF measurement also requires a two-dimensional multichannel analyzer, which is not

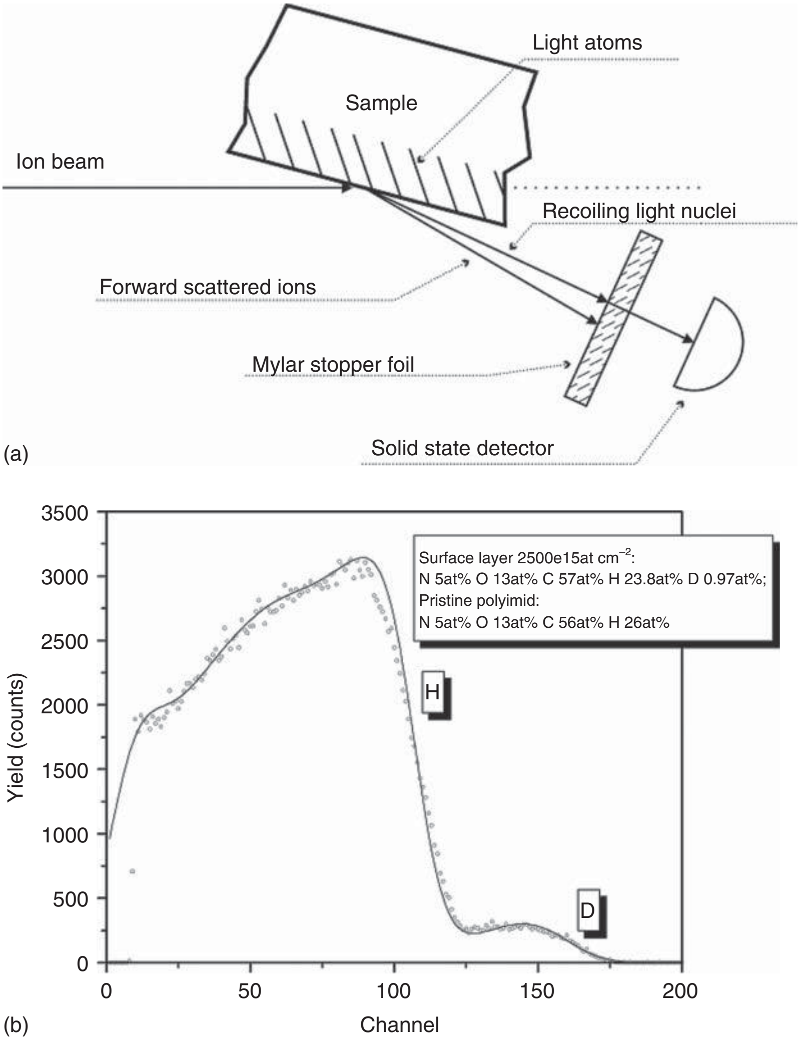

Figure 19.1 The forward recoil geometry (a) and the forward recoiled spectrum of ^{1}H and ^{2}H from 2.18 MeV ^{4}He^{+} ions incident on a thin deuterated polyimide film (b).

commonly found in every ion beam laboratory and enables us to measure the yield of recoiled particles depending on energy and TOF.

19.3.3
Sample

The sample could be multilayer system or bulk material. The lateral and interlayer homogeneity is important for a nondeformed spectrum for quantitative analysis to be obtained.

19.3.4
Analytical Information

The spectra of the forward recoiled sample atoms are detected (Figure 19.1b). In contrast to RBS, where light masses produce a signal at low energies with a low ion yield the detected energy and yield of the ERDA signals for the different masses depends strongly on the stopping power and thickness of the range foil. Each element in the spectrum has its own depth scale with a unique energy-to-depth transformation because of the difference in stopping powers for the different recoiled atoms. Using TOF spectrometer, the two-dimensional spectra are recorded, and the number of recoiled particles is separated according to energy (channels) and mass (time). Thus, the signal for each element can be worked out separately to get elemental depth profiles (Figure 19.2).

19.3.5
Performance Criteria

The sensitivity of ERDA depends on the experimental arrangement and the system-dependent background levels. Typically, 0.1 at% of ^{1}H is observable and from 0.1 to 1 at% of heavier atoms. Simple ERDAs are performed using charged particle detectors with a stopping foil and have a depth resolution of typically 20–60 nm. Accessible analytical depths depend on the projectile, its energy and sample composition: for example, 2.8 MeV He$^+$ ions have a range of around 2.75 μm in silicon. In a simple arrangement with megaelectronvolt He$^+$ ions, it is possible to profile only H to depth up to 1 μm in common materials (e.g., Si). With higher mass projectiles, heavier elements such as N, O, and F can also be analyzed by ERDA technique.

Absolute measurement of light atom contents by ERDA is best achieved by using standards. The stopping foil must be uniformly thick, free of pinholes, and its thickness must be greater than or equal to the projectile penetration range in the foil and less than the recoil range in the foil. The stopping foil method is not suitable for analyses of heavier elements using heavy projectiles than heavy ion elastic recoil detection analysis (HIERDA) or TOF-ERDA could be used.

19.3.6
Applications

As ERDA is complementary to RBS analysis, this method should be a part of every megaelectronvolt ion beam analysis system. When it is employed on small Van de Graaf accelerators, ERDA can be used for determining concentration depth profiles or areal densities of H and D [9].

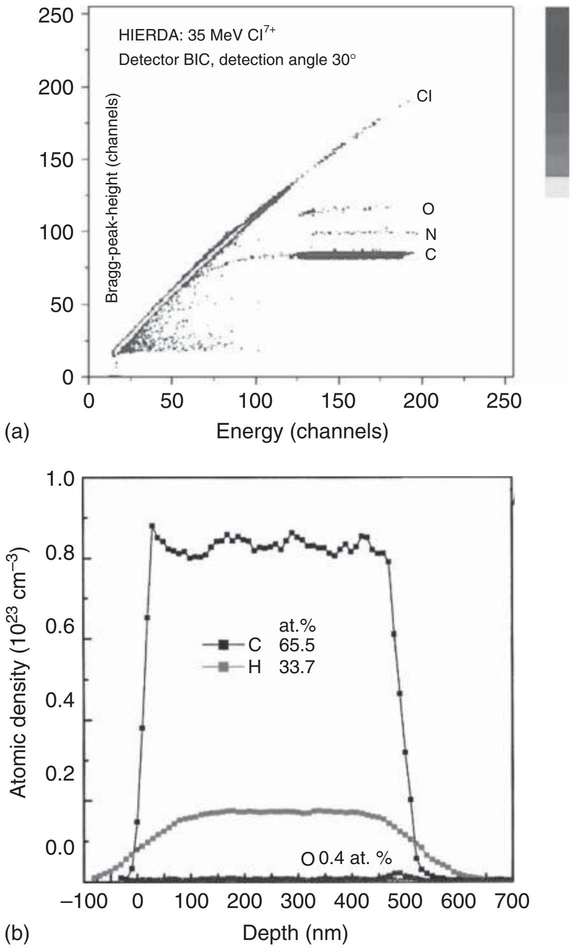

Figure 19.2 Spectrum of HIERDA measurement of layer prepared by magnetron sputtering containing O, C, N, and H elements using Cl^{7+} probing ions with energy 35 MeV (a) and the extracted elemental depth profiles are presented in (b). The worse depth resolution of hydrogen is caused by different detection technique. Although recoiled O, N, and C are detected by Bragg ionization chamber (BIC), hydrogen is detected simultaneously by semiconductor detector covered by Al foil.

19.3.7
Other Techniques

Another possible geometry for ERDA is the transmission mode. In this case, the sample must be thinner than the range of the recoiled atom to be profiled (its penetration depth in that material). The main advantage of transmission ERDA is an increased sensitivity (by up to two orders of magnitude) in comparison to conventional reflection geometry ERDA.

Elastic recoil coincidence spectrometry (ERCS) is a variation of transmission ERDA. Two detectors are used – one to detect the scattered incident particle and the other to detect the recoiled target atom. This technique is well suited to the study of polymers, which can be easily made as thin self-supporting films.

19.4
Glow Discharge Optical Emission Spectrometry

19.4.1
Introduction

This destructive method enables the rapid simultaneous determination of a variety of elements, including nonmetals and the in-depth profiling analysis of conductive samples. Atoms sputtered from the sample are excited in the glow discharge plasma by collisions with ions and electrons. The emitted characteristic radiation is in the visible and UV range.

19.4.2
Instrumentation

A GD-OES device consists of two main parts: a Grimm lamp and an optical spectrometer, which is usually a polychromator. First, the lamp is evacuated and then filled by the working gas (usually argon). The discharge is initiated by applying a voltage of typically 500–1000 V. Ar^+ ions are created as projectiles that bombard the surface of the sample. The sputtered sample atoms diffuse into the plasma. The sputter rate depends on the sample material and the discharge parameters. Some sample atoms are excited by collisions with electrons and the emitted light is analyzed with an optical spectrometer.

Heavy projectiles in the energy range of 30 eV to 100 keV are generally recommended for the excitation, but also high energy of 50 keV to 3 MeV Ar^+ ions have been applied. The usual sputter rates are in the range of 5–200 nm s^{-1}.

19.4.3
Sample

A flat solid sample is needed and the size should be of the order of centimeters.

19.4.4
Analytical Information

The intensities of emission lines of selected elements are recorded continuously by a computer during measurement. Using calibration curves obtained by means of calibration standards under identical discharge conditions, concentration depth profiles of the chosen elements in the analyzed sample are determined from the recorded intensity.

19.4.5
Performance Criteria

Owing to the well-known high sensitivity of optical emission spectrometry, detection limits reach from $\sim 10^{-5}$ g g^{-1} for metals such as C, S, P, and B to $\sim 10^{-3}$ g g^{-1} for elements such as H, O, and N, considering instantaneous analysis. For quantitative analysis using calibration standards, accuracy 0.2–1 at% has been reported for thin layer analysis. For the bulk analysis, we have to expect inferior accuracy in the range of 5–10% and also for the general case of instantaneous in-depth analysis.

The simplicity and speed of GD-OES have made it a powerful tool for rapid and accurate in-depth profiling, especially of iron and steel thin films, and selvage routine analysis. In routine analysis, a calibrated depth profile of 40–50 elements can be obtained in 1 min. Using an integration time of 0.1 s, this could result in a depth resolution of ~0.5 nm. The disadvantage of GD-OES is the need for calibration standards, which are not available for all elements and concentration ranges. The typical lateral resolution is ~2 mm.

The disadvantages of GD-OES could be the lateral resolution and the fact that calibration standards are not available for all elements and concentration ranges. GD-OES is a destructive method [10–12].

19.4.6
Application

The field of application for GD-OES is very broad and includes surface treatment studies of samples prepared by different techniques such as galvanization, nitriding, carbonitriding, carburization, diffusion, chemical and thermochemical treatments, thermal treatments, physical vapour deposition (CVD) and chemical vapour deposition (CVD), coating, electrodeposition, painting, and semiconductor multilayer growth.

19.4.7
Other Techniques

GDMS (glow discharge mass spectrometry) is a similar technique as GD-OES, but GDMS uses a mass spectrometer instead of an optical emission spectrometer.

The optical radiation, which is emitted from sputtered particles, is measured in a technique called SCANIIR (surface composition by analysis of neutral and ion impact radiation), IBSCA), or BLE (bombardment-induced light emission). Heavy particles in the energy range of 30 eV to 100 keV are recommended for the excitation in BLE. LAMMA (laser microprobe mass analysis), or LAMMS, or LMMS (Laser Microprobe Mass Analysis or Spectroscopy), is based on laser ablation. A high-frequency laser scans the area of the sample in a minimum step size, TOF mass spectra of each scan are evaluated with respect to several ion signals and transformed into two-dimensional distribution plots.

19.5
Ion Microprobe Analysis

19.5.1
Introduction

Ion probe microanalysis is a technique in which the sample is bombarded by a well-focused beam of primary ions (diameter ~1–10 μm, nanoprobes were constructed recently). The backscattered ions, emitted X- and γ-rays, or transmitted ions from the sample are detected using a detector according to a type of the produced signal, see RBS, particle-induced X-ray emission (PIXE), and particle-induced gamma-ray emission (PIGE). Lateral resolution, which is determined by ion beam diameter, gives opportunity to make an elemental mapping.

When a beam of charged particles passes through a thin specimen, the beam transmitted in the forward direction includes some particles that scattered elastically off atomic nuclei or lost energy as a result of interaction with electrons (inelastically scattered) as well as those particles that were left unscattered. An image formed with this forward transmitted beam is referred to as a *bright field image*.

19.5.2
Instrumentation

A fully equipped proton microprobe (PMP) chamber should include microscopes for transmission and reflective viewing of the specimen, a Si(Li) detector for detection of X-rays, surface barrier detectors for backward and forward scattering, and a detector for gamma-rays. It is important for microprobe work that the ion source produces a beam of the maximum possible brightness and that this brightness is maintained during transmission of the beam through the accelerator and associated beam optics. Charged particle beams are focused by means of magnetic or electrostatic lenses. The focal length of such lenses depends on the energy of the particles. The achievement of good spatial resolution requires a good ion optics design, high precision in fabrication, careful alignment, and careful elimination of sources of interference.

19.5.3
Sample

Ion probe microanalysis is suited to high-sensitivity multielement analysis of both thick and thin specimens. This method can be used for both surface analysis and element depth profiling. It is not possible to perform elemental analysis for an extended structure of irregular shape except by repeated measurements with a fixed beam at many selected points.

19.5.4
Analytical Information

In order to measure the distribution of elements along a line or map elemental distribution over an area, the focused beam spot must be scanned and the detector signal recorded as a function of the displacement of the beam from its normal position. When a beam of ions scans an area of a specimen, the emitted radiation carries information in 3 degrees of freedom – the two scanning dimensions and the energy.

Scanning ion microprobe (SIMP) and scanning proton microprobe are very useful techniques for *in situ* element or isotope distribution analysis. With protons or heavy ions, the mean free path between ionizing events is generally much shorter than the specimen thickness and hence multiple inelastic scattering occurs. The energy-loss spectrum is then a measure of specimen thickness rather then elemental content. If the specimen thickness exceeds the range of the slow heavy ions in an IMP (ion microprobe), then transmission signals are not available. However, in a PMP, where the typical energy is 3 MeV, the proton range may be some tens of micrometers and the mean free path between inelastic collisions will be <100 nm [13, 14].

19.5.5
Performance Criteria

With bright-field transmission imaging in which the unscattered transmitted beam is running directly into a detector, it may necessary restrict the beam current to $\sim 10^4$ particles s^{-1}. PMP gives 1 μm spatial resolution for microanalysis with 100 pA beams of protons or alpha particles. Each image is collected over 20 min.

Sample discoloration may occur and is usually because of ionization (whereas overheating causes physical deformation). It affects only sensitive specimens under intense bombardment. The sensitivity depends inversely on the beam diameter. Some effects must be taken into account, such as the charging of insulating components, and the sputter removal of some components, which prevents repeat investigations. Image contrast may also arise from chemical or topographic rather than isotopic differences.

19.5.6
Application

Metallurgy–metals provide an ideal specimen for microbeam analysis, their high thermal conductivity minimizes thermal damage and their high electrical conductivity removes any possibility of specimen charging giving rise to a beam deflection.

It is possible to extract a microbeam from the vacuum system to use external beam measurement for specimens that cannot be placed in the vacuum, but the beam will suffer considerable scattering from the air or gas as well as from any exit foil. Nevertheless, such an external microbeam can be very useful for low-resolution studies, for example, in archaeology or biological sciences. The technique has successfully been applied to the examination of nuclear membranes and the processes of etching of latent tracks in polymers.

19.5.7
Other Techniques

IPM can be used simultaneously with RBS, NRA, PIXE, or PIGE. More specialized examples include the FIM that gives better than atomic resolution in the study of high melting point materials.

19.6
Low-Energy Ion Scattering Spectrometry

19.6.1
Introduction

LEIS is a typical surface-specific method that detects particles scattered only from the uppermost surface layer of the solid. The scattering of low-energy ions of inert gases from the surface of a sample is measured. At low energies (<5 keV), the ions are neutralized, if they penetrate below the top two or three monolayers, so only a few monolayers of the solid participate in the ion scattering process. In this way, LEIS differs from RBS, in which the neutralization processes are negligible.

