Note: Usage of acronyms is very typical for surface analysis methods. Synonyms or different acronyms are used often for very subtle clones of the techniques; therefore, this list cannot be regarded as complete. A system for generation of acronyms for the names of the individual techniques is given by IUPAC recommendation [46].

Further Information

Information on some other techniques or acronyms, software for surface science studies, surface science databases, research centers and institutes, user groups and bulletin boards, academic research groups, teaching resources for surface science, conferences, commercials services and suppliers, sources of practical information, and also, a collection of links to lecture courses and tutorials covering a broad range of surface science can be found on web sites, for example: *http://www.uksaf.org/tech/list.html*.

Single-Molecule Spectroscopy

Frank Schleifenbaum, Christian Blum, Marc Brecht, and Alfred J. Meixner

21.1
Motivation and Necessity of Single-Molecule Studies

All types of spectroscopy have in common that they are concerned with information about molecular structures, may it be the monitoring of individual chemical bonds, the observation of an electronic structure and its interaction with its environment, or the spatial composition of atoms in a crystal lattice. As powerful as these methods are, they typically refer to averaged data derived from a huge number of molecules and thus report on the typical, but not on individual features of these types of molecules. However, the ultimate goal of any science is to go to the innermost item of nature, which is considered to represent the properties observed in bulk studies. This innermost item can, for example, be regarded as an individual molecule as the basis of the current understanding of the composition of nature. Thus, an approach to single-molecule spectroscopy would open the field to investigate the most reduced functional fraction in nature. This becomes even more obvious regarding, for example, chemical symbolic language [1]. Here, the incorporated models depict chemical reactions of single molecules, such as $A + B \rightarrow C$, whereas the observation is ensemble. Thus, specific details typically remain concealed, but might be uncovered by the investigation of a single molecule. Moreover, a single molecule, given that it is not isolated in the gas phase, is always accompanied by neighboring molecules, the so-called local chemical environment, which might affect its individual (spectral) properties [2]. Thus, single-molecule spectroscopy does not only provide information about the basic functional composition element of nature but it might also be useful as a reporter for the local chemical environment.

In this chapter, we first discuss the intrinsic problems to be solved toward optical single-molecule detection. We present approaches to overcome these problems with both methodical and technological respect. After that we proceed to a chronological journey through the field of single-molecule spectroscopy, demonstrating the huge potential of these techniques. Starting from a very general concept, the different peculiarities that have developed are shown along with what modern single-molecule spectroscopy is capable of in order to provide a deeper understanding of

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

molecular processes in nature. Finally, novel applications and developments are discussed in a compact outlook.

21.2
Intrinsic Problems and Difficulties in Optical Single-Molecule Techniques

It was not until the 1990s that the first optical single-molecule studies could be carried out [3–6]. The basic reason this technique developed so late simply lies in the intrinsic properties of a single molecule. This is small in size, is expected to give low signals, and typically is accompanied by neighboring species interfering unspecifically with the target molecule [7]. These were the main challenges that have to be fought on the course to single-molecule spectroscopy. The first concern of the low signal level is mainly a technical issue. Here, highly efficient detectors, in combination with decent computation power for instrument control and data analysis, were required. Regarding typical absorption cross sections in different regimes of the electromagnetic spectrum, it becomes obvious that the amount of radiation absorbed by an individual molecule is too weak to be separated from the excitation radiation [1]. This, in turn, limits the types of spectroscopies capable of single-molecule detection to those that are self-emitting rather than solely absorbing. We utilize the fact that generally it is more feasible to detect a weak signal in the dark than to identify a missing fraction in a bright signal. For illustration, imagine a big city at night. We probably would not notice one single light turned off. Contrarily, we would immediately identify a single bulb turned on in a lonely cottage in the mountains at night. The most prominent technique that fulfills this basic requirement is the optical fluorescence spectroscopy [3]. Here, the emitted light is shifted both spectrally and temporally with respect to the excitation radiation, which, accordingly, can be easily separated from the fluorescence signal.

So far, we have already learned that fluorescence-based techniques are one method of choice for single-molecule detection. This leads us to the next problem, which is about discrimination: if we do not work in the gas phase (which is experimentally very challenging and would not give any information about the interaction of an individual molecule with its local chemical environment), the ‘‘single’’ molecule to be investigated is always surrounded by neighboring molecules. Accordingly, in a sample volume, which is spatially more extended than a molecular structure (which is typically the case), a large number of molecules would be simultaneously addressed. To nevertheless perform single-molecule studies, one out of these many molecules in the sample volume has to be special, for example, one molecule in the investigated area must provide a recordable signal, whereas the moiety remains undetected. This important criterion can again be met by fluorescence-based approaches if a fluorescent molecule is embedded in a nonfluorescent surrounding matrix. In this way, merely the fluorescent label can be addressed optically to emit fluorescence photons, whereas the surrounding matrix remains invisible. However, although we claimed that the molecules of interest are embedded in a nonfluorescent matrix, the summation of a vast multitude of ''nonfluorescent'' species, will result in a noticeable signal due to, for example, nonperfect materials or impurities. Hence, the matrix typically will contribute to an unspecific background signal that overlaps with the desired molecular emission. If the amount of background signal gets too dominant, the signal-to-noise ratio (SNR) drops under the detection level and the emission of the individual target molecule cannot be resolved. To overcome this problem, the easiest way is to keep the amount of background signal as small as possible by reducing the detection volume, that is, the sample volume from which emitted light is detected, to a minimum. Accordingly, a preferably small sample volume, which confines the contribution of undesired neighboring molecules, is a prerequisite for single-molecule spectroscopy and imaging. A more detailed discussion is given in Section 21.3.

The need for luminescent species suited for single-molecule spectroscopic studies actually does not limit the number of molecular systems suited for single-molecule studies as much as we might expect at a first glance [8]. Currently, there is a huge variety of different fluorescent dyes, commercially available and absorbing and emitting over the entire visible spectral range [3, 9, 10]. Moreover, biotechnological progress offers a number of autofluorescent proteins (AFPs) with emission from the dark blue over green and yellow to the dark red spectral region [11–15]. These proteins are of high interest, as they can be expressed by a living organism and external staining can be avoided. Moreover, nanometer-sized quantum emitters based on inorganic semiconductors are available as highly photostable luminescent species [16–21]. Recently, even metallic nanoparticles have been reported as promising systems for single-molecule spectroscopy [22–25].

21.3
Technical Realization

These thoughts lead to the issue as to how these requirements can technically be met. Unlike in typical classical spectrometers, cuvette-based techniques cannot be used for single-molecule spectroscopy because of the large sample volumes. Here, a single dye molecule is surrounded by a huge number of solvent molecules, which induce background signals. These corrupt the SNR and thus hamper single-molecule detection as discussed earlier.

The most appropriate tool to achieve a minimal detection volume is given by microscopic techniques, especially by confocal microscopy, where the detection volume is confined by the diffraction limit of electromagnetic waves [26, 27]. For a typical wavelength of 500 nm, the diffraction-limited focal volume of a confocal microscope becomes as small as 0.2 fl (2×10^{-16} l). To further reduce the detection volume, the molecules can be embedded in a thin polymer film, strongly confining the sample volume in the axial direction [28]. In this case, regarding a surrounding matrix with a typical thickness of 50 nm and assuming a molecular size of 1 nm^3, in the focal volume there are roughly 1–5 million molecules. Accordingly, to detect one individual molecule out of 1 million, the product of absorbance cross section and the fluorescence quantum yield of this target molecule as a measure for molecular brightness have to exceed the sum of this product from all matrix molecules to obtain a reasonable SNR. This requirement is met for the combination of typical transparent polymers such as polystyrene (PS), polyvinylalcohol (PVA), or poylmethylmethacrylate (PMMA) with typical fluorescent dyes with high fluorescence quantum yields such as xanthene and perylene derivatives.

The technical requirements for a confocal microscope feasible of single-molecule spectroscopy are relatively moderate as depicted in Figure 21.1.

The collimated monochromatic excitation light, typically from a laser source, is focused onto the sample via a high NA microscope objective, resulting in a diffraction-limited excitation spot. The emitted light is collected by the same objective and led through a dichroic beamsplitter, which reflects the excitation light while the bathochromically shifted (i.e., shifted to higher wavelengths) emission signal is transmitted. To filter out backscattered excitation light, which even after passing the dichroic beamsplitter is still orders of magnitude more intense than the weak fluorescence signal, steep-edge longpass filters are inserted into the beam

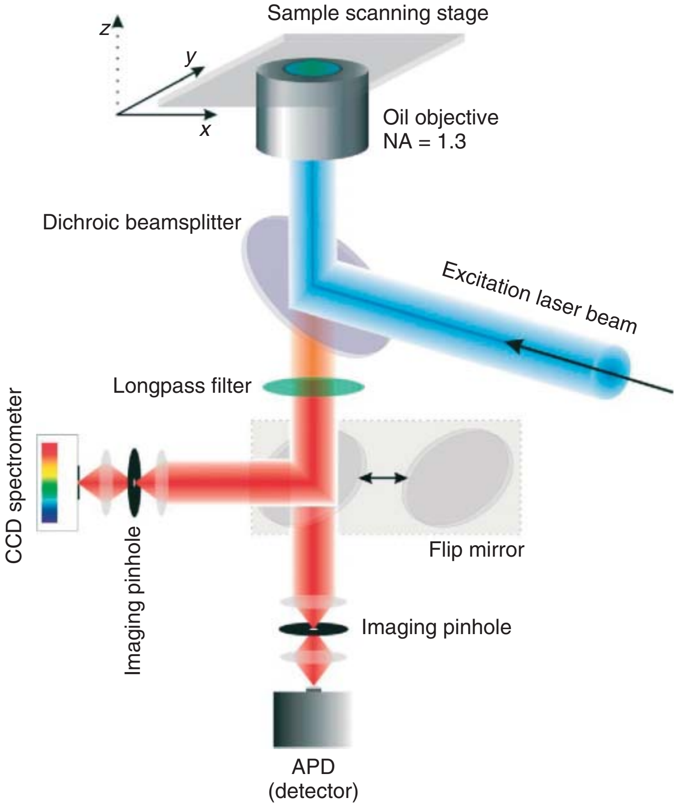

Figure 21.1 Confocal sample scanning setup.

path. The light is then focused through a pinhole onto the active area of a detector unit.

The kind of detector depends on the spectroscopic requirement. To record an intensity image of the sample or to record the intensity behavior of single molecules overtime, spectral integrating detectors such as avalanche photodiodes (APDs) with single photon sensitivity and a high time resolution, are used. To record frequency-resolved spectra of the individual emitters, the emitted light can be led to a spectrometer, typically consisting of a spectrograph coupled to a highly sensitive CCD camera. This configuration is crucial for single-molecule spectroscopy and deviates from standard ensemble spectrometers. However, in these spectrometers, fluorescence spectra are recorded by rotating a grating or a prism and directing the spectrally dispersed light onto a point detector. For single-molecule detection, it is not feasible to rotate the dispersive element due to the digital characteristics of single-molecule emission, which will be discussed in detail later on. Using a two-dimensional CCD chip, we can record the entire spectrum at a time, and thus the spectrum is not corrupted by, for example, temporal unstable emission.

The confocal principle comprises point-to-point imaging of a sample area [29]. Accordingly, to generate an image, the sample must be raster scanned relative to the detection volume. Currently, there are several methods to accomplish this raster scanning (e.g., beam scanning and spinning disk), but for single-molecule studies, the sample-scanning technique has prevailed in most cases because of high spatial precision together with superior beam quality. In the sample- or stage-scanning technique, the sample is scanned through the focus of a stationary objective via a feedback-controlled piezo-driven sample stage. Thus, a position accuracy of a few nanometers is obtained, while the optical beam path remains unaffected from the scanning routines. An alternative technique utilizes a movable excitation beam, which is raster scanned along the back aperture of the microscope objective. Although this technique allows for fast image acquisitions, the excitation profile is inhomogeneous over the sample and not every molecule experiences the identical excitation field.

21.4
How it Began: Low-Temperature Studies

The first single-molecule spectroscopy studies were carried out in the early 1990s by W.E. Moerner and M. Orrit at liquid helium temperatures [6, 30–32]. In those early days, the available equipment could not meet all requirements reported earlier. Especially, high-precision scanning stages were not available and the necessity of precisely scanning a sample had to be circumvented. Moreover, it was necessary to detect as many photons as possible from an individual molecule.

Still, it had to be ensured that the addressed molecule was different from its surrounding medium so that it could be observed individually. This was met by keeping the detection volume small and by utilizing some characteristics observable at cryogenic temperatures below 4 K. Here, special characteristics of molecular emission that are covered by thermal noise at room temperature come into play, which is discussed in brief in the following [33].

Typical fluorescence spectra at room temperature are very broad and unstructured because of various mechanisms increasing the linewidth. Most of these mechanisms can be suppressed by lowering the temperature. In the low-temperature limit, the linewidth of a fluorescence spectrum is solely defined by the excited-state lifetime, that is, the timespan a molecule remains in the excited S_1 state after the absorption of a photon [34]. The resulting natural, homogeneously broadened spectral linewidth is as small as 10–100 MHz for typical fluorescent molecules with nanosecond excited-state lifetimes as shown, for the example of terylene at different temperatures, in Figure 21.2.

The transition energy of a fluorophore basically represents its electronic properties. However, the local chemical environment wherein a fluorophore is embedded holds the ability to tune the transition energy remarkably. Depending on the matrix, the composition of the environment of every individual fluorophore can be different. Accordingly, each fluorophore in this host matrix experiences slight differences in its local chemical environment, leading to slight shifts in the frequency of the transition for both, the excitation ($S_0 \rightarrow S_1$) and the emission ($S_1 \rightarrow S_0$). At very low temperatures, these differences become visible in the excitation and emission

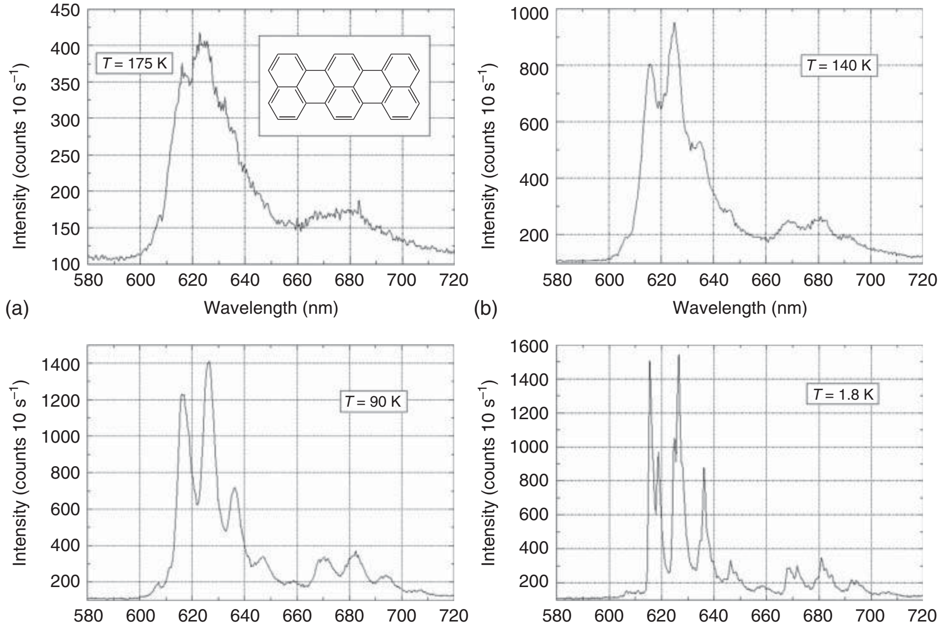

Figure 21.2 (a–d) Fluorescence spectra of an ensemble of terylene dyes in a Sphol'skii matrix at different temperatures.

spectrum of an individual molecule [35, 36]. This, in turn, can be used to selectively address individual emitters among others, as will be explained in the following.

For an ensemble of emitters, all molecules in the focal volume contribute to the measured signal, which results in an averaged spectrum that is broadened to a full width at half maximum (FWHM) of up to 30 GHz as shown in Figure 21.3.

While this broadening might definitely tell us something about the heterogeneity of the matrix system, still we are not investigating single molecules. Yet, the inhomogeneous line broadening opens the way to single-molecule detection. Two strategies are applicable: (i) using a single-mode laser source with a spectral linewidth comparable to the homogeneous broadened linewidth of a molecule, we can scan the excitation wavelength along the inhomogeneously broadened ensemble spectrum. At the very edges of the distribution (blue curve in Figure 21.3), finally we achieve an excitation wavelength, where exactly one molecule in the focal volume is in resonance with the excitation light. As a result, we can monitor the emission of an individual emitter at low temperatures by exactly tuning the excitation wavelength of a small bandwidth laser source. (ii) The other, maybe more straightforward, approach uses diluted dye solutions. Thus, for a given excitation wavelength, the number of molecules in the detection volume, which are in resonance with the excitation, can be reduced to an extent, where exactly one molecule is excited.

As discussed earlier, narrow line spectra were crucial for the first single-molecule investigations in solids at cryogenic temperatures. The line shape of these molecules depends thereby remarkably on the properties of the solid. The main differences

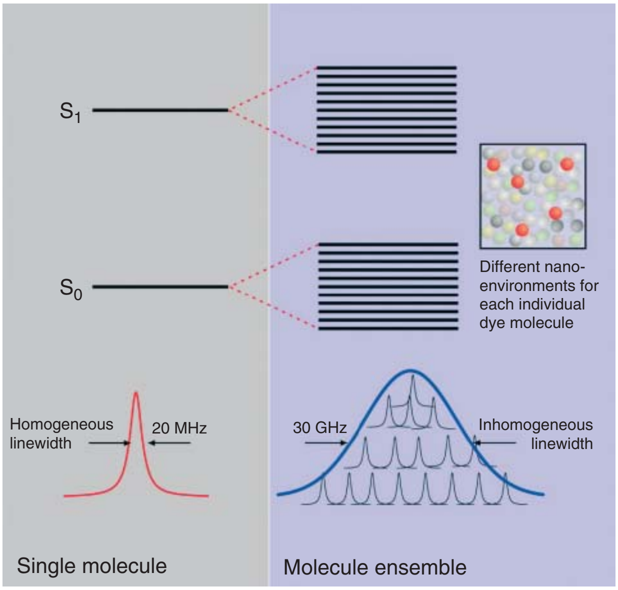

Figure 21.3 Homogeneous and inhomogeneous spectral line broadening at low temperatures.

between the optical bands of a molecule embedded in a solid and those in the gas phase are due to the interaction of the molecules with lattice vibrations (phonons). The shape of vibronic bands is determined by the electron–phonon coupling. At low temperature, the emission of every vibronic band consists of a narrow zero-phonon line (ZPL) and a relatively broad phonon wing (PW) at the long-wave side of the ZPL. The ZPL corresponds to a transition of the molecule without changing the number of phonons in the matrix, whereas the PWs are related to the transitions that create or annihilate phonons. The intensity Z of the optical band profile can be described in the form

$$I(\upsilon, T) = I_{\mathrm{ZPL}}(\upsilon, T) + I_{\mathrm{PW}}(\upsilon, T) \tag{21.1}$$

The ZPL has a Lorentzian shape with width γ. The ratio of ZPL and PW intensities can be characterized by the Huang–Rhys factor S [37] that is closely related to Debye–Waller factor $\alpha(T)$, which depends on temperature according to

$$\alpha(T) = I_{\mathrm{ZPL}}/(I_{\mathrm{ZPL}} + I_{\mathrm{PW}}) = \exp(-S(T)) \tag{21.2}$$

When temperature is increased, $S(T)$ increases, so that I_{ZPL} and $\alpha(T)$ decrease rapidly. Therefore, sharp ZPLs can only be observed at low temperatures and weak electron–phonon couplings.

The dependency of the I_{ZPL} and I_{PW} for the emission of a single fluorophore on the electron–phonon coupling is shown in Figure 21.4 by simulations. Values of $S \leq 0.7$ are considered as weak electron–phonon coupling. In those cases, needlelike ZPLs can be easily observed in fluorescence emission. For larger values of S, the intensity of the ZPL becomes much smaller. In this case, a much higher S/N ratio is necessary to observe ZPLs.