19.6.2
Instrumentation

LEIS uses a low-energy ion beam to interact with the sample surface. Ion source producing ions by electron impact ionization of noble gases (He, Ne, and Ar) or by heating of wafer containing alkali atoms is used (alkali ion scattering spectroscopy, AISS). The range of energies most often in LEIS is 500 eV to 20 keV. In LEIS, either electrostatic energy analyzers or drift tube in TOF setup are used to detect velocities and energy of scattered ions, electrostatic analyzers are suited to a low-energy analysis, they are simple to operate, and they provide good energy resolution. LEIS is a surface-sensitive technique and it should be performed under clean high vacuum conditions. In most research systems, 10^{-8} Pa in the target chamber is a minimum requirement. Any inert gas ions from the beam penetrating below the surface are neutralized [15–17].

19.6.3
Sample

The sample should be solid, with a size of around 1 cm. The requirements are the same as for RBS measurements and the sample must be cleaned because of atmospheric and other surface contaminants, to obtain a pure surface composition measurement.

19.6.4
Analytical Information

LEIS measurements result in an energy spectrum of the backscattered ions from the sample surface. The energy of scattered ions provides information on the mass of the surface atoms, which is directly related to their chemical identity. The cross section, solid angle, and transmission factors (the analyzer acts as an energy filter, with transmission characteristics that depend on the mode of operation) are used for these calculations. The most reliable method for quantitative analysis using LEIS involves a comparison with elemental standards to determine concentrations in alloys or chemical compounds. There is an inherent assumption that the scattered ion fraction does not change significantly between the elemental surface and the alloy surface [15–17].

19.6.5
Performance Criteria

In order to optimize the mass resolution of LEIS, it is advisable to use a projectile with a mass close to that of the target atom and to employ the largest possible scattering angle. Under these conditions, it is possible to detect low levels of contaminants on the surface. For high atomic mass impurities, the ultimate sensitivity is 5.10^{-4} monolayers using He^+ ions and 1.10^{-4} monolayers using Ar^+ ions, while the detection limit for O is between 10^{-2} and 10^{-1} monolayers. The ultimate accuracy of quantitative elemental composition analysis is 5–10% when applying a suitable calibration procedure.

The use of LEIS for the determination of ordered atomic positions at the surface atomic layer is based on its extreme surface selectivity. When other atoms, which result in, may shadow changing the scattering geometry by rotating the crystal, different atoms in the first atomic layer changed intensities of the respective LEIS signals. The limited mass resolution is the major problem in LEIS. This method is insensitive for the detection of low levels of C on surfaces. The detection sensitivity is also a function of the state of the surface. A highly contaminated (O or CO) or insulating surface produces an energy spectrum of scattered ions with a relatively high background. The charge-exchange phenomenon is simultaneously one of the greatest strengths of LEIS and one of its greatest weaknesses. The preferential neutralization of inert gas ions that penetrate below the surface atom layer is responsible for the extreme surface sensitivity of LEIS. The weakness is introduced by the uncertainty in ion yield that results from surface scattering.

19.6.6
Application

The main characteristic of LEIS is its high selectivity for the outermost layer of a solid owing to the large scattering cross section. For practical analysis, this results in the requirement of cleaning the solid surface in UHV before analysis to remove contamination and adsorbed layers. LEIS is frequently used for segregation, adsorption, and reaction studies on well-defined surfaces, which were carefully prepared within the UHV system rather than for the analysis of thin unknown layers. LEIS is a powerful tool in studies of chemistry, crystallography, and electronic structure in the monolayer range on a solid surface.

19.6.7
Other Techniques

In general, LEIS is based on the same principle as RBS, high-energy ion scattering (HEIS), and medium energy ion scattering (MEIS), but it uses a low-energy ion beam. HEIS and MEIS work with high- or medium-energy projectiles, respectively. The energy range of initial projectiles is chosen with respect to the measured sample characteristics (especially the elements present) and taking into account what information is needed about the sample.

Low-energy electron diffraction (LEED) is often used in combination with LEIS in order to have detailed structural information about a sample including surface superstructures and alignment of adsorbates.

19.7
Metastable Deexcitation Spectroscopy

19.7.1
Introduction

The sample is exposed to a beam of low-energy metastable rare gas atoms [18]. Interaction with the surface results in deexcitation of the atoms causing the emission of electrons. These are collected by an electron energy analyzer to reveal information regarding the surface electronic, chemical, and magnetic properties.

19.7.2
Instrumentation

This technique requires UHV conditions. A thermal energy ($\sim$0.1 eV) beam of metastable rare gas atoms is created (usually by electron collision in a DC discharge source) and directed onto the sample surface. Approximately 0.3–0.5 nm from the surface the atom deexcites through a mechanism that depends on the conducting properties of the sample. For conducting surfaces, the electron in the metastable state of the rare gas atom tunnels into a degenerate empty level of the solid, a process known as resonance ionization (RI). The rare gas ion formed is then neutralized by an electron from the surface with the excess energy causing the liberation of a second electron from the surface in a process known as Auger neutralization (AN). For semiconducting and insulating surfaces, or for low work function metals, an alternative deexcitation process called *Auger deexcitation* generally occurs (also referred to as *Penning ionization*). In this case, an electron from the surface fills the ground state of the atom causing the release of the electron in the excited metastable state through an Auger process. In both deexcitation mechanisms, the electron emitted as a result of the atom–surface interaction is detected with an electron energy analyzer such as a hemispherical energy analyzer to build up an ejected electron energy spectrum measuring the intensity of electrons as a function of kinetic energy.

Magnetic lenses or resonant laser light forces may be applied to intensify the metastable atom beam, which usually comprises helium atoms in the 2^3S metastable state because of its high internal energy (19.82 eV) and long lifetime ($\sim$8000 s).

To study magnetic samples, the metastable atom beam is electron spin polarized using optical pumping, and the technique is then referred to as spin-polarized MDS (SPMDS).

19.7.3
Sample

Any vacuum-compatible solids, whether metals, semiconductors, or insulators, and in some cases liquids. Magnetic samples may be studied with SPMDS.

19.7.4
Analytical Information

As the energies of the metastable states are in the range of 11–21 eV, MDS reveals complementary information to ultraviolet photoemission spectroscopy (UPS) regarding the surface valence band electronic density of states. However, as the cross section for deexcitation is so large, there is no penetration into the sample making MDS extremely surface sensitive, with no contribution from the bulk as may be the case for UPS (Figure 19.3). This allows a direct comparison between MDS spectra and the surface electronic density of states and may also enable the identification of the orientation of molecular adsorbates. Spin polarizing the metastable atom beam allows the study of spin-resolved adsorbate and electronic structure.

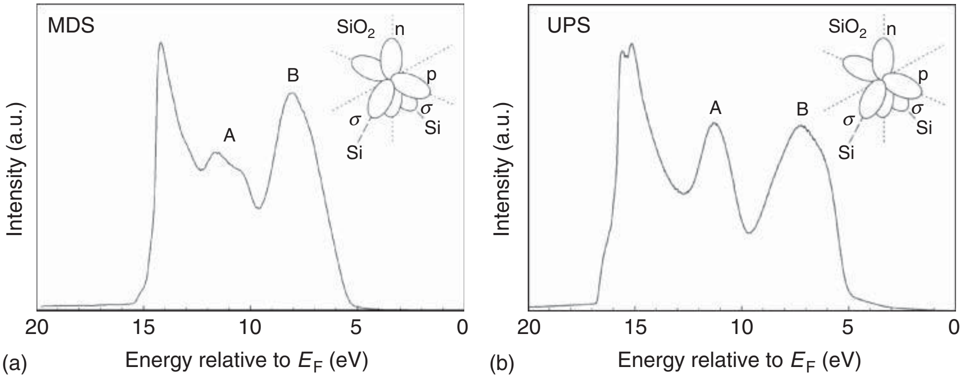

Figure 19.3 Comparison of (a) MDS and (b) UPS spectra from a Si(111)-SiO$_2$ surface demonstrating the surface sensitivity of MDS. Emission as a result of nonbonding orbitals normal (n) and parallel (p) to the surface (peak B) is enhanced in MDS when compared with emission from surface bonds (σ, peak A).

19.7.5
Performance Criteria

With modern energy analyzers, the energy resolution may be <1 meV with a spatial resolution in the micrometer range.

The excitation energy may be changed by using different metastable states of the rare gases.

The technique is extremely surface sensitive and may determine the composition and molecular orientation of the topmost atomic layer of a sample. However, this surface sensitivity makes MDS vulnerable to contamination, necessitating the use of UHV procedures. The low energy of the emitted electrons means the technique is also vulnerable to stray magnetic fields and so magnetic shielding is normally required.

Analysis of spectra is complicated by the presence of multiple deexcitation channels and the convolution of features although spectra may be deconvolved for interpretation.

19.7.6
Applications

The high surface sensitivity and nondestructive nature of the technique means MDS is suitable to the study of the surface properties of a wide range of materials, including semiconductors, magnetic thin films, and biomedical and organic surfaces.

19.7.7
Other Techniques

Ion neutralization spectroscopy is very similar to MDS, but makes use of ions (of energy no <5 eV) rather than metastable rare gas atoms.

19.8
Neutron Depth Profiling

19.8.1
Introduction

NDP is a prompt nuclear analysis technique, which employs a nuclear reaction that results in emission of charged particles with a specific kinetic energy. It is one of the most powerful nondestructive techniques for depth profiling of some light elements especially for ^{10}B and ^{6}Li, which have very high thermal neutron capture cross sections of 3837 and 940 barn, respectively.

19.8.2
Instrumentation

The samples are kept in a vacuum chamber and are irradiated with thermal neutrons produced by the nuclear reactor. Neutron flux $\sim 10^7\,\mathrm{cm}^{-2}\,\mathrm{s}^{-1}$ is used. NDP analysis leaves only trace amounts of residual radioactivity. Conventionally, a silicon charged particle detector or passivated implanted planar silicon (PIPS) detector is used for measurement of the residual energies of charged particles. In this configuration, the semiconductor detector is placed opposite to the surface of the sample being analyzed, and an energy spectrum of charged particles emitted by the neutron-induced reaction is acquired. TOF-NDP is a variation of the traditional NDP. It uses TOF techniques with superior resolution compared to conventional energy measurements conducted with semiconductor detectors.

19.8.3
Sample

Solid sample is required that can be placed into a vacuum chamber.

19.8.4
Analytical Information

If the thermal neutron capture takes place beneath the sample surface, the energy loss of charged particle stopping in the sample can be used to obtain information

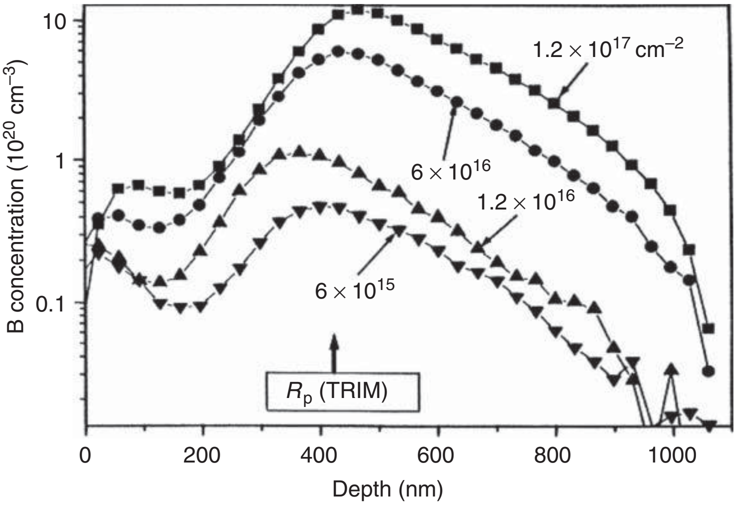

Figure 19.4 Concentration depth profiles of boron atoms implanted at 100 keV into polyimid to the fluences indicated. *R*p (TRIM) is typical range of 100 keV atoms simulated by TRIM code.

about the Li or B concentration profile (Figure 19.4). The amount of energy loss is related to the distance that the charged particle has traveled within the specimen isotopic sensitive, and exhibits the irreplaceable ability to probe the light NDP-active elements in materials up to tens of micrometers depth.

19.8.5
Performance Criteria

In each of the reactions ^{10}B (n,α) ^{7}Li and ^{6}Li (n,α) T, two charged particles are emitted. These particles carried out characteristic energy given by the reaction. The coincidence method, where both produced are detected can be used for very thin samples. It leads to improvement in the lithium or boron detection limit by several orders of magnitude. The element depth distribution can be reconstructed with a resolution of 10–20 nm. NDP is extensively used for the determination and depth profiling of the following elements (typical detection limit in 10^{15} at cm^{-2} is given in the parentheses): ^{3}He (10^{-3}), ^{6}Li (10^{-3}), ^{10}B (10^{-2}), ^{14}N (1), and ^{35}Cl (10). NDP technique is suitable for determination only of a few light elements [19, 20].

19.8.6
Application

The NDP method is an excellent tool for studying numerous problems in solid-state physics (diffusion and sputtering), materials science (corrosion), and life science and especially in microelectronics, where the tight control of boron distribution and transport is vital to semiconductor device fabrication.

19.9
Nuclear Reaction Analysis

19.9.1
Introduction

As a result of ion beam irradiation of a material, two distinct phases exist during which the emission of a particle (NRA) and gamma-rays (PIGE) or X rays (PIXE) takes place. Nuclear reactions are isotope specific (the nuclear reaction takes place on the specific isotope only) with no direct relationship between the mass of the target nucleus and the energy of the emitted particles. The detection of small amounts of isotopes is very easy, especially in the case of a sharp nuclear resonance cross section for the reaction, which is used in RNRA (resonant nuclear reaction analysis). NRA is induced by protons, deuterons, or alpha particles with an energy from 100 keV up to several megaelectronvolts. NRA in combination with RNRA has become very popular for depth profiling of light elements. RNRA uses the resonant cross section dependence on the initial ion beam energy, which can be many times higher than the nonresonant one. As RNRA is not only depth sensitive but also selects particular target isotopes, this technique opens the way to detailed isotope-sensitive studies.

19.9.2
Instrumentation

The equipment required for ion–ion analysis is typically a vacuum chamber, a solid-state detector, and an accelerator, which produces the ions (protons, He^+ ions, and deuterons) with energies 0.5–2 MeV. Energies above 3 MeV make the (d, p) reaction useful for the study of metals. The samples are irradiated by the ion beam and the products of the reaction can be monitored by measuring the emitted charged particles and/or subsequent gamma-radiation of the resulting nucleus. Magnetic analyzers should be used to separate reaction products from scattered ions and to achieve better energy resolution. In general, the probing ion beam hits the sample at normal incidence. If the ion energy used is equal to the resonant energy, the resonance reaction takes place on the nuclei located at the surface. If the beam energy is higher than the resonant energy, the resonance occurs at depth because of the energy losses of the initial ions. By measuring the yield for constant cumulated charge and varying the beam energy in small steps, the yield as a function of ion beam energy can be interpreted as the amount of the element at various depths, that is, it provides the concentration depth profile. Of course, the finite resonance width, the beam energy spread of the accelerator, and the energy straggling of the ion beam projectiles in the target have to be considered in the analysis. Incident ion energies from 0.5 to 2 MeV are most useful for minimizing interference from reactions on heavy isotopes [5, 21].

19.9.3
Sample

The sample should be a solid material; usually, the trace elements or impurities in the bulk material are investigated.

19.9.4
Analytical Information

The spectrum of charged products of the nuclear reaction is measured. The yield of nuclear reaction products is directly dependent on the cross section (which defines the probability of a specific type of interaction) and the density of target atoms in the sample.

High peak cross sections at resonances give high sensitivity of RNRA. Energy loss by the incident ion can be used to determine depth profiles by resonance scanning. Energy loss by both incident and product ions may be used for depth profiling of particular isotopes in the manner analogous to RBS. The advantage of RNRA is that there is no natural background from the high Z components of the target in comparison with methods using backscattering, where the ions backscattered from the heavy elements in the sample produce a background in the spectra and hence decreases the sensitivity for the light elements.