The requirements needed to observe the ZPLs in emission are perfectly matched for crystalline systems, and line narrowing was demonstrated for such samples. However, it is little convenient to dope solid-state crystals with organic (poly-) aromatic dye systems. Therefore, we have to find a host matrix with a quasi-crystalline structure, which simultaneously is capable of dissolving organic dye molecules. This requirement is met by low-molecular-weight linear alkanes, referred to as *Shpol'skii matrices* [40], and low-molecular-weight nonpolar fluorophores. Alkanes have strong absorption bands in the UV but are transparent in the visible regime, where fluorescent dyes are excited and emitted. Owing to their chemical nature, alkanes are good solvents for nonpolar aromatic compounds such as typical organic fluorophores. Moreover, at cryogenic temperatures, these compounds form crystal-like ordered structures, providing a uniform environment for the embedded chromophores. However, as the chromophores are not actually integrated into a crystal lattice, the chromophore–matrix coupling is minimized, leading to small Hunag–Rhys factors. Owing to this weak coupling, not only the fluorescence linewidths are narrowed but the PW of the fluorescence spectrum is also suppressed. This wing is caused by collective vibrations of the chromophore and the host matrix. A weak coupling reduces the probability for these vibrations to form. As a result, the spectral bandwidth of the molecular emission is reduced as

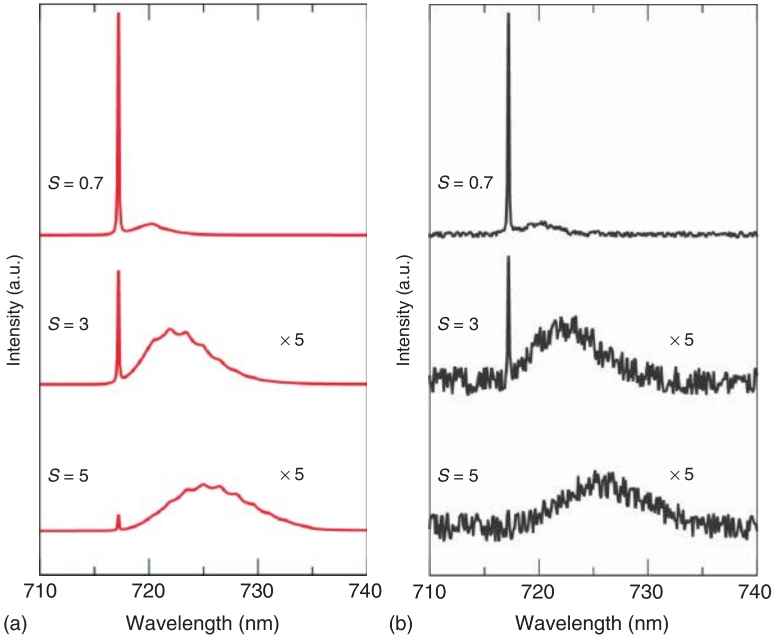

Figure 21.4 Simulations of the line shape of a single emitter as a function of the strength of the electron–phonon coupling. The Huang–Rhys factor S was changed as indicated in the plots (a). A noise level was added to these data, while the integrated intensity of the whole emission line (ZPL and phonon wing) was kept constant (b). The comparison illustrates clearly that observability of an ZPL depends on S. Simulation parameters are width of the ZPL, $\gamma ZPL = 2\,\mathrm{cm}^{-1}$; mean frequency of the phonon distribution $\omega = 30\,\mathrm{cm}^{-1}$; width of the phonon distribution, $\Delta\omega = 30\,\mathrm{cm}^{-1}$. For simulation, the expressions given in Ref. [39] were used.(The figure is adapted from [38].)

a prerequisite for the frequency selective single-molecule spectroscopy described earlier.

Figure 21.5 shows a typical fluorescence spectrum of a single terylene dye molecule at 1.8 K in a Shpol'skii matrix. Clearly, the inhomogeneous broadening dominating at higher temperatures (see Figure 21.2 for comparison) vanishes and the spectrum is composed of sharp, natural lifetime limited lines. Owing to the line narrowing, even the distinct vibronic levels of the molecule become accessible, enabling fluorescence spectroscopy for vibronic studies. Typically, in the ensemble, these lines cannot be resolved because of averaging over a large number of emitters (Figure 21.2d). However, if a single molecule is investigated, the individual vibronic levels appear and can be assigned to distinct vibration energies (Figure 21.5).

To unequivocally prove that in fact an individual emitter has been observed, the nonclassical properties of an individual molecule have to be considered. Molecular fluorescence is a successive one-photon process of excitation and emission. Accordingly, if only one single emitter is investigated, it is impossible to observe

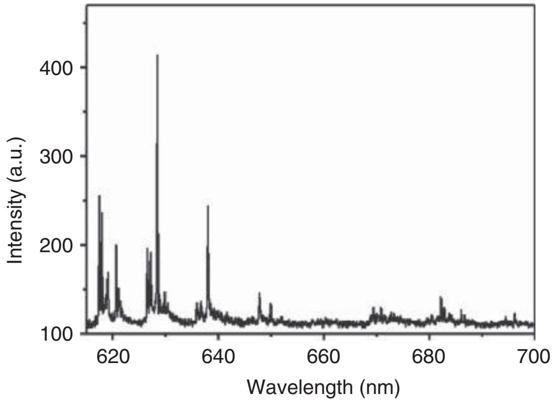

Figure 21.5 Emission spectrum of a single terylene molecule at 1.8 K in a Shpol'skii matrix.

two-fluorescence photons at a time. On the contrary, as soon as more than one emitter is observed, there is a certain probability of detecting two or more photons simultaneously at the same time [31].

One experimental demonstration based on photon correlation measurements can be achieved using a Hanbury–Brown and Twiss (HBT) setup [41, 42] (Figure 21.6a).

In an HBT configuration, photons emitted from a sample are split in two paths by a beam splitter. The photons are detected by two independent detectors A and B, and the time correlation between the arrival times is calculated numerically. Note that typically two detectors are used to compensate for detector dead times after a photon-counting event. For a detailed explanation of the experimental setup,

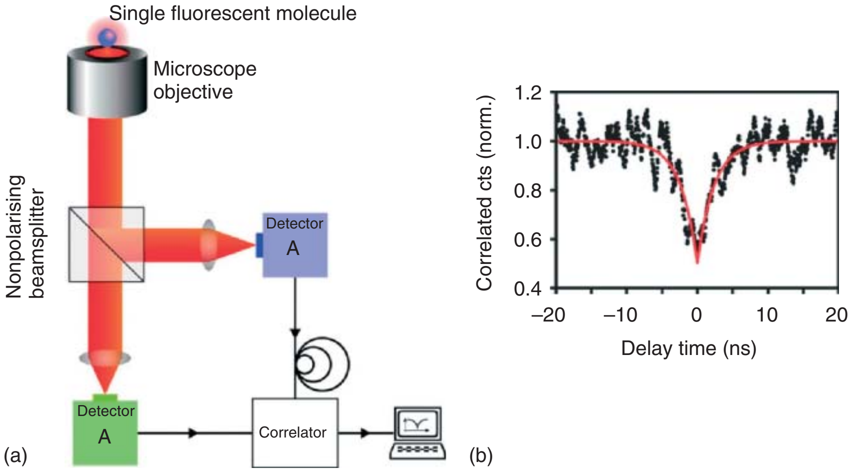

Figure 21.6 (a) A schematic representation of a Hanbury–Brown and Twiss configuration and (b) photon antibunching curve of a single molecule at cryogenic temperatures.

see [43]. The time correlation of photon arrival times provides the probability of detecting a photon on both detectors in a given time interval $t_0 + \Delta t$. For $\Delta t = 0$, this probability becomes zero for a single emitter because of the successive excitation–emission process discussed earlier. Accordingly, simultaneous photon detection on both detectors A and B is impossible. Therefore, correlating the photon arrival times on both detectors reveals a zero correlation at a certain time t_0, representing the zero probability of detecting two photons at this time.

This zero correlation is only expected for an isolated molecule and is represented by a dip in the correlation curve (Figure 21.6b), due to the isolated, ''antibunched'' photons emitted by a single quantum emitter. In Figure 21.6b, such a photon antibunching curve recorded from a single terylene dye molecule at 1.8 K is depicted. Strictly, we would expect the correlation function $g^2(\tau)$ to be zero at t_0. However, owing to a certain amount of dark counts generated randomly by the solid-state detectors and electronic noise, we have recorded some photon-counting events without a photon reaching the detector, causing the $g^2(\tau)$ curve not to drop to zero at t_0. Typically, $g^2(\tau)$ values ≤ 0.5 are accepted as a proof for single-molecule detection [44].

21.4.1
Recent Applications of Single-Molecule Spectroscopy at Low Temperatures

In the first period of single-molecule research, the interest was focused on the properties of single molecules that became observable for the first time. Soon after the initial stage, the newly developed techniques were also used to study much more complex systems such as light-harvesting systems of the photosynthetic apparatus [45].

The interaction of the chromophores within a protein is different from that in crystalline matrices. One reason for this difference is the ''material'' of which a protein is made. In its largest parts, this material consists of chains of amino acids that differ in their side chains (residues) attached to their alpha carbon. The size of the attached residues can vary remarkably in size from just one hydrogen atom in glycine to a large heterocyclic group (indol) in tryptophan. Among the amino acid residues, there are polar and unpolar as well as charged and neutral groups. The fold of the amino acid chain is one key component that determines the shape and function of the proteins in general. At the molecular level, the fold determines geometrical and chemical composition of the pocket wherein the chromophores are bound.

For one kind of protein, the composition of the amino acid chains is identical. Thus, the binding pockets are also similar. The transition energy of a chromophore is tuned by the electrostatic properties of the binding pocket. This type of tuning gives proteins the ability to modify the transition energy of the chromophores to maintain optimal protein function.

The forces holding a protein in its conformation are mostly much weaker than the forces of a covalent bond. As a consequence, there is not one well-defined conformational state of a protein, but a huge number of conformational states that differ only slightly in energy. It depends on the availability of energy and/or heights of the barrier between two conformations whether a protein remains in its present conformational state or it undergoes a conformational change.

The best description of this type of conformational dynamics is the picture of an energy landscape. On the basis of this description, the dynamic occurs on a complex, rugged energy landscape characterized by a large number of different conformational substates, as shown by the pioneering experiments of Frauenfelder and co-workers [46] on myoglobin, which is also called the *H-atom* of biophysics. The conformational substates correspond to local minima in the potential energy surface. Protein energy landscapes are characterized by the existence of many, nearly isoenergetic, local minima, which are organized in a hierarchical structure. At ambient temperatures, this results in fast fluctuations between many conformational states involving also large-scale motions as visualized in Figure 21.7c).

The motion of proteins also influences their bound chromophores. The largest effect on the site energy is due to the conformation of the chromophore itself and/or its close surrounding. The variation in the site energy over time is also called *spectral diffusion* (Figure 21.7c). A huge number of these spectral changes undergo much faster than the actual time needed to acquire an emission spectrum from a single protein ($\ll$1 ms). As a consequence, the acquired spectra are much broader than it is expected for a single emitter; and the determination of the electron–phonon coupling or the properties of the binding pocket is not possible. One option to reduce conformational motion is to lower the temperature. At low temperature, the activation energy for crossing the barriers between conformational states in the highest hierarchical levels of the energy landscape is no longer available. An additional advantage for investigations at low temperature is the increased photostability of chromophores [47]. Under these preconditions, spectroscopic investigations with high spectral resolution are possible. The advantage of this approach was well demonstrated in single-molecule experiments on light-harvesting complexes, where different absorption properties of individual chromophores were found as well as a dynamical hopping between conformational substates of single chromophores [48]. An example of the power of low-temperature spectroscopy on proteins is shown in Figure 21.8. The emission of two different chromophores bound to one photosystem I complex is visible in the sequence of emission spectra (Figure 21.8a). In both cases, the ZPL and the PW are resolved. The ZPLs undergo changes in the wavelength, which are visible as a shivering as well as line jumps in the range of several nanometers (Figure 21.8b). It is possible to determine the strength of the electron–phonon coupling for both emitters (Figure 21.8c) based on the intensity distributed between the ZPL and the PW [38].