19.9.5
Performance Criteria

The nuclear reaction methods are suitable for the determination of several isotopes from ^{1}H to ^{32}S. The most frequently used reactions are (p,α), (d,p), and (d,α) providing useful alternative methods for the determination of isotopes, such as ^{2}D, ^{12}C, and ^{16}O compared with RBS or ERDA. Alpha-induced reactions have a limited use. Some ^{6}Li-induced reactions have been tested and the (^{11}B,α) reaction has been used for hydrogen determination and profiling. Cross sections of 10–100 mb sr^{-1} are observed for proton- and deuteron-induced reactions with light isotopes, such as D, Li, Be, and B. Detection limits of the order of 10 μg g^{-1} or even less are then possible with measuring times of the order of tens of minutes. Isotopes up to ^{32}S can be determined in heavier matrices at milligrams per gram levels depending on the maximum beam current that the sample can withstand.

The use of glancing incidence or emergence for heavy incident ions or produced ions, respectively, can give typical depth resolutions at the surface of 10–100 nm. The maximum analysis depth is usually limited to 1 μm. The composition of the target usually cannot be estimated from one measurement.

19.9.6
Application

This method is very useful especially for the determination of light elements (isotopes) in the sample due to the specific nuclear reactions. RNRA is complementary method to RBS, PIXE, and PIGE; therefore, final analysis gives more complex information about the sample.

19.9.7
Other Technique

NDP and CPAA. See following part.

19.10
Particle-Induced Gamma Emission

19.10.1
Introduction

PIGE or particle-induced gamma-ray emission (PIGME) is a versatile nondestructive depth profiling technique, which is complementary to other ion beam technique (especially PIXE). It is the most common application of nuclear analysis.

19.10.2
Instrumentation

The high-energy proton beam from an accelerator is used to irradiate the sample. PIGE is mostly based on the (p,γ), $(p,p'\gamma)$, and $(p,\alpha\ \gamma)$ nuclear reaction induced by megaelectronvolt protons where nuclear gamma rays are produced. In most cases, high purity germanium (HPGe) detector or scintillation detectors with multichannel acquisition systems are used for detection of gamma rays. A typical detector solid angle is 0.1–0.5 sr, the sample to detector distance is typically a few centimeters. The lower the incident ion energy, the fewer resonances are involved in ion–gamma reactions and nonuniform angular distributions are more likely to be observed. The choice of geometry affects the depth of ion penetration and hence the thickness of the layer that can be analyzed. For metals and other good thermal conductors, it is possible to use a beam current of the order of 1 μA without special cooling arrangements. The energy scale, including nonlinearity, can be calibrated using radioactive sources [19, 22, 23].

19.10.3
Sample

The same requirement as PIXE, but the gamma ray absorption in the sample is negligible.

19.10.4
Analytical Information

The PIGE method is typically less sensitive than the related methods utilizing X-ray detection (PIXE). The gamma-ray peaks are generally well isolated and the energy is high enough that no correction for absorption is necessary. The energy and intensity of the γ-ray lines produced indicate the elements that are present and their amounts, respectively. Sophisticated peak search and fitting routines are widely used for computer analysis of complex γ-ray spectra. The effect of multiple scattering causes the continuum to be higher at the low-energy side of a peak than on the high-energy one. The background elimination in the analysis should be taken into account.

19.10.5
Performance Criteria

For protons with energies from 1 to 3 MeV, the best sensitivities are found for Li, B, F, Na, and Al. These elements can be determined simultaneously in many cases. For example, a precision of better than 1% can be obtained for F and Na determination with a measuring time of a few minutes. At proton energies above 3 MeV, the gamma-ray emission from medium and heavy elements begins to compete with the light elements. The highest cross sections are for light isotopes (A-mass number <30), which can be determined with good sensitivity ($1\,\mu g\,g^{-1}$ or less). Many reactions have resonances, which are suitable for depth profiling with a resolution of 1–10 nm. In PIGE analysis, the γ-ray yield from many heavy elements is sufficiently high that these can be determined provided that light elements are not present in high concentrations.

19.10.6
Application

The most notable application of PIGE has been in the depth profiling of hydrogen using beam of ^{7}Li and ^{11}B. Analysis of heavier isotopes can be carried out with heavy ions by exploiting Coulomb excitation. The main improvement in the use of PIGE in the last decade has been introduction of external beams. The external beams offer several advantages, such as the ability to measure organic sample (even volatile ones) or large specimen (e.g., paintings) that cannot be placed within the normal analysis chamber.

19.11
Particle-Induced X-Ray Emission

19.11.1
Introduction

PIXE is a method using X-ray emission for elemental analysis. A high energetic proton beam excites emission of characteristic X-rays from the sample atoms because of inner-shell ionization. PIXE is not a true nuclear technique, as the ionization of the atoms by the ion beam and the subsequent emission of characteristic X-rays are purely atomic electromagnetic (rather than nuclear) processes. Methods and data for using K and L lines of X-rays, produced by ion beams (mostly proton beams) are well established and thick or thin samples can be analyzed with an absolute precision of 10% or better PIXE's main advantages are its good sensitivity, multielement capability, and speed of analysis.

19.11.2
Instrumentation

Ions, in particular protons from a particle accelerator, in the energy range 1–4 MeV, are used for excitation with beam spots 1 μm to 10 mm in diameter. Alpha-particles from radioactive sources (^{241}Am) can also be used for excitation of X-ray emission. The X-ray photons emitted from the sample are detected by means of wavelength dispersive (WD) Bragg spectrometer or an energy-dispersive (ED) semiconductor detector (Si(Li) or Ge(Li) detectors). Methods and data on K and L X-ray production by ion beam (mostly proton beam) are well established and thick or thin samples can be analyzed with precision of 10% or better.

19.11.3
Sample

PIXE is able to investigate solid samples with sizes of the order of a centimeter and thickness on the scale of micrometers. However, PIXE can also be used for unusual samples such as liquids and gasses. Owing to low absorption of X-rays in the sample it is better to investigate thin samples, the composition of which can be determined with better accuracy.

19.11.4
Spectrum

The typical PIXE spectrum of the sample from environmental research is shown in Figure 19.5.

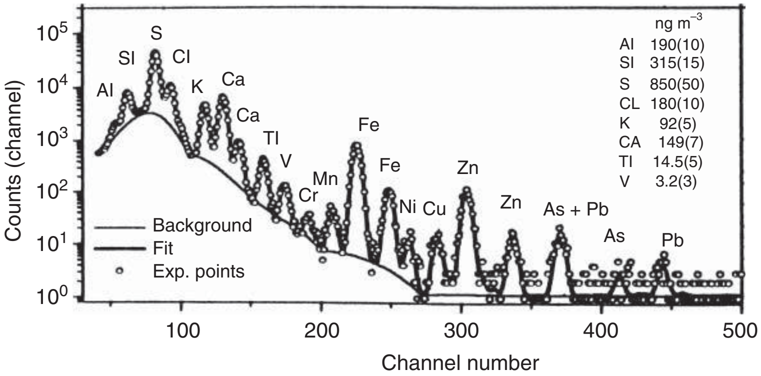

Figure 19.5 PIXE spectrum and composition of fine aerosol fraction collected on nucleopore filter at a suburban station.

19.11.5
Analytical Information

The energy dependence of the emitted X-rays is a monotonously increasing function of atomic number (Moseley law). Hence, the position of the peaks in the spectrum is characteristic of individual elements. Intensities of the characteristic X-ray lines can be converted into concentration data. X-ray yield depends on the number of atoms in the sample, the ionization cross section, the detector angle, intensity of the ion beam, and so on, and so the determination of an absolute concentration of an element in an unknown matrix represents a complicated problem. In practice, the evaluation of the sample composition involves the comparison of X-ray yields from the unknown sample with that from known standards. It is necessary in PIXE to take into account some correction factors for thickness evaluation as a result of X-ray absorption in the sample [21, 24–28].

19.11.6
Performance Criteria

PIXE should achieve sensitivities for all elements in the range of 0.1–1 $\mu g\,g^{-1}$, but this depends on the target and measurement arrangement. PIXE has a very low detection limit of 10^{-8} to 10^{-10} g in standard practice. This method is not used for elemental depth profiling, because of its low depth resolution. The depth accessibility for approximately megaelectronvolt protons is a few tens of micrometers. In PIXE, strong matrix effects are encountered. The major advantage of PIXE's use of ions is a reduction in the background in comparison to that obtained when electrons are used (electron microprobe-induced X-ray emission, EDX). The optimal depth range for useful results appears to be between 0.1 and 10 μm. PIXE enables the determination of composition for all elements with Z, atomic number, higher than 5. An examination of PIXE spectra shows that the characteristic X-ray peaks are superimposed on a background, which forms a limiting factor in sensitivity. It is possible to obtain limited depth profile information using ion-induced X-ray emission. The depth resolution is angle- and ion-energy dependent and is not as good as for other techniques.

19.11.7
Application

PIXE is the preferred method for such applications as the analysis of 15–20 elements in a thin sample, such as air filters (detection limit $1\,\mu g\,g^{-1}$) or for automated analysis of large numbers of geological or archaeological samples, as a result of its short measurement time. The low absolute detection limit and good sensitivity for elements, such as S, P, Cl, K, and Ca, Fe make PIXE of great importance in biological and medical applications.

Particle-induced X-rays can be generated with a microbeam (of order 1–10 μm) to perform high sensitivity-lateral mapping of trace elements distributions. Such a beam can also be brought into air for analysis of biological and vacuum-degradable samples.

19.11.8
Other Techniques

X-ray-induced fluorescence (XRF) is the main alternative to PIXE. However, electrons or gamma photons can stimulate X-ray fluorescence too. If large samples that cannot be placed in the usual vacuum chamber are involved (such as archeological samples or artifacts that might have dimensions of meters), then XRF may be the preferred, but for small samples or microprobe application PIXE is more advantageous.

TRXRFA (total reflection X-ray fluorescence analysis) offers very good element resolution and is especially useful for profiling medium Z (proton number) atoms in a low Z substrate. From experiment, it was concluded that this technique is best at glancing geometry (small incidence and exit angles with respect to the surface plane).

19.12
Positron Annihilation Auger Electron Spectroscopy

19.12.1
Introduction

A beam of low-energy positrons is directed onto the sample [29–32]. The positrons thermalize within a few 100 nm and move back to the surface and remain in a surface state until the positron is annihilated. Some of the positrons annihilate core electrons of the surface atoms, leaving them in an excited state, which decays by Auger emission of an electron. The energies of the Auger electrons are characteristic of the atoms involved and so measurement of the electron energies reveals information about the elemental composition of the sample surface.

Typical emitted electron energy range is 50–2000 eV.

19.12.2
Instrumentation

This technique requires UHV conditions. A low-energy positron source is required. Traditionally, ^{22}Na source beams are used, but the low-beam intensities result in spectra requiring days to acquire. More intense positron sources are becoming available, but these are expensive. Positron energies of ∼10–15 eV are used.

This technique is identical to Auger electron spectroscopy (AES) with the exception that positron annihilation is used to excite the core hole rather than a beam of high-energy electrons. The use of a positron beam has a number of distinct advantages. An electron beam that is energetic enough to excite core holes for AES will also produce a huge background signal of backscattered and secondary electrons, which is many times larger than the Auger signal of interest and must be removed during data analysis. This background is completely absent in positron annihilation Auger electron spectroscopy (PAES) resulting in true peak shapes that are free of distortions caused by background subtraction.

The electron beam used in AES delivers a large energy dose and a high electric charge density to the surface of the sample that can cause extensive damage to some materials. The energy dose in PAES is some five orders of magnitude lower than in AES and has charge densities 1000 times lower, eliminating any damage or charging.

Positron annihilation occurs almost exclusively in the topmost atomic layer, making the technique much more surface sensitive than AES.

19.12.3
Sample

UHV compatible materials. PAES may be used on insulators or delicate samples, such as weakly physisorbed molecules that cannot be studied easily with conventional AES.

19.12.4
Analytical Information

Elemental composition of the topmost atomic layer with peak shapes that are free of data manipulation artifacts.

19.12.5
Performance Criteria

This technique is extremely surface sensitive. Virtually, all positron annihilation occurs in the very topmost atomic layer.

Contents of 1% of the surface layer can be detected, depending on the intensity of Auger emission for the element concerned. Typically, Auger electron emission is high for low atomic number elements and gradually drops as the atomic number increases.

PAES is sensitive to all elements except hydrogen and helium.

Its extreme surface sensitivity makes this technique vulnerable to the presence of contamination.

Access to low-energy positron beams is extremely limited and so PEAS is only available at a few facilities.

Peak overlaps can make some element identification difficult.

19.12.6
Applications

PAES can be used to study weakly adsorbed molecules and insulators that cannot be studied easily by AES.

PAES is also used where the composition of the very topmost layer is important, such as in catalysis.

PAES is, particularly, useful in studies where determining the true shape and relative magnitude of the Auger peak free from background subtraction errors is important, such as for the compilation of Auger reference standards, instrument calibration, and verification of theoretical models of Auger emission.

19.12.7
Other Techniques

Auger photoelectron coincidence spectroscopy (APECS) is another technique that is used to produce background-free Auger spectra.

19.13
Rutherford Backscattering Spectrometry

19.13.1
Introduction

RBS is the most commonly used nondestructive nuclear method for elemental depth analysis of nanometer to micrometer thin films. It involves measurement of the number and energy distribution of energetic ions (usually protons or He^+) elastically backscattered within the near-surface region of solid targets. From such measurements, it is possible to determine, with some limitations, both the atomic mass and concentration of elemental target constituents as a function of depth below the surface.

19.13.2
Instrumentation

An ion beam with an energy of the order of several megaelectronvolts is provided by an accelerator and impinges on a sample located in a vacuum chamber (vacuum of the order 10^{-3} to 10^{-5} Pa). Samples are mounted, several per load, on the table of a goniometer, which allows 3 degrees of freedom, two for the sample position and one for the angle, so as to enable sample changing and manipulation without breaking vacuum. PIPS detector or surface barrier detectors are primarily used for ion detection.

19.13.3
Sample

The sample could be multilayer system or bulk material. The lateral and interlayer homogeneity is important for a nondeformed spectrum for quantitative analysis to be obtained. In case RBS is applied on study of nanoparticles, composites, or colloids, additional microscopic information is needed to interpret data obtained from RBS.

19.13.4
Analytical Information

Two main phenomena provided the analytical information: (i) the energy transfer and (ii) the kinematics in elastic collisions between atomic nuclei and ions. The Rutherford scattering cross section is a function of atomic number, target mass, and scattering angle and depends on the initial projectile energy. From the number of detected scattered particles, the content of a particular element in the target can be determined. Finally, the incident particle loses energy in penetrating the solid both along the incident path before scattering and the exit path. The measured energy loss can be transformed into a depth measurement using known stopping cross section (ion stopping in material). Thus, energy differences in the energy spectra can be used to identify scattering depths and hence provide a depth profile of target constituents [21, 33–37]. An example of an RBS spectrum is shown in Figure 19.6.

19.13.5
Spectrum

The RBS spectrum is yield of ions versus channels. The channel scale can be transformed into energy scale by means of energy losses determined by sample composition.