The observed spectral hopping of lines in single-molecule experiments relies often on the higher barrier crossing probability between conformational substates in the excited state of the chromophore than in the ground state. These activated barrier crossings enable single chromophores to map the energy landscape even at low temperatures and thus provide a spectroscopic tool to obtain general insights into the characteristics of protein energy landscapes [49].

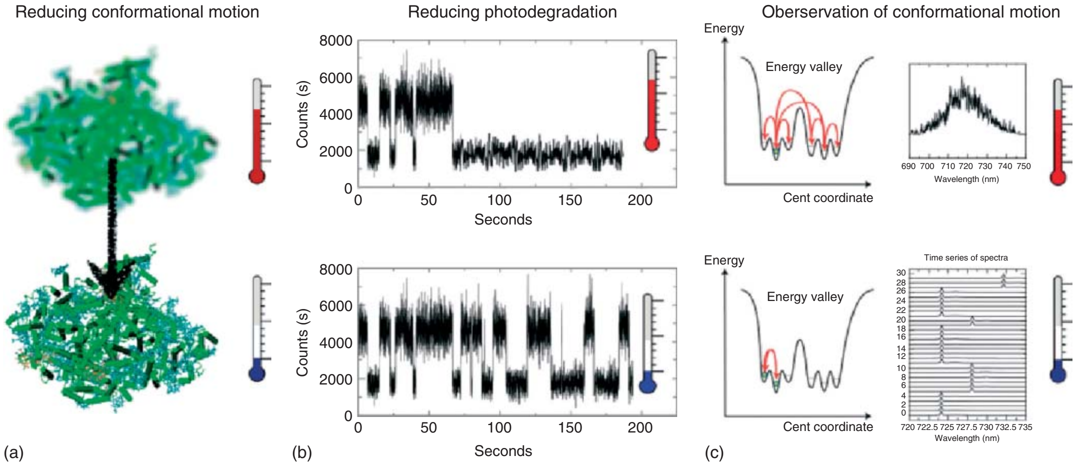

Figure 21.7 (a–c) Illustration of the advantages of single-molecule spectroscopy on proteins at low temperatures.

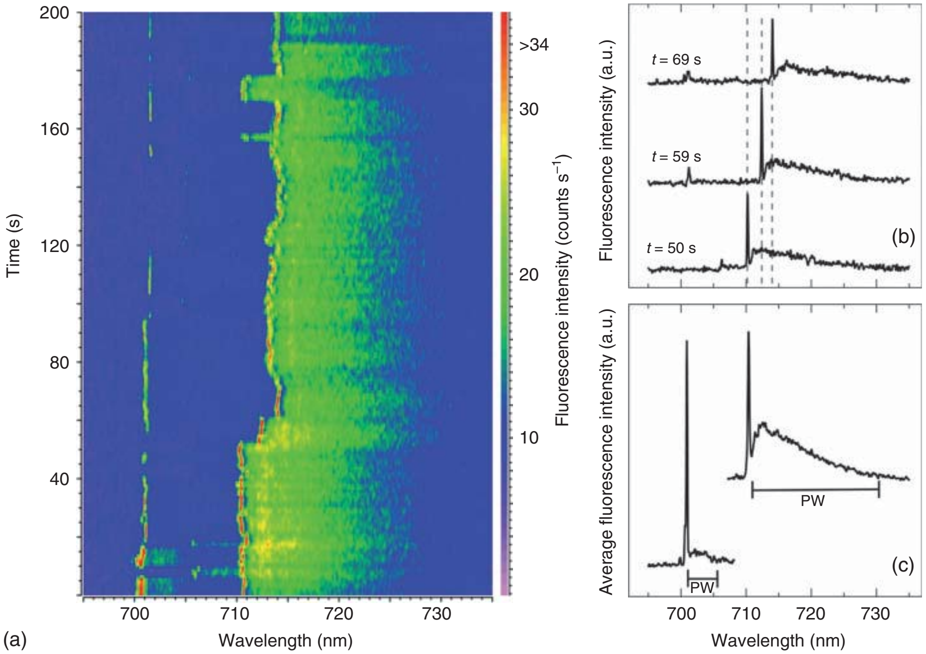

Figure 21.8 (a) Sequence of 200 fluorescence spectra taken continuously from a single photosystem I complex from Synechocystis PCC 6803. The acquisition time of the single spectra was 1 s. (b) Three single spectra out of the sequence given in (a). (c) For the emitter in the range of 710–715 nm, 16 spectra where the ZPL resides almost on the same position were summed up, and the assumed width of the PW (710.8–730 nm) is given by a bar. (a) On the basis of the width of the phonon wing, a value of the Huang–Rhys factors $S = 2.9 \pm 0.5$ was determined. For the ZPL in the range 700–706 nm the spectra between 15 and 17 s were summed up, the assumed width of the PW (from 701.3 to 705.5 nm) is indicated by a bar resulting in $S = 0.53 \pm 0.05$.(The figure is adapted from [38].)

21.5
Single-Molecule Spectroscopy at Room Temperature

Although the low-temperature studies already gave a fascinating new insight into the molecular world and demonstrated phenomena that could not be seen before in an ensemble, it was desirable to develop techniques that allow for single-molecule spectroscopy also at room temperature for several important reasons: obviously, investigations at temperatures as low as a few Kelvin are experimentally demanding and expensive. Hence, they are only available in a few laboratories to investigate scientific questions, which require cryogenic temperatures where, for instance, molecular diffusion or molecular folding are frozen or hardly observable. However, in many fields, such dynamic processes are essential, for example, in life sciences. Accordingly, it was desirable to detect single molecules to room temperature conditions. Similar to cryogenic studies, the basic requirements of (i) a small detection volume and (ii) sample systems where the target molecules are isolated and embedded in a nonfluorescing environment have to be met. A small detection volume is achieved by confocal microscopy techniques, allowing for the investigation of sample volumes as small as a few femtoliters [29]. For the second requirement, the isolation of an individual molecule, the major low-temperature strategy, which uses line narrowing of the fluorescence spectrum to address single molecules, cannot be applied. As both, absorbance and fluorescence spectra are inhomogeneously broadened at room temperature, resulting in unstructured fluorescence bands of several tens of nanometers at FWHM, spectral selection using narrow-band laser sources is not feasible. To circumvent this problem, a very straightforward approach was established: diluting a dye solution down to the picomolar range results in spatially isolated chromophores statistically dispersed in the overall volume. In this way, in a given detection volume, typically we will observe just one molecule at a time [1].

21.5.1
Single-Molecule Room-Temperature Studies in Solution

This approach was indeed used successfully in the early single-molecule detection experiments performed at room temperature in solution either in a hydrodynamic flow, in microdroplets, or freely diffusing through the diffraction-limited focus of a confocal microscope in the early 1990s [50] techniques, which were developed independently from cryogenic single-molecule spectroscopy. In a highly diluted solution of dye, molecules such as Rhodamine 6G in water and ethanol as a solvent were allowed to freely diffuse through the focus of a confocal fluorescence microscope as the detection volume. In such studies, the detection volume is irradiated with laser light for exciting the molecules and each time one chromophore passes by, the Stokes-shifted fluorescence light is recorded with an APD with millisecond time resolution. Histograming the integrated intensity versus the measurement time reveals a constant background level with single intense bursts (Figure 21.9).

These bursts are fluorescence signals from individual molecules, which diffuse into the confocal detection volume where they are excited and thus emit fluorescence photons. After a characteristic time, the molecule diffuses out of the focal volume

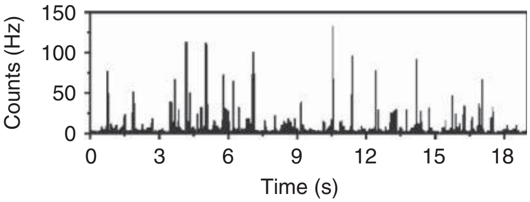

Figure 21.9 Intensity trajectory recorded from a highly diluted Rhodamine 6G dye solution in a confocal detection volume. Every time a molecule diffuses through the focus, a fluorescence burst is observed.

and the intensity abruptly drops back to the background level. Such liquid-phase intensity trajectories have been among the first examples demonstrating the feasibility to study single molecules at room temperature. Although the information content of these measurements seems to be rather low at first glance, direct information about, for example, the viscosity of the solvent and the free diffusion of molecules can be gained from these studies. As is discussed in the section about fluorescence correlation spectroscopy (FCS), even a quantitative determination of aggregation sizes of individual molecules can be achieved by an adoption of this measurement procedure. Nonetheless, the most important impact of these early room-temperature studies was the demonstration of the technical feasibility to detect the weak signal of a single molecule under relevant room-temperature conditions.

21.5.2
Single-Molecule Studies in Solid Hosts

Although it was a great progress that single-molecule studies could be performed at room temperature, it was desirable to keep the target molecules spatially fixed during the investigation. This would open the way for a careful spectroscopic characterization of molecular emission, which was expected to increase the insight into molecular matter. However, before the first studies of spatially fixed and isolated emitters were reported, some major requirements had to be met. First, for solid-host single-molecule spectroscopy, the technical issue of high-precision sample scanning had to be addressed. Contrary to liquid-phase studies, the molecules under investigation had to be actively shifted into the detection volume, that is, the confocal focal volume. For that, high-precision piezo-controlled scanning stages, which could precisely scan the sample through the focal spot, were mandatory. For further confining the excitation volume below the diffraction limit, single molecules were excited in the optical near-field of small apertures of ∼100 nm diameter at the end of pointed optical fiber probes. A specific advantage of this technique is that the sample topography can be obtained simultaneously to the optical measurement from the feedback control used to keep the aperture at nanometer distance from the sample surface [51].

Feedback-controlled piezo-based scanning stages, which allow for repeatedly addressing a defined sample position, are commercially available since mid-1990s and considerably helped to detect and localize single molecules in solid matrices or on surfaces [52].

An important requisite for such studies is the solid matrix, which is capable of solving the target dye molecules and is simultaneously nonfluorescent at the chosen excitation wavelength. While organic solvents, composed of small molecules, are often nonfluorescent at wavelengths in the visible regime, this is not necessarily true for solids. Here, owing to larger and stronger interacting molecules, side products can be formed or impurities embedded. Both can lead to the formation of impurities, which might interact with the excitation light. This, in turn, would cause a luminous matrix background, corrupting the SNR and thus hampering the detection of single-molecule fluorescence. However, it turned out that polymers such as PS [53], PMMA, or PVA [54] meet the requirements for a sufficiently low-fluorescence background and can serve as a host material for unpolar (PS and PMMA) or polar (PVA) dye systems for recording sequences of many spectra from one and the same single molecule and observing considerable spectral dynamics essentially until the molecule photobleaches.