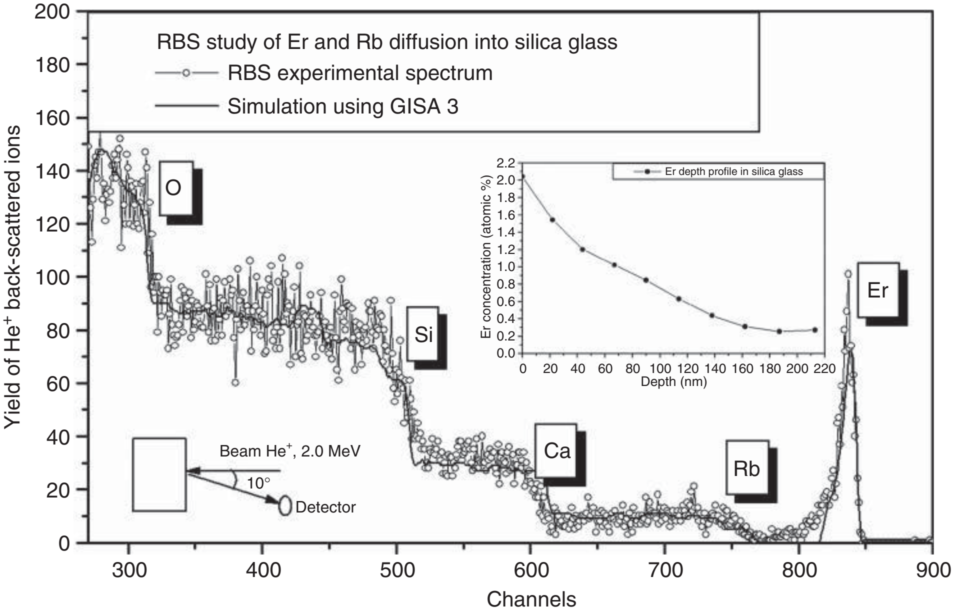

Figure 19.6 Measured and simulated RBS spectra of shallow Er depth profile in silica glass for optical applications measured by RBS, extracted depth profile in the inset.

19.13.6
Performance Criteria

The sensitivity of RBS for the detection of trace impurities in bulk samples depends strongly on the sample composition and the experimental conditions. For impurities heavier than the substrate, the signal of which lies in the background-free region, it is possible to measure infinitesimal amounts of impurities simply by increasing the integrated charge.

It would be possible to measure heavy impurity concentration ~0.01 at%. The lowest detectable amount by RBS is usually indicated $\sim 10^{14}$ atoms cm^{-2}. For near surface, the depth resolution can be improved by selecting glancing angle incident or exit geometry to the value lower than 10 nm, this improvement results from the increased path length through the surface region. The example of measurement of very shallow depth profile of indiffused Er into the glass substrate is shown in Figure 19.6.

Impurities that are lighter than the substrate are usually detected with poor sensitivity and several atomic percent are needed for their detection. The major strengths of RBS are absolute composition measurement of layered structures or trace impurity concentration through a precise knowledge of the cross section. RBS is not usually employed for the analysis of samples of totally unknown composition or for the depth profiling of sample containing a multitude of unknown elements. A problem arises if the material contains several elements with overlapping signals in the RBS spectra, or if the sample is inhomogeneous, resulting in deformed spectra.

19.13.7
Applications

Principal applications include bulk composition analysis and major element profiling, minor element identification, and study of multilayered systems including depth profiling. Thin film analysis is used for studies of solid-state reactions, interdiffusion, stoichiometry, film thickness, uniformity, and impurity content. Investigated systems are prepared by various techniques, for example, by conventional and reactive evaporation, RF and DC magnetron sputtering, laser ablation, ion-beam-assisted deposition, sol–gel techniques, ion implantation, or plasma surface treatment. The investigated materials are used for optics, microelectronics, hard and protective coatings, diffusion studies, magneto-optic recording media, and so on.

19.13.8
Other Techniques

Non-Rutherford backscattering spectrometry (non-RBS or n-RBS) measurement improves the detection sensitivity of light impurities, the light elements have a resonant cross section for light highly energetic projectiles (e.g., protons), which could be many times higher than for RBS. The measurement at resonant energy is sensitive to the light elements, for example, C (proton energy 1742 keV), N, and O.

RBS has also been combined with nuclear microscopy, in which a focused ion beam is scanned across a surface in a manner similar to a scanning electron microscope. The energetic analysis of backscattered signals in this kind of application provides compositional information about the surface; although the microprobe itself can be used to examine features such as periodic surface structures. Rutherford backscattering spectrometry-channeling (RBS-C) is a method for the investigation of adventitious atoms in the interstitial space of monocrystals (see next chapter).

19.14
RBS-Channeling Spectrometry

19.14.1
Introduction

RBS-C spectrometry is a method for investigation of adventitious atoms in the interstitial space of single crystals. Channeling is the steering of a beam of energetic ions into open spaces (channels) between close-packed rows or planes of atoms in a crystal.

19.14.2
Instrumentation

A channeling experiment requires the following basic components: a source of collimated high-energy ions from an accelerator, a detector of scattered particles (the same as for RBS), and an accurate crystal manipulator (called a *goniometer*). A goniometer is a crucial part of the channeling equipment. With this equipment, the crystal axes can be aligned with the collimated beam of particles.

19.14.3
Sample

A single crystal of a good quality is needed. Typically, bulk or thick single-crystalline layers are investigated using RBS/C analysis, which enables the channeling effective. Epitaxially grown layers could also be studied. Single-crystal quality is necessary to find the alignment of the crystal with the probing ion beam.

19.14.4
Analytical Information

The energy transfers or kinematics in elastic collisions between atomic nuclei and ion are used to get information about the composition and structure of the investigated sample. The number of scattered particles measured by a detector can be converted to the concentration of a particular element in the target. The incident particle energy losses are much lower in the channeling regime compared to random incidence. The energy spectrum of particles scattered back from an aligned crystal is dramatically different from that of nonaligned, randomly placed crystal (Figure 19.7). In the aligned spectrum, the scattering yield from the bulk of the solid is reduced of about two orders of magnitude and the surface peak occurs. The presence of defects can significantly enhance the dechanneling yield comparing to a perfect crystal. Distortions and dislocations in the crystal lattice also enhance dechanneling. The backscattering yield from nonsubstitutional atoms does not exhibit the same decrease as that of the host crystal and can be used either for evaluation of the impurity position in a host crystal lattice or for the study of the displacement of host atoms from their lattice sites [38–40].

19.14.5
Performance Criteria

The sensitivity of RBS/C for detecting trace impurities in bulk samples depends very much on the sample composition and the experimental conditions. For impurities heavier than the substrate, it would be possible to measure low amounts of impurities simply by increasing the integrated charge similar to RBS (see earlier). The major strength of RBS/C is an ability to determine the position of impurity atoms in a host crystal lattice. RBS/C is usually employed for the analysis

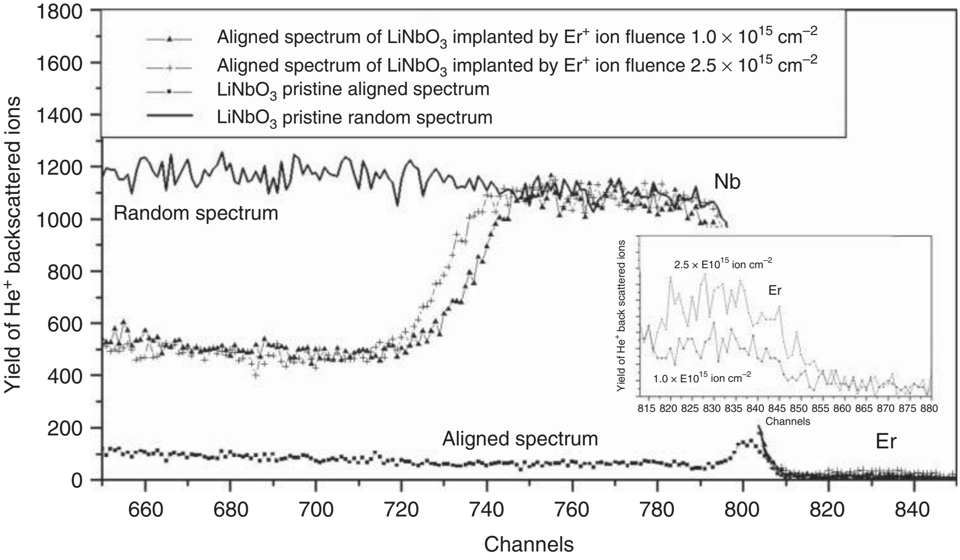

Figure 19.7 RBS/C spectra of $LiNbO_3$ along <11−20> axis of the modified layer in the host lattice caused by implantation of Er^+ ions, 330 keV. Yield of backscattered He^+ ions from the surface-modified layer in aligned spectra is comparable to the yield in random spectra. Thus, the fluences of Er^+ ions 1.10^{15} and 2.5×10^{15} ions cm^{-2} were so high that the implanted layer of crystal lattice was amorphized. Enlarged Er signal in the inset.

of samples of known composition with the focus on impurity atoms or number of defects. The study of impurity sites in the host lattice implies that the impurity is heavier than the host lattice atoms.

19.14.6
Application

The application of channeling to thin crystalline films, ion-implanted crystals, crystalline interfaces, and epitaxial structures is possible. Channeling is used to study many surface properties, such as surface reconstruction and relaxation of the outermost atom layer. Study of optical and semiconductor single crystals are provided using RBS/C to get information about the crystal quality, amount, and position of dopant atoms in a host lattice. Study of ion-implanted single crystals (semiconductor crystals, optical crystals, doped single crystal, etc.) are provided using RBS/C analysis BS/C spectra of lithium niobate implanted by Er^+ ions for photonics application are shown in Figure 19.7. When the signal is channeled to remove the bulk signal, manipulation of the incident and detection angles can be used to determine the relative positions of the first few layers of atoms using blocking effects. Surface reconstruction or relaxation can be detected if a higher-than-usual intensity or a wider surface peak appears to indicate that the first layers of atoms are failing to block the layers beneath.

19.14.7
Other Techniques

RBS/C analysis is combined very often with X-ray diffraction measurement or microscopy study (transmission electron microscopy – TEM). This complex multi-analytical study can give the full information about the studied structural changes in the crystal lattice.

19.15
Secondary Ion Mass Spectrometry

19.15.1
Introduction

In SIMS, a beam of ions (with an energy a few kiloelectronvolts) is used to sputter the surface of a solid sample. The resulting secondary positively or negatively charged ions are analyzed in a mass spectrometer. There are two modes of SIMS application differing primarily in the ion current and energy used. In the static mode, an extremely low primary ion current density of $1\,\mathrm{nA\,cm^{-2}}$ with a low primary ion energy of 0.5–2 keV is used resulting in a negligible sputtering rate of $0.1\,\mathrm{nmol\,h^{-1}}$. Dynamic mode uses a higher ion current density and the sputtering rate is typically $1\,\mu\mathrm{mol\,h^{-1}}$. Hence, in the static mode, the outermost surface layer may exist for hours before being completely removed in contrast to the dynamic mode where the surface layers are stepwise removed and depth profile analysis is possible.

19.15.2
Instrumentation

The primary ions, generated by plasma discharge ($O_2{}^+$, O^-, and Ar^+), by thermionic surface emission (Cs^+ and Li^+) or by liquid metal field emission (Ga^+ and In^+), are accelerated (2–50 kV) and focused onto the sample. The secondary ions are transferred by ion optics into a mass spectrometer.

Three types of instrumentation exist for dynamic SIMS: nonimaging ion probes, direct-imaging ion microanalyzers, and scanning ion microprobes–microscopes. Nonimaging ion probes are often an accessory of AES, electron spectroscopy for chemical application (ESCA), or electron microscopy systems and allow a point analysis. Imaging equipment allows a point-to-point analysis of the surface with a primary beam of the size 10–300 μm (microanalyzers) or below 10 μm (microprobes–microscopes). SIMS requires clean UHV conditions to avoid contamination and reaction with residual gas components and normally has a relatively large analyzed area.

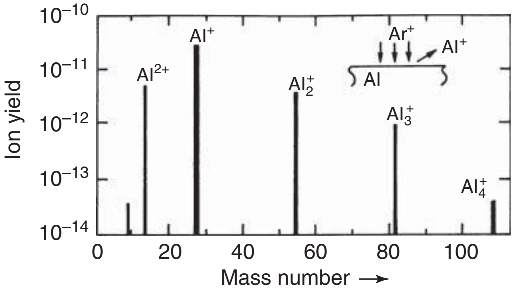

Figure 19.8 Secondary ion cluster spectrum from Ar bombardment of Al (note that the ordinate is a log scale).

19.15.3
Sample

The secondary ion yield is sensitive to surface roughness and contamination, which may change the relation between ion yield and element concentration.

19.15.4
Analytical Information

Analytical information is extracted from the mass spectrum, that is, from the dependence of intensity (total counts) on the mass-to-charge ratio. The spectra of both positive and negative secondary ions are complex exhibiting not only singly and multiply charged atomic ions but also all ionized clusters of target atoms (Figure 19.8). All elements including hydrogen can be detected. In static mode, the conditions are optimized to detect large molecular ions free from the ions formed in some recombination processes. Elemental micromapping combined with depth profiling provides a three-dimensional analysis of the elemental structure.

Quantitative analysis is not easy because of extremely large variations in secondary ion yield (as a result of the matrix effects – the target matrix affects the secondary ion yields markedly), up to five orders of magnitude, and the lack of simple quantitative algorithms. The best accuracy for quantitative SIMS analysis can be achieved by calibration using suitable standards [41–43].

19.15.5
Performance Criteria

High mass resolution is necessary for avoiding peak interference in SIMS. However, relative intensity is strongly reduced with the increasing mass resolution because of narrower entrance slits in the mass spectrometer. Lateral resolution of 0.3 μm or less is possible, but the sensitivity is reduced in proportion to the resolution. The excellent mass resolution, very low detection limits, and a wide dynamic range are available for many elements. SIMS is a method with a very low detection limit, typical $10^{-7}\,\mathrm{g\,g^{-1}}$ range. The main limitation in trace analysis arises from interference in the SIMS spectra as a result of detected clusters, hydrocarbons, oxides, and hydrides. SIMS is an excellent and powerful analytical destructive technique, but it is based on processes that are not yet sufficiently understood.

19.15.6
Application

SIMS applications cover a wide range of fields from pure research to industrial material control.

19.15.7
Other Techniques

SNMS makes use of the sputtered neutral particles by using post-sputter ionization. This is accomplished by laser (laser beam SNMS or SALI-surface analysis by laser ionization) or electron beams (e-beam SNMS), collisions of electrons generated by RF discharge (electron gas SNMS), excitation in various forms of plasma or discharge cell, or surface ionization. A major difference from a conventional SIMS lies in the insertion of an ionizing plasma chamber in front of the mass spectrometer. The grids placed before the plasma environment for postionization act as an electrical diaphragm between the sample and the chamber, which prevents ions entering or leaving the chamber. Thus, only neutral species enter the ionizing chamber, and species ionized within the chamber cannot reach the sample. Ionization of neutral species within the chamber is achieved by low-pressure high-frequency plasma.

Further Information

Information on some other techniques or acronyms, software for surface science studies, surface science databases, research centers and institutes, user groups and bulletin boards, academic research groups, teaching resources for surface science, conferences, commercials services and suppliers, sources of practical information, and also, a collection of links to lecture courses and tutorials covering a broad range of surface science can be found on Web sites, for example: *http://www.uksaf.org/tech/list.html* and *http://www.chem.qmw.ac.uk/surfaces/*.

Photon Probe Techniques

Simon Morton

The interaction of probing photons with surfaces is closely linked to various processes, including absorption, emission or scattering, changes in polarization, nonlinear effects, and so on. From the wide variety of techniques that are based on the detection of photons, the following will be discussed in detail: infrared reflection–absorption spectroscopy (IRRAS), ellipsometry (ELL), surface-enhanced Raman scattering (SERS) spectroscopy, sum frequency generation vibrational spectroscopy (SFG), laser-induced breakdown spectroscopy (LIBS), and total reflection X-ray fluorescence spectroscopy (TXRF). The discussion of techniques that are based on detection of released electrons will include X-ray photoelectron spectroscopy (XPS), electron spectroscopy for chemical analysis (ESCA), or ultraviolet photoelectron spectroscopy (UPS).

Individual techniques are presented in alphanumerical order.

20.1

Angle-Resolved Ultraviolet Photoelectron Spectroscopy

20.1.1

Introduction

Samples are exposed to monochromatic ultraviolet radiation (typically 10–100 eV) and the energies and emission angles of the ejected photoelectrons are measured to reveal information on the valence-band electronic structure [1–3].

20.1.2

Instrumentation

The measurement is carried out in an ultrahigh vacuum (UHV) chamber. Ultraviolet photons from a source such as a He lamp (21.2 or 40.8 eV) or synchrotron radiation (SR) illuminate the sample in order that photoelectrons are emitted from the surface. The emitted electrons are collected by an electron energy analyzer, such as a hemispherical mirror analyzer that has a narrow angular acceptance, to

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

produce a spectrum of the number of electrons emitted with a given kinetic energy and at a given angle. Varying the emission angle by moving the sample or the analyzer enables spectra to be acquired across a range of emission angles. Such data sets allow the momentum vectors of the emitted electrons to be determined to produce ‘‘bandmaps’’ of the electronic structure of the valence bands. By using a synchrotron source instead of a He lamp, the momentum of the emitted electrons can be varied by changing the photon energy, enabling different regions of the band structure to be explored for a given range of emission angles.

20.1.3
Sample

Samples must be single-crystal metallic or semiconducting UHV compatible materials.

20.1.4
Analytical Information

‘‘Bandmaps’’ of the electronic structure of the top few atomic layers. Evidence of energy gaps such as in superconductors.

20.1.5
Performance Criteria

Spatial, angular, and energy resolutions are strongly dependent on the electron energy analyzer and photon source used. However, spatial resolution may be as good as 10 μm, energy resolution as good as 5 meV (or 1 meV using SR), and angular resolution as good as 10 mrad.

Typically, concentrations of a few atomic percentages at the surface can be detected, depending strongly on the cross section of the particular elements present. Sensitivity decreases rapidly with depth below the surface and is often negligible below a depth of approximately five atomic layers.

High surface sensitivity makes the technique vulnerable to contamination, necessitating the use of UHV procedures. The low energy of the emitted electrons makes the technique vulnerable to the presence of stray magnetic fields and hence magnetic shielding may be required.

The spectrum is influenced by the particular crystal structure of the sample’s top few atomic layers, which may not be completely representative of the bulk material. The technique is only applicable to single-crystal materials and is generally not suitable for insulating materials.

20.1.6
Applications

Angle-resolved ultraviolet photoemission spectroscopy (ARUPS) is used to probe the three-dimensional band structure of the electronic states near the Fermi level that are responsible for determining a material's electronic properties as well as to study the nature of the bonding between the atoms in the sample or between the sample and adsorbate molecules on its surface.

20.1.7
Other Techniques

UPS is similar to ARUPS, but spectra are collected at a fixed angle to determine the sample's overall valence band density of states (DOS). UPS is not restricted to single-crystal samples. Spin-polarized ultraviolet photoelectron spectroscopy (SPUPS) allows the DOS to be determined independently for the spin-up and spin-down electrons of a magnetic material by using a polarization sensitive detector.

20.2
Attenuated Total Reflection Spectroscopy

20.2.1
Introduction

The attenuation of a beam of radiation passing through an optical element from a high-refractive index material, under the condition of total internal reflection, is measured [4–6]. The sample must be in good optical contact with the surface of the optical element at which total internal reflection occurs.

Ranges of operation are from ultraviolet to infrared, but mid-infrared typical.

20.2.2
Instrumentation

Attenuated total reflection (ATR) spectroscopy is realized on standard spectrometers using an attachment introduced into the sampling area. Different geometric arrangements are used to direct the radiation through the optical element and onto the detector. The primary difference is in the shape of the optical element. Single (usually denoted as ATR) or multiple reflections (typically 8–20 for multiple internal reflection (MIR) or frustrated multiple internal reflection (FMIR)) can be achieved. Typical materials (crystalline and amorphous) for the optical element are As_2Se_3, AgCl, CdTe, diamond, Ge, KRS-5 (thallous bromide iodide), quartz, Si, ZnSe, and glass. The choice of material depends on the frequency range of operation.

20.2.3
Analytical Information

The ATR spectrum (i.e., the dependence of the reflectance on the wave number) for a sample resembles the transmission spectrum, but two features exclude a direct comparison:

- The depth of penetration is directly proportional to the wavelength; this means that the absorption bands at shorter wave number are intensified in the ATR spectra.
- The maximum shifts and intensity distortions can occur as a result of optical dispersion. These differences are more pronounced for smaller band separations and stronger bands.

A Kramers–Kronig analysis allows us to separate the absorption index and refractive index spectra. Different algorithms for this analysis are available.

20.2.4
Performance Criteria

The penetration depth is a complex function of the absorption and refractive indexes of the sample and ATR element.

The angular dependence of the penetration depth allows depth profiling, but because of superposition of the contributions from different depths an analysis can be difficult.

20.2.5
Applications

This method is not suitable for powders (particularly if they are hard). Study of the surfaces of compact samples is very sensitive to the quality of the optical contact reached between the sample and the ATR attachment. Good contact can be easily obtained when analyzing surfaces of elastomeric materials. The optical contact is usually poor for rough and rigid samples.

By using the MIR or FMIR techniques, a longer effective path length can be obtained through multiple reflections.

On the other hand, the ATR technique is very useful in cases when the ATR attachment can be used as an integral part of the surface experiment. If covered by an optically transparent thin-layer electrode (e.g., Pt), electrode phenomena can be studied. Langmuir–Blodgett monolayers can be transferred onto the attachment or *in situ* experiments can be carried out with the ATR attachment in optical contact with the hydrophobic part of the Langmuir–Blodgett layer.

20.3
Auger Photoelectron Coincidence Spectroscopy

20.3.1
Introduction

In coincidence spectroscopy, two or three particles originating from a single event are detected simultaneously [7–10]. In Auger photoelectron coincidence spectroscopy (APECS), an X-ray beam is directed at a sample to excite photoelectrons from core levels, leaving behind excited core-hole states. These decay virtually immediately by Auger emission of an electron. Simultaneous detection of the photoelectron/Auger electron pair allows all other electrons not directly involved in that event to be eliminated. This produces spectra that are completely free of background signal from scattered secondary electrons and eliminates overlapping peaks from closely related decay events.

20.3.2
Instrumentation

An electron energy analyzer such as a cylindrical mirror analyzer (CMA) is used to detect photoelectrons emitted at a kinetic energy precisely corresponding to the core level of interest. A second CMA is used to sweep continuously through the energy range of the corresponding Auger peak. Only those Auger electrons whose detection coincides exactly with the simultaneous detection of a photoelectron by the first CMA are counted. This eliminates all electrons not directly involved in the particular photoemission process of interest, including secondary electrons or Auger electrons that have been generated by photoemission from other core levels with very similar energies. This produces Auger spectra that are free of backgrounds and other, superimposed, peaks, allowing the true Auger peak shape to be determined. The process can also be reversed, scanning the first (photoelectron) CMA while keeping the second CMA at a fixed (Auger) energy to produce true, background-free photoelectron peaks instead.

20.3.3
Sample

UHV-compatible conductors that are stable over an extended period of UHV and X-ray exposure.

20.3.4
Analytical Information

True peak shapes for Auger electron spectroscopy (AES) or XPS that are free from the backgrounds, overlapping peaks, and satellite features that are present in conventional AES or XPS are obtained.

20.3.5
Performance Criteria

The requirement that only events where both emitted electrons are detected significantly reduces the count rate compared to standard XPS or AES as the probability of both electrons entering the correct analyzers is very low. Count rates are between 1 count min^{-1} and 1 count s^{-1}.

Energy resolution of 0.5–1 eV is significantly worse than in conventional AES or XPS as emphasis must be placed on maximizing the achievable count rate at the expense of overall resolution. Spatial resolution is around 0.5 mm. Typical energy range is 50–2000 eV. APECS is sensitive to all elements except H and He.

The requirement that both electrons must be ejected from the sample without undergoing scattering, combined with the geometrical effects resulting from the angle between the two detectors, means that APECS is significantly more surface sensitive than either XPS or AES alone, by about a factor of 2. Hence, sensitivity is negligible, below about five atomic layers.

UHV is required for this technique. High surface sensitivity combined with long acquisition time means that it is limited to samples that will remain stable and clean in vacuum for many hours under the X-ray beam.

20.3.6
Applications

APECS is used in studies where determining the true shape of the XPS or Auger peaks free of background subtraction errors or overlapping features is important, such as for compiling standard reference spectra, instrument calibration, and verification of theoretical models of photoelectron and Auger emission.

20.3.7
Other Techniques

Positron annihilation Auger electron spectroscopy (PAES) is another technique for producing true AES peak shapes that are free of the secondary electron background. PAES is identical to conventional AES except that the sample excitation is attained using a low-energy beam of positrons rather than a higher energy beam of electrons.

20.4
Diffuse Reflection Spectroscopy

20.4.1
Introduction

The diffusely scattered radiation from a sample is collected, refocused, and detected [5, 11]. Typical range of operation is from ultraviolet to infrared.

20.4.2
Instrumentation

Special reflectometers or emission photometers are constructed for measurement of diffuse reflectance, but, by using a suitable attachment, the measurement can be realized, in principle, using any spectrometer. The main requirement is an integrating sphere (Ulbricht sphere) or mirrors covering a large solid angle (particularly in the infrared region). Separation of the specular and diffuse reflection components is critical for the quality of diffuse reflection spectra that rely on spatial filtering (irradiation normal to the surface or out-of-plane configuration) or mechanical beam stops (blocker).

20.4.3
Analytical Information

It is not usually possible to measure the absolute reflectance of a sample and so, instead, the relative reflectance is measured as the ratio of the reflectance of the sample to the reflectance of a reference nonabsorbing material. Powdered samples are usually diluted with a nonabsorbing particulate matrix such as KBr. This helps meet the prerequisites of the Kubelka–Munk model. KBr is then also used as a reference medium.

If the scattering coefficient is independent of wavelength, the information obtained is similar to that obtained from transmission measurements. Under this condition, a linear dependence between the Kubelka–Munk function and the concentration should be found. For low absorption, the sensitivity of diffuse reflectance is greater than that of transmittance, while strong absorption bands are less pronounced in the diffuse reflection. The scattering coefficient increases with diminishing particle size, while the depth of penetration of the radiation diminishes. The mean layer thickness penetrated within the sample becomes smaller and hence the absorbed fraction is reduced. This fact is particularly useful for investigating adsorbed species on finely dispersed samples. Restrahlen bands can sometimes complicate the spectrum and their elimination is very difficult. The origin of these bands lies in the total reflection that occurs when the refractive index of air is higher than the refractive index of the sample.

20.4.4
Performance Criteria

The quality of the spectra depends critically on the sample material (its crystal form, refractive index, and absorbance), particle shape and size, packing density, and texture of the macroscopic surface as well as on the experimental arrangement (angles of incidence and observation, prevention of the specular fraction from reaching the detector). The presence of the specular component results in strong compression of the spectrum. This compression also occurs in the case of strong absorption in the sample, when the specular component can be the main contribution to the detected signal. The usual method of overcoming band suppression is a dilution of the sample as mentioned.

In general, the reproducibility of the measurements is often limited.

20.4.5
Applications

Diffuse reflection spectroscopy is particularly useful for measuring the spectra of adsorbed molecules, chemically modified surfaces, and catalysts. All spectral ranges from the UV to the infrared are used. Different information can be obtained in different spectral ranges. Adsorption under the influence of van der Waals forces generally only slightly changes the electronic spectrum of the substrate, but significant changes are observed in the case of chemisorption. Acid–base reactions, charge–transfer complexes, redox reactions, reversible cleavage reactions, and photochemical reactions of the adsorbed substance can all be studied.

20.5
Evanescent Wave Cavity Ring-Down Spectroscopy

20.5.1
Introduction

Evanescent wave cavity ring-down spectroscopy (EWCRDS) is based on the measurement of the rate of attenuation of a radiation pulse during intracavity total internal reflection [12, 13].

20.5.2
Instrumentation

A laser beam is focused on a cavity formed by two mirrors and a Pellin–Broca prism and the time behavior of the radiation intensity inside the cavity is monitored by the small fraction of radiation that is transmitted through the second mirror to a detector. Another arrangement uses a properly shaped monolithic, totally internally reflecting polygonal minicavity (from square to octagonal, with at least one convex facet to induce stability). Photon tunneling through the piezoelectrically driven prism introduces radiation into the cavity and extracts a small portion for monitoring. The time needed for attenuation of the pulse to $1/e$ of the original intensity is denoted as the *base ring-down time*.

20.5.3
Performance Criteria

This technique is critically dependent on the quality of the mirrors and cavity, respectively. Super polishing to <0.05 nm root-mean-square of surface roughness is essential. Under such conditions, the arrangement with the Pellin–Broca prism exhibits a base ring-down time of ~1 μs and yields a minimum detectable absorbance change of ~32 ppm. A ring-down time of ~800 ns is found for a 1 cm^2 minicavity.

20.5.4
Applications

Submonolayer detection of adsorption phenomena is possible (e.g., 0.04 monolayer of I_2 on fused silica).

20.6
Near-Edge X-Ray Absorption Fine Structure Spectroscopy

20.6.1
Introduction

A monochromatic X-ray beam is directed onto a sample, which typically has a molecular film on the surface [14–16]. The wavelength of this beam is ramped through an absorption edge of one of the elements that constitutes part of the film. As a monochromatic beam of X-rays at various wavelengths is needed, SR is used as the X-ray source for near-edge X-ray absorption fine structure (NEXAFS) spectroscopy. Data are acquired from a region near to the absorption edge (~50 eV wide).

20.6.2
Instrumentation

SR of high intensity and polarity (>90%) is required. The X-rays must pass through a monochromator before striking the sample. The sample is usually placed in a low-vacuum chamber for experiments in the soft X-ray energy range. The NEXAFS signal can be detected through a number of routes; often, the total electron yield (TEY) from the sample is measured and this signal is divided by the total photon flux striking the sample to normalize out any variations that might result simply from changes in the flux of SR.

20.6.3
Sample

The sample is usually not <2 mm across and must be able to withstand the intense X-ray beam from the synchrotron.

20.6.4
Analytical Information

NEXAFS spectra are frequently dominated by intramolecular resonances of π or σ symmetry. The energy, intensity, and polarization dependence of these resonances can be used to determine the orientation and intramolecular bond lengths of the molecule on the surface. NEXAFS probes the element-specific empty electronic states and has local electronic and bonding structure sensitivity. The orientation of the molecules can be determined using angular-resolved spectra and analysis of the π^* resonances.

20.6.5
Performance Criteria

The primary X-ray energy is typically 1000–4000 eV. NEXAFS is sensitive to ~1% of a single monolayer. Samples need to be able to survive intense doses of X-ray radiation.

20.6.6
Applications

NEXAFS is used to determine the orientation of and bonding structure of adsorbates on a surface. For instance, it is used for the analysis of self-organizing monolayers.

20.6.7
Other Techniques

Extended X-ray absorption fine structure (EXAFS) is similar to NEXAFS but makes use of a wider energy region around the adsorption peak to determine information about the type of atoms surrounding the atom of interest and their distances from it.

20.7
Photoacoustic Spectroscopy

20.7.1
Introduction

Photoacoustic spectroscopy (PAS) is a technique based on the so-called optoacoustic effect [17, 18]. When a short pulse of electromagnetic radiation interacts with condensed matter, the absorbed energy is converted into heat by fast nonradiative relaxation processes. Subsequently, the thermal expansion of the instantaneously heated medium causes an acoustic pulse, which is detected.

20.7.2
Instrumentation

A PAS spectrometer consists of a source of intensity-modulated electromagnetic radiation, a monochromator if necessary, a photoacoustic cell, and the electronics for detecting and storing the photoacoustic signal. The photoacoustic cell is the section containing the sample and the microphone, with its preamplifier, or a piezoelectric detector in intimate contact with the sample. In the infrared range, a Michelson scanning interferometer is used. The moving mirror is additionally sinusoidally driven to obtain a modulation of the output radiation.

20.7.3
Analytical Information

Analytical information is gained from the dependence of relative acoustic signal on wavelength, which represents the absorption spectra of the compound. By changing the modulation frequency, absorption information from different depths of the studied material can be obtained. For materials with low thermal diffusivity, this layer can be $\sim 0.1\,\mu\text{m}$ at a chopping frequency of 10–100 kHz, but 10–100 μm for a frequency of 5 Hz.