For sample preparation, a diluted polymer solution (1–2% by weight) is doped with a highly diluted dye solution ($c_{\text{dye}} = 10^{-9}$ to 10^{-10} M). Afterwards, this sample solution is spincoated on a glass substrate, typically a microscope coverslip, to form a thin film of dye-doped polymer. The achieved film thickness, which can be adjusted by the rotation speed and the number of droplets from the polymer solution, is conveniently around 50 nm. Thus, the confocal detection volume is reduced by one order of magnitude down to 0.02 fl. As a consequence, the SNR is enhanced, which is then high enough for extended single-molecule spectroscopy in solid film at room temperature.

Before any spectroscopic investigation, the individual molecules have to be localized. This is typically accomplished by raster scanning a certain area of the sample through the confocal volume. Thus, an intensity image is obtained, where individual molecules appear as diffraction-limited bright spots. The spot size accounts for the fact that the physical dimension of a molecule can be neglected compared to the diffraction-limited focal size. Therefore, a single molecule can be regarded as a point emitter and thus reflects the point-spread function of the optical setup (Figure 21.10).

The most intuitive type of investigation possible with this polymer film sample systems is, in analogy to the liquid-phase studies, the measurement of the fluorescence intensity evolution with time. For an ensemble of emitters, we observe

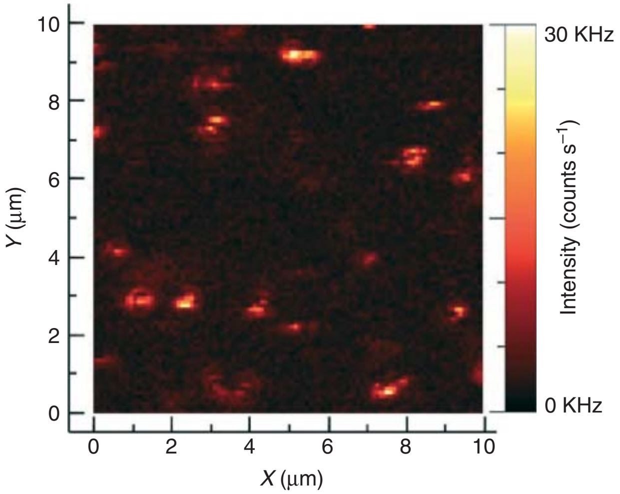

Figure 21.10 Raster scan image of single perylene dye molecules appearing as diffraction-limited fluorescence spots embedded in a thin PS polymer layer at room temperature.

a steady decrease in intensity as a function of time due to photobleaching of the chromophores. These trajectories obey a simple exponential decay and can be used to determine the photostability of a given dye system. This behavior is expected in the ensemble where a multitude of undistinguishable emitters contributes to the recorded signal. Photobleaching of a certain amount of these emitters hence results in the corresponding decrease of fluorescence intensity.

For an individual molecule, we have to consider its singular, binary nature, for example, a single molecule emits photons one by one on excitation until the molecule changes its structure permanently, for example, by the interaction with the environment such that it can no longer be excited or emit photons. At this moment, the molecule abruptly photobleaches and stays dark. Hence, recording the intensity trajectory, we expect to observe a binary behavior when photobleaching occurs.

Figure 21.11a depicts a typical example of an intensity trajectory of a single fluorescent molecule fixed in a polymer film. Clearly, we find two distinguishable intensity levels, as indicated by the histogram in the inset. The molecule is in a strongly radiating ''on-state'' at the beginning of the measurement, revealing photon counting rates of 16 KHz. After ∼19 ms, photobleaching occurs and the intensity abruptly drops to a low level with a photon counting rate of 5 KHz, representing background level. This switching behavior between ''on-'' and ''off-state'' is a clear demonstration of the binary nature of a single fluorescent molecule and thus is well accepted as a proof for single-molecule detection [55–57]. Note that the duration of the time interval for which a molecule emits fluorescence photons under constant illumination until it photobleaches abruptly (i.e., the photobleaching time) is an arbitrary process and hence the summation of photobleaching times of a large ensemble of individual emitters reveals a steadily decreasing function, which exactly samples the ensemble photobleaching behavior of these molecules in the same environment.

Although this binary behavior is often observed in single-molecule studies, more complex intensity trajectories are also frequently observed as shown, for

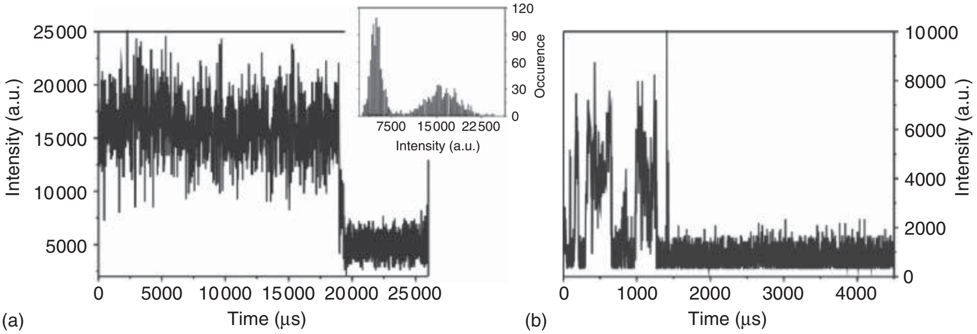

Figure 21.11 Single-molecule fluorescence trajectories. (a) Binary transition from an emitting on-state to a dark off-state and (b) instable fluorescence emission with short-lived off-states, causing intermittencies of the emission intensity [58].

example, in Figure 21.11b. Contrary to Figure 21.11a, here we do not observe stable emission, before photobleaching sets in after ∼14 ms, but the signal exhibits strong intensity fluctuations, flickering, or blinking. This observation is astonishing for a binary system, where stable emission (on-state) is expected before the molecule photobleaches and the intensity drops to background level. However, if blinking events are observed, at least a different nonradiative but reversible state of the molecule must be postulated. These fluctuations are often observed in addition to photobleaching in single-molecule studies [55]. Interestingly, Figure 21.11b reveals intensity values, which lie in between the defined on- and off-state intensities. Accordingly, these intermediate intensities can be interpreted as fast fluctuations between an on- and off-state below the temporal resolution of the experiment [59]. As a result, in the experimentally defined time interval, we observe the averaging between short-lived on- and off-states of the molecule.

The molecular origins of these fluctuations are widely discussed in the literature and range, depending on the dye systems and the dye/host arrangements, from fast cis/trans isomerizations or the formation of short-lived charge-transfer complexes to changes in the transition energy between S_0 and S_1, which tune the molecule to be off resonant with the excitation wavelength [60–62]. In addition to these short-lived off-states, single-molecule intensity trajectories often reveal long-lived dark states in the range between milliseconds and even seconds. These states are discussed to originate from reversible excitation energy migration from the dye to the host matrix (fluorescence quenching) or arise when a molecule undergoes intersystem crossing (ISC) to be trapped in a long-lived triplet state [7, 63, 64]. Especially, transitions to the triplet state are of great interest, if the characteristic triplet lifetime, that is, the average time a molecule remains in the triplet state before relaxation, is determined, for example, by transient methods. Then, single-molecule on–off statistics can be used to monitor triplet dynamics induced by external triggering such as specific and local host–matrix interactions [65]. Accordingly, these single-molecule triplet dynamics can be used to characterize a crystalline or amorphous host system for homogeneity. Clear enough, these dynamics are concealed in ensemble studies owing to averaging and local diversities in a matrix system remain unseen. Moreover, the described single-molecule triplet dynamics can be directly used in highly sensitive applications: oxygen, which, because of its electronic configuration, occupies a triplet level in its ground state, is known to be an effective triplet state quencher, transferring an excited molecule back into its singlet state. This effect can be used for oxygen-sensing applications [63, 66, 67], that is, as soon as oxygen diffuses through a porous material and permeates a dye-doped polymer matrix, the average triplet lifetime as derived from the offstate statistics is reduced. This technique is much more accurate than ensemble techniques that monitor overall intensity changes due to dye–oxygen interactions.

Intensity-based fluorescence studies are intrinsically problematic as the fluorescence intensity depends on many influences such as excitation power, detection efficiency, or photostability of the fluorescent dyes. In single-molecule-based sensor system, most of these limitations are circumvented, as the absolute intensity value is not used as quantification parameter, but data analysis can rely on the binary discrimination between two digital states. However, photostability still remains an issue, but might be circumvented, for example, by active dye-refreshing techniques that continuously provide new dye molecules to the system.

As discussed in the earlier sections, even the most straightforward approach, spectrally integrated intensity studies with moderate time resolution, provide significant insight into molecular processes, which are concealed in the ensemble. However, the significance of single-molecule studies can be extended if additional experimental parameters are accessible. In the following, two prominent approaches are presented.

21.5.2.1 Polarization-Resolved Measurements

A typical organic dye molecule is characterized by its transition dipole moment. Generally, the orientation of this dipole moment describes the direction of oscillations of delocalized electrons in resonance with an external (optical) field [7]. In other words, an absorbing (and emitting) dye molecule can be regarded as an antenna for both receiving (absorption) and sending (fluorescence). Accordingly, the emission is not isotropic, but highly directed and is described by a dipole emission pattern (Figure 21.12).

This intrinsic characteristic of molecular emission can be used to monitor molecular orientations and rotational motion of individual molecules in their host matrix, if polarization-sensitive techniques come into play [68].

After excitation with circularly polarized light, the fluorescence radiation is directed via a polarizing beam splitter to two detectors, each of which thus detects only horizontally and perpendicularly polarized light, respectively (Figure 21.13). As shown, the molecules are statistically oriented in the sample and the two detectors measure different intensities for the same molecule dependent on the orientation of its transition dipole moment. For data analysis, the ratio of the measured intensity can be used to determine the exact spatial orientation of the molecule under investigation. Plotting the intensity ratio of the two detectors in a false color

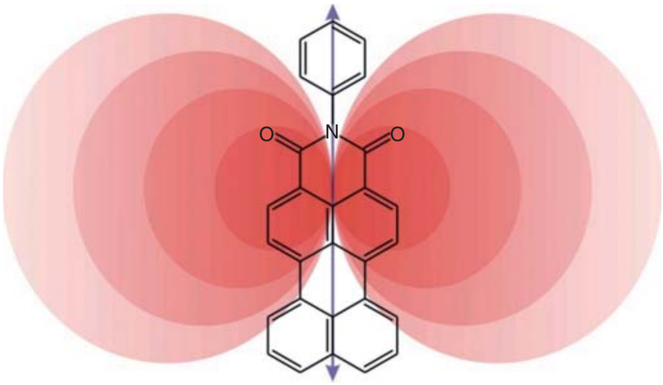

Figure 21.12 Dipole radiation characteristics of an organic dye molecule.

scheme (Figure 21.13b) we can directly derive the molecule's orientation from the color map.