20.7.4
Performance Criteria

Temperature changes of 10^{-7} to 10^{-6} °C can be detected with a piezoelectric detector in intimate contact with the sample, detection with microphone is 10–100 times less sensitive. As only absorbed radiation contributes to the detected signal absorption spectra of highly scattering materials, such as powders, amorphous solids, gels, and colloids, can be obtained. A wide range of electromagnetic radiation can be used with the same detection system, the only limitation being sufficient energy of the source (minimum of $10\,\mu\text{W cm}^{-2}$) and sufficient transparency of the other optical components of the measuring system across the full energy range of interest. Hence, spectra from the UV to infrared range can be measured with the same equipment. PAS is not considered suitable for fast measurements and it is limited by the speed of sound, the slow microphone ($<20\,\mu\text{s}$), or the piezoelectric response time ($<0.1\,\mu\text{s}$).

20.7.5
Application

Spectra of adsorbed or chemisorbed species on nonabsorbing or highly reflecting substrates can be measured. PAS is a simple and highly sensitive method for identification of compounds separated on TLC plates and catalysts.

20.8
Photoemission Electron Microscopy

20.8.1
Introduction

X-rays are directed onto a sample to eject photoelectrons [19–21]. These are collected and focused onto a phosphor screen to produce a magnified, real-time, high-resolution image of the distribution of elements, and/or magnetic domains over the sample surface.

20.8.2
Instrumentation

This technique generally requires UHV. An X-ray beam from an anode or synchrotron source is used to excite photoelectrons from the sample. These pass through a series of electrostatic lens, which focus them to form a magnified real-time image of photoelectron distribution on a phosphor screen in a manner that is analogous to optical microscopes but which is element specific. This image can either be viewed directly by eye or with a CCD camera interfaced to image analysis software.

The tunable photon energies available at a synchrotron source can be used to significantly enhance the elemental contrast available in photoemission electron microscopy (PEEM) by choosing a photon energy that corresponds to an absorption edge of a particular element of interest, thus greatly increasing the number of photoelectrons emitted from those areas that specifically contain that element.

By using circularly polarized X-rays from a synchrotron source, the intensity of photoemission becomes dependent on the magnetization of the sample. This can be used to provide element-specific magnetic contrast for imaging magnetic domains, whose behavior can then be studied in real time.

Topographical features of the sample produce distortions in the image and this effect can be used to provide additional topographical contrast.

20.8.3
Sample

UHV-compatible, solid samples. Samples must be reasonably flat to avoid excessive topographic distortions.

20.8.4
Analytical Information

PEEM provides high-resolution real-time images of elemental or magnetic domain distribution with topographic sensitivity.

20.8.5
Performance Criteria

- Energy range is 50–2000 eV.
- Spatial resolution as good as 30 nm.
  Magnification up to ×10 000.
- Element-specific magnetic contrast capability for imaging magnetic domains.
- Real-time element-specific imaging.
- PEEM is sensitive to all elements except hydrogen and helium.
  Atomic sensitivities of a small percentage of a monolayer at the surface.

When used for element-specific magnetic imaging, PEEM is sensitive to all three components of the magnetization.

The technique can be used to study both ferromagnetic and antiferromagnetic domains, depending on the polarization of the X-rays.

Sensitivity decreases rapidly with depth and is generally negligible below ~10 atomic layers depending on energy.

Its surface sensitivity makes the technique vulnerable to surface contamination; hence, it is generally carried out under UHV conditions.

Magnetic imaging is limited to use at SR facilities because of the requirement for circularly polarized X-ray beams.

Electrostatic electron focusing is susceptible to the presence of stray magnetic fields and therefore magnetic shielding may be necessary.

20.8.6
Applications

PEEM is particularly useful for imaging semiconductor microstructures, doing microparticle analysis, studying real-time processes such as surface diffusion, or for magnetic domain imaging in data-storage applications as well as in other applications where real-time high-resolution imaging of elemental or magnetic domain distribution is required.

20.9
Raman Spectroscopy

20.9.1
Introduction

By irradiation of the sample with monochromatic radiation, a small proportion of the radiation is reemitted (scattered), with the wavelengths differing by frequencies corresponding to the vibrational modes of the sample [5, 14, 22–24]. Frequencies smaller (Stokes process) or higher (anti-Stokes process) than the excitation frequency are observed. The strength of the effect is determined by the derivative of the molecular polarizability of the sample with respect to the vibrational coordinates.

20.9.2
Instrumentation

Dispersive Raman spectrometers are used with excitation in the visible range (typically He–Ne or Ar^+ lasers are used), Fourier transform Raman spectrometers are used with excitation in the near-infrared range (Nd : YAG laser). For both ranges, microscopic techniques working with a laser beam diameter of micrometer size are commercially available.

20.9.3
Sample

Raman spectroscopy is not particularly surface sensitive but a surface-enhanced Raman scattering (SERS) effect is observed on some metals (copper, gold, silver, nickel, etc.). On an appropriately prepared (roughened) surface or on metal colloids, the surface coverage of molecules can be measured by Raman spectroscopy with high sensitivity. Tip-enhanced Raman scattering technique (TERS) reaches the same effect by scanning of a sample by a tip (metal nanoparticle or metallized tip of diameter of apex <30 nm) irradiated with laser light. It allows a nanoscale chemical analysis.

20.9.4
Analytical Information

The Raman spectrum, represented as the dependence of the relative intensity of the detected signal on the wave number, provides information on the sample's composition, structure, and vibrational modes that is complementary to the infrared spectrum (Figure 20.1).

20.9.5
Performance Criteria

The Raman effect is a very weak effect in comparison with inherently accompanying Rayleigh scattering (which can be eliminated by using good quality monochromatization or filtering) and with fluorescence of the sample or any accompanying impurities. The last effect can be eliminated using near-infrared radiation for excitation of the Raman spectra.

SERS effect allows an enhancement of the signal on the order of 10^3–10^6. It means that even subnanomolar amount of the component in the irradiated area can be detected.

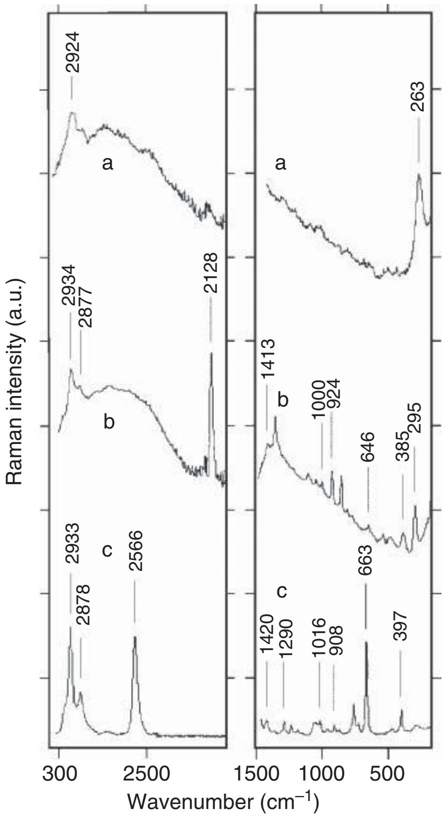

Figure 20.1 FT Raman spectra of a layer of 2-mercaptoethanol on polished (a) and (b) rough gold substrate compared with the spectrum of (c) pure 2-mercaptoethanol.

20.9.6
Application

Used in the study of catalysis and electrochemistry.

20.10
Reflection–Absorption Spectroscopy

20.10.1
Introduction

Measurement of sample layers of thickness ranging from many times the wavelength down to fractions of a monolayer placed on a mirror [5, 14, 25–27]. Absorption by the sample reduces the mirror's reflectance.

Range of operation is typically mid-infrared.

20.10.2
Instrumentation

In a typical setup (constructed as an accessory to be mounted in the sample compartment of a commercial FT spectrometer), infrared radiation is focused on the sample surface at a defined angle. The reflected beam is focused onto a detector. Irradiation with a polarized IR beam is often used.

Reflection–absorption spectra of fairly thick surface films (i.e., thickness between 0.2 and 20 μm) are easily achieved using standard accessories for specular reflectance spectrometry with incidence angles from 15° to 75°. Incidence angles $<15^\circ$ are difficult to attain with conventional optics as it becomes difficult to separate the incident and reflected rays. A so-called grazing angle accessory is needed to attain angles of incidence $>75^\circ$. Grazing incidence geometry leads to an increase in the path length in comparison with the transmission experiment, an increase in the irradiated area proportional to the secant of the angle of incidence, and an enhancement in the electric field vector of the IR photon perpendicular to the surface. Near grazing incidence, the contribution of the incoming wave interferes constructively with the 180° – phase-shifted reflected wave. In total, a sensitivity increase on the order of a factor of 20 in comparison with the transmission methods is to be expected on a highly reflective sample, such as a metal single-crystal surface.

In the extreme case of grazing incidence, the component of the electric field perpendicular to the plane of incidence is very small.

20.10.3
Sample

Mirror-like surfaces are required.

20.10.4
Analytical Information

Reflection–absorption infrared spectroscopy RAIRS results in a spectrum that is similar to that of a transmission measurement. For grazing incidence geometry, only molecular vibrations giving rise to a dynamic dipole perpendicular to the surface are infrared active; this is termed as the *surface selection rule* for surface vibrational spectroscopy.

20.10.5
Performance Criteria

Grazing incidence allows us to measure monomolecular or submonomolecular layers. For a thickness of ~1 nm, band absorbances on the order of 10^{-3}–10^{-4} are measured with an 85° angle of incidence. The overall size of the sampled area achieved with the given geometrical arrangement is critical for sensitivity.

An outstanding gain in sensitivity, allowing us to identify and quantify surface layers of some nanometer thickness, can be observed for strong oscillators owing to the Berreman effect.

20.10.6
Limitations

Strong dispersion associated with intense absorption bands can cause significant changes in the absorption peak position and shape, for example, 1–4 cm^{-1} for moderately absorbing species (benzene and acetone) and 22 cm^{-1} for strongly absorbing species (copper oxide on copper).

With layers of the thickness comparable to the measured wavelengths, the increase in the absorption with the thickness can be corrupted by a modulation connected with the regularly varying standing wave formed. With a thickness below one-quarter wavelength, the response decays not only with the thickness but also with the field amplitude approaching the node. Thus, zero sensitivity is to be expected at the very surface of the metal substrate.

For a number of practical reasons, low-frequency modes ($<600\,\mathrm{cm}^{-1}$) are not generally observable. This means that it is not usually possible to see the vibration of the metal–adsorbate bond and attention is instead concentrated on the intrinsic vibrations of the adsorbate species in the range of 600–3600 cm^{-1}.

20.10.7
Applications

RAIRS is used for characterization of adsorbates on metal surfaces, their transformations and kinetics (e.g., CO on metallic surfaces), catalytic reactions, characterization of semiconductor structures, high-temperature oxidation of metals (use of the so-called Berreman effect), electrode/electrolyte interface, Langmuir–Blodgett, and other ultrathin organic films.

20.10.8
Other Techniques

Modulation spectroscopy uses a periodic (sinusoidal) variation of a parameter influencing the reflectivity of the sample, such as wavelength, angle of incidence, electric field (electroreflectance), temperature (thermoreflectance), surface charge density (piezoreflectance), and magnetic field strength (magnetoreflectance). This technique allows the effect of an external perturbation on the sample to be studied and also enhances otherwise weak details on a large background.

If a photoelastic modulator is used to generate alternately parallel and perpendicular polarized radiation, the AC signal detected will be due to the difference in the absorption of radiation of each polarization. The effect of the background can be eliminated in this way. In the infrared region, this type of experiment is denoted as *polarization modulation*, PM FTIRRAS.

20.11
Spectroscopy of Surface Electromagnetic Waves

20.11.1
Introduction

A thin dielectric film deposited on a metal increases surface electromagnetic waves (SEWs) attenuation, which becomes stronger as eigenfrequencies of the film vibrations are approached [28].

20.11.2
Instrumentation

Modulated radiation from a tunable IR laser falls onto a prism at the condition of attenuated total reflection. Arising evanescent radiation can excite SEW on a metal surface at a suitable distance from the prism base. SEW propagates along the metal surface and can be attenuated by a thin dielectric film deposited on this metal. By means of a similar prism placed at a certain distance from the first one, the SEW is transformed into normal radiation and detected by a pyroelectric detector.

20.11.3
Performance Criteria

The SEW excitation efficiency is affected by both the angle of incidence in the prism and the gap height, the last being different for the coupler and decoupler prism. The size of the gap depends on the metal and the conditions of its evaporation. An absorption spectrum is obtained by a differential method in which the ratio of intensities is measured for an SEW on the metal surface with a film and without a film at various distances between the prisms.

20.11.4
Applications

Very thin films of organic and inorganic substances on metal surfaces can be measured down to monolayers.

20.12
Sum Frequency Generation Vibrational Spectroscopy

20.12.1
Introduction

SFG is a second-order nonlinear optical process in which two laser beams overlap in a medium and generate the sum frequency [14, 25, 29, 30]. As a second-order process, it is allowed on surfaces or interfaces, where the inversion symmetry is broken. In a typical experiment, one beam of infrared and the other of visible wavelength are mixed, allowing SFG vibrational spectroscopy.

20.12.2
Instrumentation

A typical experimental setup consists of a pulse Nd : YAG laser, which is used to pump an optical parametric/difference frequency generation system to produce tunable infrared radiation with a wavelength up to 9 μm. The infrared beam is then overlapped with a frequency-doubled output beam from the laser (532 nm) at the sample surface. A photomultiplier is used for detection. Sum-frequency vibrational spectra are generated by scanning the IR frequencies through the energy range of vibrational excitations.

20.12.3
Analytical Information

Information about molecular orientation and conformation at a surface, and sometimes even surface structure, is gained from the dependence of the SFG signal on wave number.

20.12.4
Performance Criteria

Typically, a spot of several hundred micrometers of the sample is irradiated by the infrared and visible pulse energies at 100 μJ and 1 mJ, respectively. A gain of ∼100 photons per pulse is observed, but the maximum signal we can get is limited only by the local maximum input intensity that the interface can tolerate without damage.

The strength of the resonant SFG response depends on several factors: the surface density of the molecule of interest, the line width of the transition, the IR transition moment, and the Raman transition strength. The last two factors restrict the technique to the study of vibrational modes, which are both infrared and Raman active.

Some of the disadvantages include low-detected signal levels and difficulties in determining a quantitative relationship between the peak intensities and the number of sampled molecules.

20.12.5
Applications

Although solid–solid interfaces can be studied, SFG represents the most powerful analytical tool for liquid interfaces. A wide range of systems has been studied including neat liquid–vapor, liquid mixture–vapor, neat liquid–solid, and neat liquid–liquid interfaces, and also surfactants at liquid–air, liquid–solid, and/or liquid–liquid interfaces, and electrochemistry at solid–liquid interfaces.

20.12.6
Other Methods

Second harmonic generation (SHG) spectroscopy is based on the same principles (two photons of frequency ν are converted to one photon of frequency 2ν). SFG has appeared to be the more successful and versatile technique to date.

20.13
Surface Plasmon Resonance Spectroscopy

20.13.1
Introduction

The surface resonance phenomenon in a thin metallic film is measured by attenuated total reflection as a function of either incident angle (using monochromatic light) or excitation wavelength (at a constant value of the incident angle) [31–33].

Ranges of operation are from visible to infrared, typically visible.

20.13.2
Instrumentation

A surface plasmon resonance (SPR) spectrometer has the following four principal components: a source of radiation, an optical coupling element, a thin metallic film, and a detector. Thin layers of SPR-active metals are most often produced by vacuum evaporation or sputtering.

Two arrangements of ATR optical prism couplers are used: the Kretschmann-type arrangement with a metallic film deposited directly onto the coupling prism and the Otto-type arrangement with a metallic film separated from the coupling prism, by air or other dielectric material of a thickness of about one wavelength of the radiation used in the experiments. The Kretschmann configuration is more convenient and is used in most applications.

SPR sensing platforms are combined with transducing layer(s) to enable the use of SPR for chemical sensing and biosensing.

20.13.3
Analytical Information

SPR is a general spectroscopic method for sensing refractive index changes near the surface of a metal film. The dependence of reflectance on the incident angle or excitation wavelength is defined as an *SPR spectrum*. The corresponding curve is characterized by position, width, and depth of the resonance dip in reflectance as a function of incident angle or wavelength. These features depend on the nature of the metal and thickness of its film. The position of the reflectivity minimum is the quantity that is most sensitive to the refractive index of the adjacent medium, and therefore it is usually used for the purpose of sensing. By fixing the wavelength or the angle of incidence at an appropriate constant value, the resonance can be positioned at any particular value of the incident angle or wavelength, respectively. The thickness, reflection, and absorption indexes and optical parameters of the thin layer under study may be determined from SPR reflectivity spectra.

20.13.4
Performance Criteria

Amplitude-based SPR sensing devices typically attain a refractive index resolution in the range of 10^{-6}–10^{-5}. Angular- and spectral-interrogation-based systems provide even better resolution, allowing the measurement of refractive index changes as small as 10^{-7}. This corresponds to a detection limit for an adsorbed protein layer of $<1\ \mathrm{pg\,mm^{-2}}$.

20.13.5
Applications

SPR is used in sensors and biosensors, but this method can also be used for the study of adsorption or chemical reactions in thin films as well as for the study of molecular interactions, conformational changes, and so on.

20.14
Time-Resolved Two-Photon Photoemission Spectroscopy

20.14.1
Introduction

A laser pulse strikes the sample and an electron is photoexcited to an unoccupied level [34–37]. A second laser pulse then causes the excited electron to be photoemitted. The kinetic energy of the electron can be used to estimate the energy of the unoccupied state. The time delay between pump and probe pulses can be used to determine the lifetime of the excited state. The non-time-resolved technique is known as *2PPE*.

20.14.2
Instrumentation

The experiment is carried out in UHV. The laser sources are capable of producing femtosecond pulses. Repetition rates between 10 and 250 kHz are typical. The photoelectrons are detected by an electron energy analyzer such as a concentric hemispherical analyzer.

20.14.3
Sample

The sample must be conducting and capable of withstanding UHV.

20.14.4
Analytical Information

For non-time-resolved data, this technique provides more precise information than inverse photoelectron spectroscopy (IPES) concerning the spectral line shapes and line widths of unoccupied states. In the time-resolved mode, we can obtain detailed information regarding the electron dynamics. The lifetimes of excited electrons can be compared with theoretical GW and GW + T calculations. Relaxation times can be determined from line-width measurements from high-energy resolution 2PPE experiments and cross correlations from TR-2PPE.

20.14.5
Performance Criteria

Better time-resolved experiments can be performed but only by reducing energy resolution. For extremely short-lived excited states (<1 fs), it can be difficult to make estimates of the relaxation times.

20.14.6
Applications

Image potential states, electron dynamics, coherence phenomena, interface states, and electrical currents.

20.14.7
Other Techniques

The information acquired by TR-2PPE is related to that obtained by IPES and STS (i.e., unoccupied states) and by UPS (i.e., filled states).

20.15
Total Reflection X-Ray Fluorescence Spectroscopy

20.15.1
Introduction

An X-ray beam hits a flat sample at a highly grazing angle so that total external reflection occurs [14, 38]. As a result, the X-rays only penetrate the top few atomic layers, where they cause X-ray fluorescence (XRF) emission. Thus, this technique combines high surface sensitivity with the high atomic sensitivity of the (otherwise normally bulk sensitive) fluorescence technique.

Typical energy range is 1–20 keV.

20.15.2
Instrumentation

A narrow beam of X-rays is directed at a flat sample at grazing incidence, typically <10 mrad, so that total external reflection of the X-rays occurs. As a result, the X-rays only penetrate the top few atomic layers, where they excite X-ray fluorescence. The emitted photons are then detected with a Si(Li) detector. Fluorescence detection is extremely sensitive to very low concentrations (1 part in 10^8 for transition metals and 1 part in 10^{10} for low atomic mass elements) but is normally a bulk-sensitive technique; TXRF allows it to be used in a surface-specific manner. TXRF is used particularly in semiconductor wafer processing for quantitative analysis of surface contamination present at very low concentrations. A map of contamination over the whole wafer can be obtained by rotating the sample in the beam.

UHV is not required and the technique can even be used to study liquids; however, the emphasis on detecting low levels of surface contamination means that either UHV or clean room conditions will normally be used. This technique may be used in conjunction with a high-intensity synchrotron source or with the X-ray standing wave (XSW) technique to boost sensitivity still further.

20.15.3
Sample

The sample need not be conducting but must be very flat because of the grazing incidence of the beam, and TXRF is often used on silicon wafers.

20.15.4
Analytical Information

Quantitative element-specific and surface-specific measurement of extremely low atomic concentrations on flat surfaces.

20.15.5
Performance Criteria

- Angle of incidence is generally 1–10 mrad.
- Energy range is 1–20 keV.
- Beam size is a few square millimeters.
- Beam spot size on sample – a few millimeters across the beam, but the full width of the sample along the beam axis as the grazing incidence angle that is required spreads out the beam spot considerably. Thus, by rotating the sample, the whole area of a wafer can be mapped in a few minutes.

This technique is not restricted to UHV, and it can be used in atmosphere or in clean room conditions.

Increased sensitivity can be obtained by using a powerful synchrotron source or by using TXRF in conjunction with the XSW technique. When X-rays are incident on a material that contains distinct boundaries between different layers, standing waves of X-rays will form. The standing waves are used to obtain a depth profile of the fluorescence signal for different angles of incidence or exit. The acronyms GIXRF (grazing incidence X-ray fluorescence) and GEXRF (grazing-exit X-ray fluorescence) are used for these methods.

- The spatial resolution of TXRF is generally only several millimeters.
- Analysis area is several square centimeters.
- Atomic contents of 1 part in 10^8 for transition metals or 1 part in 10^{10} for low-atomic mass elements are possible.
- Depth sensitivity is 50 Å.

TXRF can detect all elements with atomic masses from sulfur to uranium.

20.15.6
Applications

Nondestructive, non-UHV measurement of very low concentrations of impurities on the surfaces of flat samples, particularly, Si wafers.

20.16
Transmission Spectroscopy

20.16.1
Introduction

The ratio of the radiant power after and before the transmission of the electromagnetic radiation through the absorbing layer, that is, transmittance, is measured [14].

Range of operation is mid- and far-infrared.

20.16.2
Instrumentation

Conventional dispersive or Fourier transform spectrometers are used. Transmission spectroscopy of surfaces employs the same basic experimental geometry as that used for bulk samples.

20.16.3
Performance Criteria

The transparency of the substrate and the ability to compare the combined transmissivity of the substrate and its deposited surface layer with that of the substrate without this layer is crucial. A film thickness on the order of 1 μm is typical.

For characterization of surfaces or adsorbed molecules on fine powders, a mixture of the sample with KBr powder pressed into a disk is used. The so-called scattered transmission method is based on the measurement of the transmittance of a very thin layer of pulverized material. This method takes advantage of the fact that with increasing wavelength, the scattering media, which are composed of very small particles, become more transparent, and it is possible to record good absorption spectra with scattered transmission, especially in the mid-infrared region. Disks are usually prepared by pressing the powdered sample into a wafer between 0.1 and 0.25 mm thick. Good results can be obtained for solids with a high surface area.

20.16.4
Applications

Adsorption and heterogeneous catalysis have been studied by this method.

20.17
Ultraviolet Photoelectron Spectroscopy

20.17.1
Introduction

Samples are exposed to monochromatic ultraviolet radiation (typically in the range of 10–100 eV), and the energies of the emitted photoelectrons are measured to reveal information on the valence-band electronic structure of the sample [1–3, 14, 39].

20.17.2
Instrumentation

The measurement is carried out in a UHV chamber. Ultraviolet photons from a He lamp (21.2 or 40.8 eV) are directed at the sample to eject photoelectrons. The emitted electrons are collected by an electron energy analyzer, such a hemispherical mirror analyzer, to produce a spectrum showing the number of electrons emitted with a given kinetic energy. Such spectra are representative of, although not identical to, the sample's valence-band electronic DOS.

By using a synchrotron source instead of a He lamp to provide the ultraviolet photons, photon energy that preferentially favors emission from a particular element by exploiting variations in photoemission cross section can be selected. The partial DOS contribution from each individual element can then be determined.

20.17.3
Sample

Samples are normally metallic or semiconducting UHV-compatible materials.

20.17.4
Analytical Information

The valence-band electronic structure of the top few atomic layers can be determined from the variation in photoelectron intensity as a function of electron kinetic energy and incident photon energy.

20.17.5
Performance Criteria

Spatial and energy resolutions are strongly dependent on the particular type of electron energy analyzer and photon source used. However, the spatial resolution may be as good as 10 μm and the energy resolution may be as good as 5 meV.

Typically, concentrations of a few atomic percentages at the surface can be detected, depending strongly on the cross section of the particular elements present. Sensitivity decreases rapidly with depth below the surface and is often negligible below a depth of approximately five atomic layers.

High surface sensitivity makes the technique vulnerable to contamination, necessitating the use of UHV procedures. The low energy of the emitted electrons makes the technique vulnerable to the presence of stray magnetic fields and hence magnetic shielding is normally required. The spectrum can be influenced by the particular crystal structure of the sample's top few atomic layers, which may not be completely representative of the bulk material. This technique is generally not suitable for insulating materials.

20.17.6
Applications

UPS is used to probe the electronic states near the Fermi level that are responsible for determining a material's electronic properties and to study the nature of the bonding between the atoms in the sample or between the sample and adsorbate molecules on its surface.

20.17.7
Other Techniques

Measurement of the photoelectron intensity from single-crystal samples as a function of both their kinetic energy and emission angle allows the total momentum of the photoelectrons to be determined, enabling bandmaps of the electronic DOS of the material to be produced (see ARUPS).

Filled DOS information can also be obtained from metastable deexcitation spectroscopy (MDS).

By combining the electron energy analyzer with a polarization-sensitive Mott detector separate spin-up and spin-down valence-band DOS spectra can be produced for magnetic samples. This technique is known as *spin-polarized ultraviolet photoelectron spectroscopy*.

20.18
X-Ray Absorption Fine Structure

20.18.1
Introduction

A monochromatic X-ray beam is directed onto a sample [25, 39]. The wavelength of the beam is ramped through an absorption edge of an element, which is a constituent of the sample, while the extent of the X-ray absorption is measured to produce an absorption spectrum. As a monochromatic beam of X-rays at various wavelengths is needed, SR is used as the X-ray source for X-ray absorption fine structure (XAFS).

For XANES, the energy range ($<50\,\text{eV}$) near to absorption edge is studied. However, for EXAFS, the spectrum is acquired much further from the absorption edge. Information regarding the local structure around the atom whose absorption edge is acquired can be obtained.

Range of operation is incident photon energies in the range of 1–20 keV.

20.18.2
Instrumentation

An SR source is required. EXAFS and XANES are normally regarded as bulk-sensitive techniques. However, by measuring the total electron current emitted from the sample, both methods can be made relatively surface sensitive. The detection of the electron current is called *total electron yield*. The sample is normally placed inside a ''cell'' containing noble gas atoms (Ar and He). These gases prevent the electrons from combining with atoms in the air, which might otherwise affect the acquisition of the data. The intensity of the incident synchrotron light may vary and hence its flux is continuously measured by passing the light through another cell before striking the sample. The ratio of the TEY to the incident flux provides the spectral data. Improved detection of the EXAFS signal could be carried out using gas microstrip detectors. These detectors allow a more surface-sensitive signal to be acquired.

20.18.3
Analytical Information

EXAFS spectra provide information regarding the local environment surrounding the atom whose absorption edge is studied. The specific local information includes the atom type of neighboring atomic shells, the distance of those shells from the central (absorbing) atom, and the static or dynamic disorder. The latter is given by the Debye–Waller value. EXAFS spectra can be acquired in a gaseous environment. This allows data to be acquired in non-UHV environments and gas adsorption and *in situ* catalyst studies to be undertaken.

XANES spectra provide local structure information and the oxidation state. In the XANES region, electrons that are excited from the core level (usually the K level) jump into unfilled bound states, nearly bound states (resonances), or continuum states. Owing to multiple electron scattering, XANES spectra are harder to interpret than EXAFS spectra.

20.18.4
Performance Criteria

Primary X-ray energy is 1–20 keV.

The sample should be able to withstand the intense X-ray beam from the synchrotron. For the TEY technique, the sample should be conducting. XAFS study of low atomic number elements $Z < 11$ provides less information. It can be difficult to distinguish elements in the shells surrounding the central atom if they are close in atomic number. It can be difficult to distinguish static from dynamic disorder.

20.18.5
Applications

EXAFS is used in many applications where local state information is required, such as materials analysis, catalysis, protein crystallography, or the structure of liquids and amorphous materials. XANES can also be used to determine the oxidation state of an element in a sample.

20.18.6
Other Techniques

Surface-extended X-ray absorption fine structure (SEXAFS) uses Auger or photoelectrons to detect the EXAFS signal. This ensures that this technique has a much higher surface sensitivity than EXAFS acquired using the TEY method. SEXAFS requires UHV and the detection instrumentation normally associated with the AES or XPS techniques.

20.19
X-Ray Photoelectron Spectroscopy

20.19.1
Introduction

Samples are exposed to monochromatic X-ray radiation (typically with an energy range of 1–2 keV, but energies up to 10 keV may be used) and the characteristic energies of the emitted photoelectrons are measured to reveal information about the elemental composition, elemental distribution, and chemical bonding characteristics of the near-surface region [1, 3, 14, 39–41].

20.19.2
Instrumentation

The measurement is carried out in a UHV chamber. Monochromatic X-ray photons, typically from an AlK_α (1486.6 eV) or MgK_α (1253.6 eV) X-ray source, are directed at the sample to eject photoelectrons. These electrons have energies ranging from 0 eV up to almost the same energy as the incident photons, but most are emitted at a few discrete energies that are characteristic of the elements present in the sample. The photoelectrons are collected by an electron energy analyzer such as a hemispherical mirror analyzer (HMA) to produce a spectrum of the number of electrons versus their kinetic energy. Analysis of this spectrum provides quantitative information about the composition of the near-surface region of the sample.

Although XPS generally only reveals information about a particular point on the sample surface that is typically 100 μm to 1 mm across, a number of different approaches can be used to generate image maps of the elemental distribution over a wider area. By using a microfocused X-ray source, images with a resolution of some 10 μm may be obtained by scanning the sample under the beam or scanning the beam across the sample surface. Alternatively, images may be produced by scanning the area of analyzer sensitivity across the surface using electrostatic electron deflector plates. This method is more straightforward and cheaper to implement but has significantly poorer resolution (100 μm). Many modern electron energy analyzers have imaging optics and detectors that collect XPS spectra from many discrete points simultaneously to produce an image of elemental distribution. This method produces the highest resolution spatial images with a resolution of better than 10 μm.

Tilting the sample so that the analyzer collects electrons that are emitted at a more grazing angle increases the surface sensitivity of the technique. By acquiring spectra at several different angles, which have different surface sensitivities, quantitative information about the depth distribution of the elements in the top few nanometers of the sample can be extracted; this is known as angle-resolved X-ray photoelectron spectroscopy (ARXPS).

The energy resolution of XPS may be as good as 0.2 eV, which is sensitive enough to detect the small chemical shifts in the kinetic energy of the photoelectrons that result from variations in the chemical environment of a particular element. By analyzing the shape of an XPS peak, the relative contribution from different chemical states can be determined, revealing important information about the sample chemistry and atomic bonding.

By using a synchrotron source to provide the X-rays, a photon energy that preferentially enhances emission from a particular peak by exploiting variations in photoemission cross section as a function of photon energy to increase sensitivity to the given element can be selected.

20.19.3
Sample

Samples are generally metallic or semiconducting UHV-compatible materials. However, insulating samples such as polymers can also be studied if a low-energy ‘‘flood gun’’ electron source is used to supply electrons to the surface of the sample, replacing those ejected by photoemission and preventing net sample charging that would otherwise distort the position and shape of the XPS peaks.