If a series of images is recorded with a sufficient time resolution, even molecular dynamics can be resolved. Here, a rotation of a molecule within its embedding matrix will result in a change of the polarization of the emitted light. This, in turn, can be detected by a changed intensity ratio of the two detectors, represented by a changing color in the merged image and molecular motion can be visualized.

21.5.2.2 **Single-Molecule FRET Detection**

One prominent way to investigate molecular interactions on the nanometer scale is fluorescence- or Förster resonance energy transfer (FRET) [69]. As an introduction to FRET, we consider two dye molecules that are only a few nanometers apart. If the fluorescence emission of one dye molecule, which will be called *donor* in the following, spectrally overlaps with the absorption spectrum of the second dye molecule, the latter being called *acceptor* in the following, energy can efficiently be transferred from the donor to the acceptor when the donor is excited via dipole–dipole coupling. This energy transfer leads to a quenching of the donor fluorescence and the appearance of redshifted acceptor fluorescence when the donor and the acceptor are approaching each other. As FRET is a near-field effect, the efficiency of the energy transfer is highly distance dependent and decays with $1/r^6$ of the distance r between the two chromophores [70]. Accordingly, even slight changes in the distance of donor and acceptor result in significant changes in the FRET efficiency.

Single-molecule spectroscopy can be used to analyze FRET on the single-molecule level and thus is a powerful method to monitor molecular interactions with a spatial resolution of a few nanometers [71–74]. Only recently, single-molecule FRET studies were used to quantify the internal friction in proteins by determining the reconfiguration times of unfolded proteins [75].

One approach to identify single-molecule fluorescence energy transfer uses two detectors, which operate in different spectral windows to match the donor and the acceptor emissions, respectively.

For data analysis, the anticorrelated fluorescence emission intensity of donor and acceptor in FRET pairs is used. If no FRET occurs, we observe a high-donor signal, whereas the acceptor channel remains at background level. In case of FRET, a fraction of the excitation energy is transferred to the acceptor, resulting in lower donor emission and increased acceptor intensities.

A good example of single-molecule FRET by the Chu group is shown in Figure 21.14. The upper panel shows the intensity trajectories of Cy3 as a donor (green) and Cy5 as an acceptor (orange). Chu and coworkers [76] investigated the activation of the enzyme GTPase, which is induced by binding of the ternary Cy5-labeled complex of EF-Tu, GDPNP, and aa-tRNA to Cy3 marked t-RNA p-site. At the start of the measurement, no interaction was observable, as expressed by high donor intensities. After 1 s, the acceptor-labeled complex is approached and a short interaction is observed by the anticorrelated donor-intensity drop with simultaneous acceptor intensity rise. A successful binding event leading to GTPase activation is identified after ~10 s and lasts until photobleaching occurred after 39 s indicated by zero intensity on both detection channels. In the lower panel, the FRET efficiency is plotted versus time according to

$$E_{\mathrm{ET}} = 1 - \frac{I_{\mathrm{DA}}}{I_{\mathrm{D}}} \tag{21.3}$$

where E_{ET} is the normalized transfer efficiency and I_{D} is the donor fluorescence intensity without an acceptor present. I_{DA} denotes the quenched donor fluorescence intensity in the presence of an acceptor.

In the example depicted in Figure 21.14, the GTPase activation is indicated by an abrupt rise in the FRET efficiency to a value of 0.5. Figure 21.14b demonstrates the reversibility of the GTPase activation, with a successful activation between $t = 2{-}3$ s and several subsequent unsuccessful binding attempts after ~5, 7, and 10 s. These data demonstrate the high potential of single-molecule FRET studies, which are

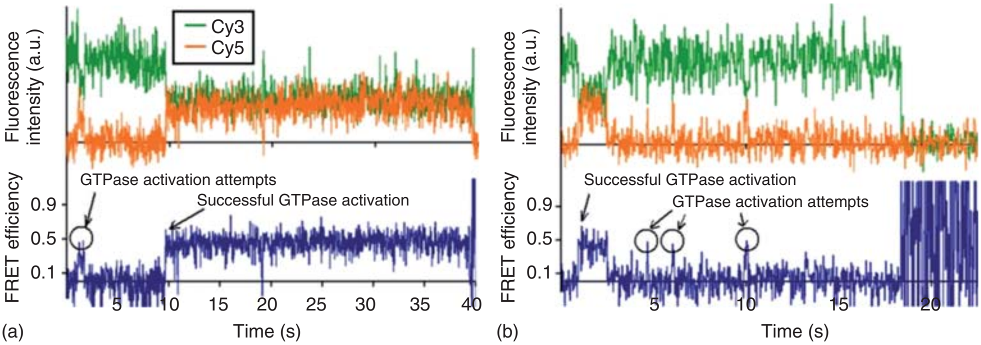

Figure 21.14 (a,b) Single-molecule FRET trajectories of a Cy3 (donor) and Cy5 (acceptor) FRET pair to monitor the activation of GTPase by binding of a Cy5-labeled complex (EF-Tu, GDPNP, and aa-tRNA) to Cy3-labeled r-RNA. The upper panels exhibit the anticorrelated donor and acceptor fluorescence intensities. The lower panels depict the calculated FRET efficiency overtime [76].

capable of monitoring essential biological interaction processes on a molecular scale.

21.5.2.3 Pulsed Interleaved Excitation FRET

Although the studies presented earlier are illustrative and demonstrate the high capability of single-molecule FRET studies, a robust and quantitative analysis of these data is often hampered by the limited stability of single fluorescent dyes against photobleaching. Moreover, a quantitative labeling of the target molecules with the marker dyes cannot be guaranteed. While this can be ignored for the donor (if no donor is present, then the entire system remains invisible in both detection channels), it becomes relevant for the acceptor; if the acceptor is trapped in a nonemitting and nonabsorbing dark state or is not present at all, single-molecule FRET analysis as described earlier will identify a noninteraction, even if the binding event was successful. To circumvent this major restriction, an alternative single-molecule measurement protocol, called pulsed interleaved excitation (PIE), has been developed [77]. Here, two pulsed laser sources are utilized, with one laser being in resonance with the donor absorption and the second with the acceptor. The repetition rates of the lasers are chosen to be well below the inverse fluorescence lifetime (typically 10–20 MHz for each laser). During a PIE-FRET measurement, the sample is alternately excited by the two lasers. Starting with the donor laser, acceptor fluorescence is detected because of FRET and, for example, on a second channel, residual donor emission owing to incomplete energy transfer (i.e., $E_{\text{ET}} < 1$) is recorded. The acceptor laser irradiates the sample after an electronic delay longer than the excited lifetime of the acceptor chromophore. This second pulse directly excites the acceptor and thus the presence of an acceptor can be registered. In this way, only intact FRET pairs contribute to subsequent data analysis and artifacts are excluded by ignoring fragmentary FRET pairs (Figure 21.15).

21.5.2.4 Single-Molecule-Based Superresolution Techniques

Single-molecule studies attracted the attention of a broader scientific community with the introduction of superresolution microscopy techniques such as stochastic optical reconstruction microscopy (STORM) or photoactivated-optical light microscopy (PALM). Both techniques rely on the photoswitching between an emitting and a nonemitting state or the irreversible photoconversion between two spectral

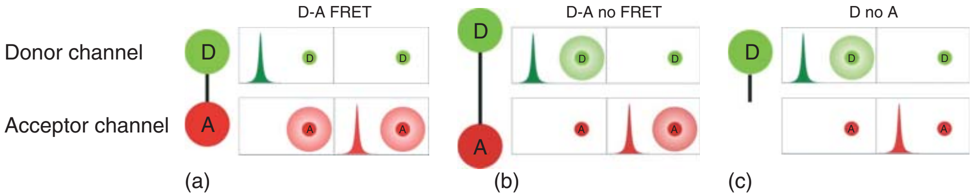

Figure 21.15 (a–c) Schematic illustration of PIE FRET. Both donor and acceptor emission is detected in distinct channels and by analyzing the (anti) correlation of the intensity signals, FRET activity is determined.

states of a single molecule. Tuning the equilibrium of these two states, we can adjust a sample system in a way that in average one or less molecules are radiating in the diffraction-limited volume in a given time interval. These molecules exhibit an isolated diffraction-limited spot in a microscopy image, which then can be fitted to a known point spread function. Having an analytical expression at hand, we can now calculate the position of the molecule with high precision, and spatial resolutions as high as 15 nm have been reported [78]. To generate a detailed image of a sample, the measurement and fitting routine are repeated several hundred times, taking advantage of the fact that the individual molecules are switched on and off in an arbitrarily manner. In this way, for each subimage, different molecules contribute and a summation of all recalculated subimages reveals a super-resolution image of the complete sample.

The prerequisite for these super-resolution techniques is the reversible switching between at least two spectroscopically different states. While it has been shown that this requirement can be met by conventional fluorescent dyes such as cyanine derivatives, which are known to be photoswitchable by a photoactivated cis/trans isomerization [79], photoactivatable fluorescent proteins (PAFPs) have great potential as they allow for the genetically encoded labeling of a protein *in vivo*. Habuchi *et al.* [80] contributed some pioneering work to this field by the first single-molecule investigation of the photoinduced switching processes in the GFP (green fluorescent protein) variant DRONPA. DRONPA was known to transit into a dark state on intense radiation with $\lambda_{\mathrm{exc}} = 488$ nm. This dark state can be recovered by illumination with 405 nm light. Using a confocal setup featuring two excitation wavelengths with $\lambda_{\mathrm{exc}} = 405$ nm and $\lambda_{\mathrm{exc}} = 488$ nm, the authors demonstrated the reversible photoswitching from an on- to an off-state of DRONPA on the single-molecule level. In contrast to other photoswitchable fluorescent proteins, DRONPA revealed a fast switching between the two states with high efficiency and repeatability as high as 170 switching events for a single protein (Figure 21.16a) [80]. On the basis of a statistical analysis of the on- and off times derived from the single-molecule studies correlated with photoswitching rate constants obtained from ensemble measurements, the authors were able to propose a kinetic scheme illustrating the photoswitching of DRONPA (Figure 21.16b). In this scheme, excitation into the 488 nm band B, which corresponds to the deprotonated form of the chromophore, a relaxation into the corresponding ground state or into the ground states of the photoswitched protonated form A_2 or a so far unknown dark state D, which is metastable and can convert into the ground state B. Interestingly, the authors found that although A_2 is a protonated form of the chromophore, a conversion into the original protonated form A_1 at a given pH is not possible. Excitation with 405 nm into either of the protonated forms A_1 or A_2, respectively, results in a very efficient nonradiative deactivation. In addition, A_2 can convert into the B ground state by an excited-state proton transfer (ESPT) process as the basis for the reversible photoswitching back to the bright form of the chromophore. However, as the ESPT from A_2 to B is very inefficient (ensemble studies revealed no emission from the deprotonated form of the chromophore for excitation with $\lambda_{\mathrm{exc}} = 388$ nm into the

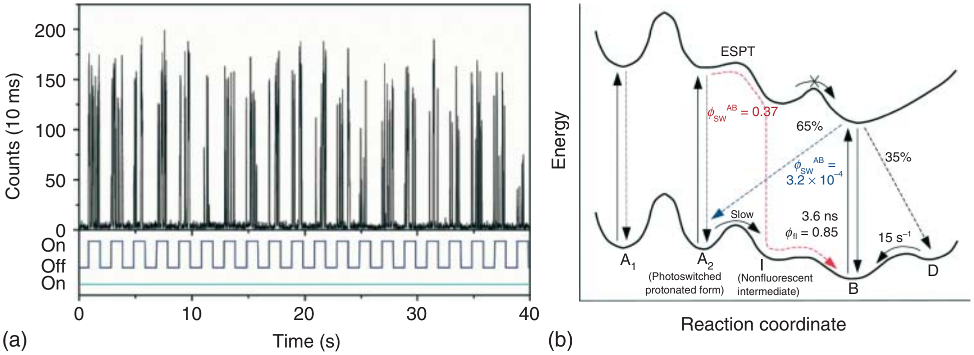

Figure 21.16 (a) Reversible photoswitching of DRONPA. The on–off scale refers to the intensity switch of the 405 nm irradiation to recover the fluorescent emission. (b) Proposed energy switching scheme in DRONPA as derived from ensemble and single-molecule spectroscopic data. (Figure adapted from [80]).

protonated form), another nonfluorescent intermediate state has to be proposed, which in turn can convert into the B ground state with high efficiency.

On the basis of this early work, the photoswitchable fluorescent proteins were further optimized and a new family of proteins was introduced, which combines irreversible spectral photoconversion from a green to a red form with reversible photoswitching known from DRONPA, opening the field of pulse-chase super-resolution imaging [81].

21.5.2.5 Spectrally Resolved Single-Molecule Fluorescence

In the earlier sections, the characteristics and potential of purely intensity-based single-molecule fluorescence studies was demonstrated. Despite the undisputable impact of these studies, access to further parameters such as a fluorescence spectrum are desirable for a deeper analysis and characterization of single-molecule fluorescence. For that, confocal microscopes can be equipped with a spectrometer consisting of a monochromator and a highly sensitive CCD camera as described earlier (see section on low-temperature studies). After a sample is raster scanned through the confocal focus, individual molecules can be identified in the intensity image. Subsequently, an identified molecule can be put into the detection volume and the detection path can be switched to enter the spectrometer and a series of fluorescence spectra of the molecule under investigation can be recorded. In this way, for example, spectral subpopulations concealed in the ensemble or distinct spectral dynamics can be investigated [82, 83]. In the following, two examples, demonstrating the ability of this technique, are introduced and briefly discussed.

Figure 21.17 depicts an example where distinct conformational states of an individual perylene molecule could be identified by single-molecule spectroscopy [84]. Here, an amino-substituted perylene imid-derivative (9-amino-*N*-(2,6,diisopropylphenyl)-perylene-3,4-dicarboximide, API) was investigated. The fluorescence spectrum of API strongly depends on the orientation of the terminal amino substituent relative to the delocalized π system of the chromophore backbone.

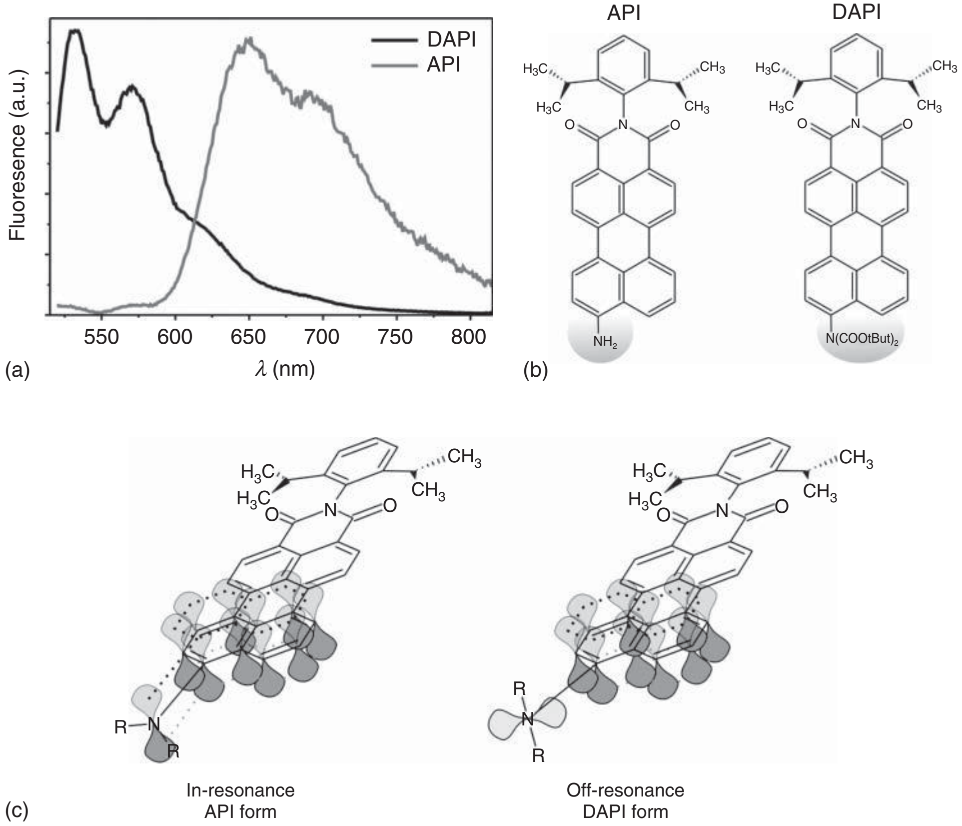

Figure 21.17 (a) Fluorescence spectra of the two perylene dyes API and DAPI. In the ensemble, DAPI exhibits a structured spectrum, while the API spectrum is less profiled and bathochromically shifted. (b) Chemical structure of API and DAPI. (c) Sketch of the two conformeric forms of API, showing the nitrogen lone pair in resonance with the chromophoric p-system (left) and off resonance with the p system (right) [58].

Investigation of derivatives of this molecule in solution revealed that in the presence of the amino substituent the fluorescence spectrum becomes less structured and shifts toward longer wavelengths as the electron lone pairs of the amino function can extend the delocalized π system. If sterically demanding, substituents such as COOtBut (*N*,*N*-di-(*tert*-butoxycarbonly)-9-amino-*N*-(2,6-diisopropyl-phenyl)-perylene-3,4-dicarboximide, DAPI) are introduced at the amino function, a free rotation around the C–N bond is inhibited, and the nitrogen lone pairs will orient perpendicular to the π system on account of sterical reasons (Figure 21.17).

For these *N*-substituted perylene derivatives, we observe a well-structured fluorescence spectrum hypsochromically shifted by ∼100 nm in the ensemble. For the amino-substituted API molecules, we find the discussed redshifted fluorescence spectrum in solution, whereas the picture entirely changes when API is embedded in a highly viscous polymer matrix and investigated on the single-molecule level. Here, for the majority of bright molecules, we observe the blueshifted emission with the nitrogen lone pairs off resonant with the chromophoric π system. The typical redshifted API spectrum as known from the ensemble could only be found from molecules, which only appeared as dim features in the raster scan image. This observation can be explained by a low-fluorescence quantum yield for the in-resonance form, that is, the lone pair in resonance with the chromophoric π system, compared to the off-resonance form. In contrast to ensemble studies in solution, a free rotation of the C–N bond is hindered because the rigid polymer matrix and transitions between the two conformeric forms are hindered. However, we found examples of single API molecules, which undergo a transition from the in-resonance to the off-resonance form and vice versa (Figure 21.18).

Switching between the two conformers as displayed for two individual API molecules as shown in Figure 21.18, which clearly demonstrates the different quantum efficiencies of the on- and off-resonant form. Although the off-resonance DAPI-like form exhibits a significantly higher fluorescence quantum yield, in the ensemble we only observe the dimmer in-resonance form. This form is energetically more favorable owing to the interaction between the nitrogen lone pair and the chromophoric π system. Hence, in solution, owing to rotation around the C–N bond, the molecules will be found in the in-resonance form, whereas in the rigid polymer matrix used in single-molecule studies the rotation is hindered and the different conformations are preserved. Thus, even with a moderate time resolution, we have access to a significant number of molecules in the energetically unfavored off-resonance form. These examples demonstrate that molecular processes such

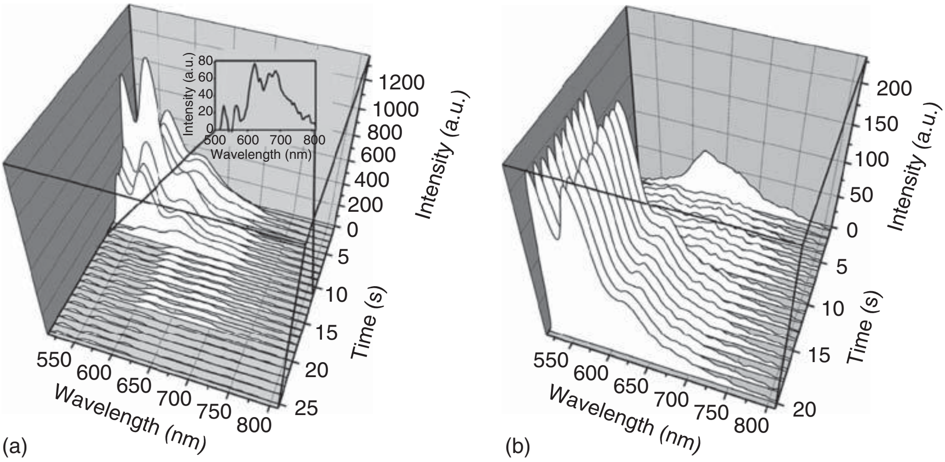

Figure 21.18 Spectral series from single API molecules demonstrating conformeric changes from the off-resonance to the in-resonance form (a) and vice versa (b) (sequence order from back to front). The inset in (a) displays spectrum number 11, where the off-resonance fluorescence has fully converted into an in-resonance spectrum [58].

as conformational changes can be visualized on a molecular level by spectrally resolved single-molecule studies.

Another prominent field of application for spectrally resolved single-molecule microscopy is the identification of spectral subpopulations hidden in the ensemble [83]. This is possible because, in contrast to the ensemble, in single-molecule studies dominant and minor spectral forms are addressed separately and, hence, mainly differ in their frequency of occurrence. In this way, the dominant forms are found more frequently, whereas a few molecules show the signature of the rare forms, which, in contrast to the ensemble, is not interfered by superposition of the dominant form. However, even at room temperatures, single-molecule spectra exhibit slight diversities such as spectral shifts, which are caused by slightly deformed energy hypersurfaces. Hence, to verify different subensembles in single-molecule studies, spectral features such as the emission maxima positions of a large number of investigated molecules must be histogrammed. In these histograms, subpopulations clearly become visible by a multimodal distribution of the maxima positions.