20.19.4
Analytical Information

XPS reveals quantitative information about the elemental composition of the top 10 nm or sample (Figure 20.2). Using higher energy X-rays from a source such as a TiK_α (2040 eV) gun, or a high-energy synchrotron, can increase the kinetic energy of the photoelectrons and hence the analysis depth.

Images of the elemental distribution across a wider area of the sample surface can be obtained either by using an imaging electron energy analyzer or by scanning the position of the sample, the X-ray beam, or the analysis spot.

Quantitative elemental depth profiles can be obtained by collecting XPS spectra at different emission angles, which have differing depth sensitivities, and on analyzing the resulting changes in the peak intensities from the different elements in the sample (ARXPS).

Small chemical shifts in the XPS peaks can be used to discriminate between contributions coming from the different chemical states of a particular element. This reveals important quantitative information about the nature of the chemical and bonding environment for each element in the sample. This is particularly important in the study of polymers where the material’s properties are determined by small changes in the bonding of the carbon atoms.

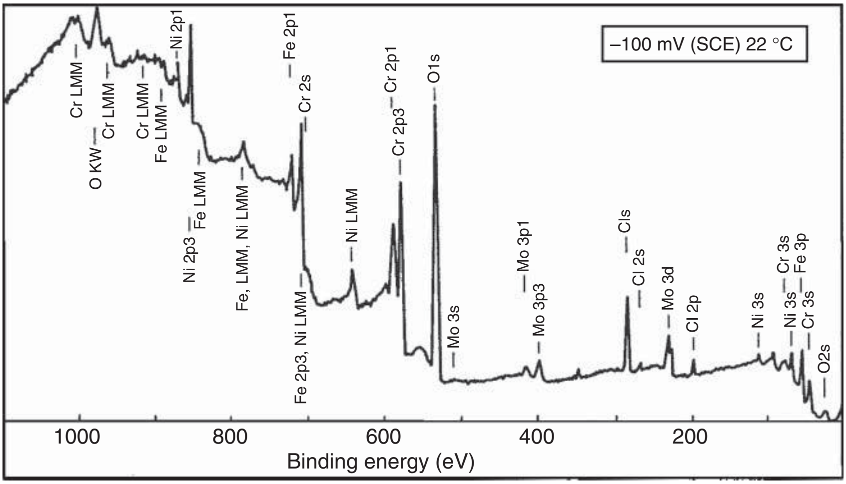

Figure 20.2 XPS survey spectrum recorded after polarization of the steel $20Cr_{18}Ni_{6}.1Mo\,0.2\,N$ to −100 mV (SCE) at 22 °C in 0.1 M HCl + 0.4 M NaCl. (Reproduced with permission from Ref. [14].)

20.19.5
Performance Criteria

Spatial and energy resolutions are strongly dependent on the particular type of electron energy analyzer and X-ray source used. However, spatial resolution may be as good as 10 μm, depth resolution may be as good as 0.2 nm, and the energy resolution may be as good as 0.2 eV.

Typically, concentrations of 1% or less at the surface can be detected, depending strongly on the photoemission cross section of the particular elements present. Using various corrections to the signal intensities, the accuracy of the surface concentration measurement can be as good as ±10%. Sensitivity decreases rapidly with depth below the surface and is often negligible below a depth of approximately 5–10 nm, depending on electron energy. All elements can be detected directly with the exception of hydrogen and helium.

High surface sensitivity makes the technique vulnerable to contamination, necessitating the use of UHV procedures. Spectra taken on crystalline samples can be influenced by diffraction effects, which can lead to variations in the peak intensity at different emission angles (see X-ray photoelectron diffraction, XPD). The composition of the surface as probed by XPS may not be completely representative of the bulk material because of surface segregation, degradation, or contamination.

Some samples such as polymers may be damaged by exposure to the intense X-ray beam.

An electron flood gun must be used to avoid charging distortions when studying insulators.

20.19.6
Applications

XPS is one of the most widely used surface and materials analysis techniques in both academia and industry. Applications include semiconductor wafer defect analysis, identification of surface contamination in industrial processes, adhesion chemistry analysis, catalysis, analysis of fracture or failure surfaces, and analysis of the strength and type of carbon bonding in polymers.

20.19.7
Other Techniques

AES requires equipment very similar to XPS and the two techniques are frequently integrated into the same analytical system to provide complementary information about a sample.

UPS is a technique very similar to XPS that makes use of much lower energy photons to emphasis variations in the low-energy valence-band electronic structure.

XPD is closely related to XPS but exploits the variations in XPS peak intensity that occur at different emission angles in crystalline samples to reveal element-specific crystallographic information.

20.20
X-Ray Standing Wave

20.20.1
Introduction

When single-crystal samples are exposed to a narrow beam of monochromatic X-rays, the regular arrangement of the atoms leads to diffraction of these X-rays at certain critical angles, a condition known as *Bragg reflection* [42–45]. The incoming and outgoing X-rays then interfere to form a standing wave that permeates the material and even extends beyond it. The resulting periodic spatial variations in the amplitude of the X-rays within the lattice mean that the X-ray absorption signal from a given element becomes very sensitive to its relative position in that lattice. Thus, XSW provides a sensitive, element-specific, probe of crystal structure, or of the bonding site of an absorbed molecule on a surface. Energy range is typically 2–80 keV.

20.20.2
Instrumentation

A narrow beam of monochromatic X-ray photons from a synchrotron is directed onto a single-crystal sample at an angle that satisfies the Bragg condition for that material in order to establish an XSW throughout the sample. The X-ray absorption signal from the element of interest is then monitored by a technique such as AES, XPS, or XRF as the relative position of the standing wave is gradually shifted through the lattice by changing the reflection angle or photon energy slightly. The relative position of the standing wave with respect to the crystal lattice can be calculated from theory for any given combination of angle and photon energy and hence by studying how the absorption signal of a particular element changes as the wave moves through the lattice the position of that element's atoms within that lattice can be established precisely. As the standing wave extends some distance beyond the surface of the sample, the technique is particularly useful for studying the bonding of absorbed molecules. Although UHV conditions are not a requirement for XSW, the emphasis on using XSW to study molecular absorption means that UHV is frequently used to avoid contamination problems. This technique normally requires a synchrotron X-ray source so that the standing wave conditions can be altered by changing the photon energy rather than the experimental geometry. Synchrotrons also have the additional advantages of producing a highly collimated X-ray beam that is extremely bright and therefore can be used for studying dilute systems.

20.20.3
Sample

Single-crystal materials, buried interfaces, and adsorbates on single-crystal surfaces.

20.20.4
Analytical Information

Element-specific and/or chemical-species-specific crystallographic and bonding information.

20.20.5
Performance Criteria

When XPS is used to detect the element of interest in the XSW experiment, the energy resolution may be as good as 0.2 eV and hence XSW can be used to probe the bonding of a particular chemical species within the lattice or on the sample surface by making use of small chemical shifts in the XPS peaks. XSW is very good at distinguishing between adsorption occurring at slightly different sites within the lattice that would otherwise appear very similar in complementary techniques such as SEXAFS.

An X-ray beam with energy 2–5 keV is required, and energies may be as high as 80 keV for some applications.

Minimum spot size for the X-ray beam is generally 0.5–1 mm.

The requirement for highly collimated intense X-ray beams with variable photon energy often restricts the technique to use at synchrotron sources, although for certain applications a laboratory X-ray source may be sufficient.

XSW has the advantage of not being inherently restricted to use in UHV conditions, and it can be used to study buried interfaces.

The depth sensitivity of XSW is dependent on the technique used to detect the X-ray absorption. If AES or XPS is used, then the technique is surface sensitive with negligible sensitivity below 5–10 atomic layers, whereas using fluorescence detection results in bulk sensitivity. Typically, concentrations of a few atomic percentage of a monolayer at the surface can be detected. The use of XPS for element detection can also make the XSW technique chemical species specific.

Very high angular resolution is required for this experiment as the width of the ‘‘rocking curve’’ of angles over which the standing wave condition is satisfied can be mere seconds of arc. However, it may be more than a degree in some configurations where the beam hits the sample at close to normal incidence (normal incidence X-ray standing wave) NIXSW.

XSW was initially restricted to very high-quality single crystals such as semiconductors owing to its extreme sensitivity to the degree of crystal perfection; however, the recent development of NIXSW techniques, which have wider angular rocking curves (and are hence less sensitive to crystal perfection), has now made it applicable to conventional single-crystal metallic samples.

XSW does not give a direct measurement of the position of a given atom; rather, it gives the atom’s position relative to the bulk unit cell of the lattice. XSW of adsorbates yields poor results in systems where extensive reconstruction of the surface has occurred, as it cannot determine where adsorbate atoms are relative to this reconstructed surface, only relative to the unreconstructed bulk lattice.

The quality of XSW data is very sensitive to the angular spread and photon energy resolution of the X-ray beam, which normally makes it necessary to use a synchrotron source.

20.20.6
Applications

Element-specific crystallography of single crystals. Study of the site-specific and/or chemical state-specific bonding of adsorbates to single-crystal surfaces. Structure of buried interfaces. Applications where UHV-specific techniques are not applicable.

Appendix to Chapters 18–20: List of Acronyms Related to Surface Analysis

(e,2e)	(e,2e) spectroscopy
AEAPS	Auger electron appearance potential spectroscopy
AEES	nuclear Auger electron (emission) spectroscopy
AES	Auger electron spectroscopy
AFS	atomic force spectroscopy
AISS	alkali ion scattering spectroscopy
APECS	Auger photoelectron coincidence spectroscopy
APFIM	atom probe field ion microscopy
APS	appearance potential spectroscopy
ARAES	angle-resolved Auger electron spectroscopy
ARIPES	angle-resolved inverse photoemission spectroscopy
ARPES	angle-resolved photoelectron spectroscopy
ARPS *.viz*	ARPES
ARUPS	angle-resolved ultraviolet photoemission spectroscopy
ARXPS	angle-resolved X-ray photoelectron spectroscopy
ATR	attenuated total reflection
BEES	ballistic electron emission spectroscopy
BIS	Bremsstrahlung isochromat spectroscopy
BLE	bombardment-induced light emission
BS	momentum-resolved Bremsstrahlung spectroscopy
BSE	backscattered electron imaging
CITS	current imaging tunneling spectroscopy
CL	cathodoluminescence
CPAA	charged particle activation analysis
DAPS	disappearance potential spectroscopy
DRIFTS	diffuse reflectance (or reflection) infrared Fourier transform spectroscopy
DSPES	gamma-ray (or depth-selective) photoelectron spectroscopy
EAES	electron-excited Auger electron spectroscopy.*viz* AES
EAPFS	extended (electron) appearance potential fine structure
EDX	energy-dispersive X-ray analysis
EEAES	electron-excited Auger electron spectroscopy
EELFS	extended electron energy loss fine structure
ELS	energy loss spectroscopy.*viz* REELS
EMPA	electron microprobe analysis.*viz* EPMA
EMS	electron momentum spectroscopy
EPMA	electron probe microanalysis
EPXMA	electron probe X-ray microanalysis
ERCS	elastic recoil coincidence spectrometry
ERDA	elastic recoil detection (analysis)
ESCA	electron spectroscopy for chemical applications (originally analysis)

ESD	electron-stimulated desorption
ESDIAD	electron-stimulated desorption ion angular distributions
ESTS	electrochemical scanning tunneling spectroscopy
ETS	electron transmission spectroscopy
EWCRDS	evanescent wave cavity ring-down spectroscopy
EXAFS	extended X-ray absorption fine structure
EXELFS	extended electron energy loss fine structure.*viz* EELFS
FIM	field ion microscopy
FIMS	field ion mass spectroscopy.*viz* APFIM
FMIR	frustrated multiple internal reflections
FRS	forward recoil scattering
GDMS	glow discharge mass spectrometry
GDOES	glow discharge optical emission spectrometry
GIS	grazing incidence spectroscopy
HEIS	high-energy ion scattering spectrometry
HFS	hydrogen forward scattering
HIAA	high-energy ion activation analysis
HIERDA	heavy ion-ERDA
HREELS or HEELS	high-resolution electron energy loss spectroscopy
IBSCA	ion beam spectrochemical analysis
IEAES	ion-excited Auger electron spectroscopy
IETS	inelastic electron tunneling spectroscopy
INS	inelastic neutron scattering
Ion excited AES.*viz*	AES
IPES	inverse photoelectron spectroscopy
IPMA	ion probe microanalysis
IPS	inverse photoelectron spectroscopy.*viz* IPES
IRAS.*viz*	IRRAS
IRRAS	infrared reflection–absorption spectroscopy
IS	ionization spectroscopy
ISS	ion scattering spectrometry
ISS	ion scattering spectrometry
KRIPES	*k*-resolved inverse photoemission spectroscopy
LAMMA	laser microprobe mass analysis or spectroscopy
LAMMS.*viz*	LAMMA
LEED	low-energy electron diffraction
LEEM	low-energy electron microscopy
LEIS	low-energy ion scattering spectrometry
LMMS.*viz*	LAMMA
MDS	metastable desorption spectroscopy
MEIS	medium energy ion scattering spectrometry
MEIS	medium energy ion scattering
MIES	metastable impact electron spectroscopy
MIR	multiple internal reflection
MQS	metastable quenching spectroscopy

NAA	neutron activation analysis
NDP	neutron depth profiling
NEXAFS	near-edge X-ray absorption spectroscopy
NIXSW	normal incidence X-ray standing wave
NRA	nuclear reaction analysis
PAES	positron annihilation Auger electron spectroscopy
PAS	photoacoustic spectroscopy
PEELS	parallel electron energy loss spectroscopy
PEEM	photoemission electron microscopy
PESIS	photoelectron spectroscopy of inner shell
PIES	penning ionization electron spectroscopy
PIGE	particle-induced gamma ray emission
PIGME.*viz*	PIGE
PIXE	particle-induced X-ray emission
PM	FTIRRAS
PMP	proton microprobe
RAIRS	reflection–absorption infrared spectroscopy
RBS	Rutherford backscattering spectrometry
RBS/C	RBS-channeling spectrometry
REELS	reflection electron energy loss spectroscopy
REM	reflection electron microscopy
RHEED	reflection high-energy electron diffraction
RNRA	resonant nuclear reaction analysis
RS	recoil spectrometry
SALI	surface analysis by laser ionization
SAM	scanning Auger microscopy
SCANIIR	surface composition by analysis of neutral and ion impact radiation
SECSA	scanning electron spectroscopy for chemical analysis
SEM	scanning electron microscopy
SEMPA	scanning electron microscopy with polarization analysis
SEMPA	scanning electron microscopy with polarization analysis
SERS	surface-enhanced Raman scattering
SEW	surface electromagnetic waves spectroscopy
SEXAFS	surface-extended X-ray absorption fine structure
SEXAPS	soft X-ray appearance potential spectroscopy
SFG	sum-frequency generation
SHG	second harmonic generation spectroscopy
SIMP	scanning ion microprobe
SIMS	secondary ion mass spectrometry
SLEEM	scanning low-energy electron loss microscopy
SNMS	secondary neutral mass spectrometry
SPAES	spin-polarized Auger electron spectroscopy
SPUPES	spin-resolved ultraviolet photoemission spectroscopy
SPIPES	spin-resolved inverse photoelectron spectroscopy

SPMDS	spin-polarized metastable deexcitation spectroscopy
SPMP	scanning proton microprobe
SPR	surface plasmon resonance spectroscopy
SRPES	synchrotron radiation photoelectron spectroscopy
SRUPS	spin-resolved ultraviolet photoemission spectroscopy
STM	scanning tunneling microscopy
STS	scanning tunneling spectroscopy
SXAPS	soft X-ray appearance potential spectroscopy
SXPS	soft X-ray photoelectron spectroscopy
TCS	total (or target) current spectroscopy
TEELS	transmission electron energy loss spectroscopy
TEM	transmission electron microscopy
TERS	tip-enhanced Raman scattering
THEED	transmission high-energy electron diffraction
TOF-ERDA	time-of-flight elastic recoil detection analysis
TOF-NDP	time-of-flight neutron depth profiling
TPD	thermal desorption spectroscopy
TPRS	temperature-programmed reaction spectroscopy