This can be used to, for example, examine the biologically relevant class of visible AFPs. These proteins are of great significance as they can be genetically fused to target proteins in a living organism. In this way, many biological processes such as protein expression, protein localization, or protein–protein interaction can be monitored *in vivo*. However, although the chromophore of these AFPs is shielded toward its external environment by a defined barrel structure composed of a well-known sequence of amino acids, a great variety of spectral forms has been observed. This photophysical versatility, which must be attributed to different chemical processes leading to different chromophores and to specific interactions between the chromophore and its adjacent protein scaffold, often hampers the quantitative and accurate interpretation of experimental data based on AFP studies.

In the example of the prominent yellow fluorescent protein (YFP), three interconvertible spectral forms, which have been identified by low-temperature studies, could be observed undisturbed by single-molecule spectroscopy at ambient conditions. On the basis of these room-temperature single-molecule spectra, the spectral forms could be assigned to distinct protonation states of the chromophoric system in combination with a conformational change in the chromophore environment [83]. Here, an intermediate state (I-form), formed during the transition from the deprotonated, anionic chromophore (B-form) to the neutral form (A-form) was found. The dominant redshifted B-form with an emission maximum at 527 nm is formed as a result of a $\pi-\pi$ interaction between the electronic system of the chromophore and a tyrosine residue at position 203 of the protein barrel. Interestingly, the I-form was found to be a spectral homolog to the chromophore of the GFP, where π stacking is impossible because of the amino acid composition. Accordingly, the occurrence of the I-form, as identified by single-molecule spectroscopy, points toward a conformational change in the chromophoric surrounding in YFP, most likely due to a turn or tilt of the phenolic group of the tyrosine residue, thus hampering $\pi-\pi$ interaction, which leads to the redshifted B-form.

If single-molecule studies are carried out with a sufficient temporal resolution and a series of single-molecule spectra are recorded, the said conformational change leading to the B-form and the I-form of YFP can be directly monitored. As can be derived from Figure 21.19, spectral dynamics of an individual YFP protein can be monitored, exhibiting the switching between the two spectral forms, which reveals that an interconversion is possible. Moreover, the two spectral forms and, hence, the two conformers must be isolated by an energy barrier that is small enough to be transcended at room temperature. However, this barrier is not negligible as the conversion between the two forms is slow enough that the spectra can be resolved isolated and no mixture of the B- and I-forms is detected.

Moreover, the single-molecule spectral series revealed that no direct transition from the B-form to the I-form and vice versa is possible but that the interconversion in all cases proceeds as a two-step mechanism via a dark intermediate state. As these data are not accessible in the ensemble, this example highlights the capability of spectrally resolved single-molecule studies to elucidate inter- and intramolecular dynamic processes.

21.5.2.6 Time-Resolved Single-Molecule Spectroscopy

In the earlier chapter, the possibilities of spectrally resolved single-molecule studies have been demonstrated. Another parameter accessible by fluorescence methods

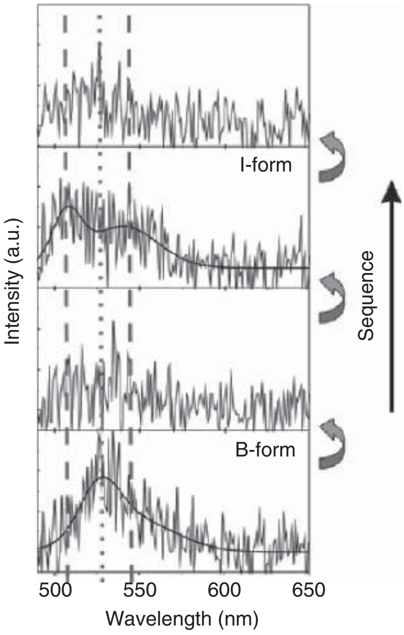

Figure 21.19 Spectral sequence of a single EYFP protein, revealing a transition from the B-form to the I-form. The transition does not occur directly, but proceeds via a nonemitting intermediate state (spectrum 2) [58].

is the fluorescence lifetime, which can be determined by time-correlated single-photon-counting (TCSPC) measurements [85–87]. In short, for a TCSPC study, a sample is excited with a short laser pulse with a pulse width of a few to a hundred picoseconds and the arrival time of the first photon is measured and its arrival time is stored. Here, the power density is adjusted in a way that maximum one photon is detected per pulse. Typically, we use excitation powers that reveal a photon count for 1% of the excitation pulses. This procedure is repeated many times and the distinct arrival times are histogrammed. This histogram represents the fluorescence intensity decay versus time and can be described by exponential decay functions (Eq. 21.4)

$$I = \sum_{i=1}^{n} A_n \times \exp\left(-\frac{t}{\tau_n}\right) \tag{21.4}$$

where the τ_n represent the excited-state lifetimes for the respective n emitting species. For a single emitting species, Eq. (21.4) becomes monoexponential with $n = 1$ and from τ the characteristic time a molecule remains in the excited state can be extracted [7]. Although this lifetime is characteristic for a molecular species, it strongly depends on the local chemical and physical environment. Parameters that can influence the fluorescence lifetime are, for example, the local pH value, physical stress, energy transfer to adjacent molecules, or the local refractive index of the surrounding matrix [88, 89]. Hence, single-molecule fluorescence lifetime data can be used as a highly sensitive local probe in complex samples.

Again, the class of AFPs deserves special attention. The chromophore of these compounds is well shielded against the protein environment by the outer protein shell. As a result, many external factors, which influence the fluorescence lifetime, can be neglected and only a limited number of parameters have to be considered as origins for variations in the fluorescence lifetime.

This finding can be used for quantitative FRET studies. In addition to intensity-based investigations discussed in Section 21.5.2.2, which are mainly applicable for qualitative FRET analysis, the energy-transfer efficiency can be monitored by the fluorescence lifetime of the donor chromophore [7, 69]. This technique utilizes the fact that because of the energy transfer an additional nonradiative relaxation channel is formed for the donor. This results in a reduced fluorescence lifetime τ_{DA} for an energy-donor chromophore that is energy transfer coupled to an acceptor molecule compared to the pure donor lifetime τ_{D} without an acceptor present. This relation can be quantified by the energy-transfer efficiency E_{ET} according to

$$E_{\mathrm{ET}} = 1 - \frac{\tau_{\mathrm{DA}}}{\tau_{\mathrm{D}}} \tag{21.5}$$

Note that in these time domain FRET measurements missing or nonabsorbing acceptor molecules can also distort data analysis. Therefore, single-molecule lifetime FRET measurements are often accompanied by PIE, as described in Section 21.5.2.3 [90–92].

Even at the single-molecule level, it is possible to combine both, spectrally and time-resolved studies on the same individual molecule. In this way, two independent spectral parameters can be determined experimentally for the same single emitter, and the correlation of these two parameters can extend the insight into molecular properties compared to the separated summation of the two spectral information. Thus, for example, coupled energy migration processes can be disentangled in a complex multichromophoric system [72, 87]. This will briefly be presented for the example of the red-fluorescent protein DsRed. DsRed natively forms tetramers, composed of green- and red-fluorescent subunits with a stoichiometry of 1 : 1 [93]. The subunits appear in a random composition and are coupled by FRET. In the ensemble, however, it is not possible to quantitatively investigate these transfer processes because fundamental photophysical parameters cannot be accessed as it is not possible to separate the native tetramers into functional monomeric subunits. However, as discussed earlier, single-molecule spectroscopy is capable of uncovering spectral subpopulations. Owing to the efficient energy transfer, we observe red acceptor emission for any tetrameric composition comprising a red-emitting chromophore. Accordingly, owing to the random composition of the tetramers, we find a major population exhibiting red emission. However, a considerable amount of tetramers is composed of solely green-emitting chromophores and hence appears as a purely green-emitting subspecies. In this way, single DsRed proteins can be sorted by spectrally resolved fluorescence spectroscopy and the green-emitting donor is accessible to further spectroscopic investigations without being interfered by any adjacent acceptor chromophore. Subsequent time-resolved measurements of the solely green-emitting tetramers provide fluorescence lifetime data of the unquenched donor chromophore of DsRed. This lifetime τ_D is indispensable for a quantitative description of the energy-transfer processes within the tetramer as the energy-transfer efficiency is dependent on this unquenched donor lifetime as demonstrated by Eq. (21.5). Furthermore, knowing τ_D gives direct quantitative access to the Förster distance R_0 of the FRET pair inherent in DsRed and thus the donor fluorescence quantum yield. Using these parameters, any energy migration pathway within the tetrameric structure can be quantitatively described and measuring the quenched donor lifetimes τ_{DA} of the red-emitting tetramers allows for a direct determination of the stoichiometric composition of the individual tetramer. This example is to show that a multiparametric approach on the single-molecule level can significantly increase the information content of a measurement, allowing for a molecular-specific analysis hampered in any ensemble-based studies.

21.5.2.7 **Dynamic Single-Molecule Studies in Solution**

One major drawback of single-molecule studies in highly viscous matrices is the hindrance of dynamical processes due to interaction of the molecule with its local host. Moreover, considering biological systems, a molecule in its native environment is not fixed at a certain position but is rather allowed to freely roam, for example, in the cytosol or diffuse along a membrane. However, to monitor the spectroscopic characteristics of an individual emitter, the molecule has to be fixed with respect to the probing volume and this fixation affects dynamic processes and emission properties and, hence, it remains equivocal to which extent the derived single-molecule data can be applied to a deeper understanding of native processes [94]. To circumvent these restrictions, Goldsmith and Moerner [95] introduced a technique that allows trapping an individual molecule in its native environment, thus making it accessible for spectroscopic investigations. A contact-free immobilization of a single emitter is achieved by using an anti-Brownian electrokinetic (ABEL) trap, which consists of four electrodes circularly mounted in an angle of 90° in a flow cell setup. If a potential difference is applied to two opposing electrodes, the solvent is displaced as a result of an electroosmotic flow with a velocity proportional to the potential gradient. If the position of a fluorescent molecule is constantly monitored, a feedback loop can trap the molecule to remain in a defined volume as small as a micrometer in square [96]. Using an intelligent triggering of all four electrodes, molecular motion in a two-dimensional space can be compensated for and the molecule under investigation is trapped in a confined space without any external mechanical distortion. By constantly rotating the excitation focus of the laser beam around the center of the trap, every detected photon can be assigned to a certain position of the focus and, hence, of the molecule at a given time. Moreover, the ABEL trap can verify that exactly one molecule is investigated. This is because the Brownian motion of different molecules is statistically uncorrelated. As the feedback-controlled voltage scheme only compensates for the motion of one specific molecule, any other fluorescent species will be pushed out of the trap by the electrokinetic forces after a short time. Goldsmith and Moerner [95] demonstrated the potential of the ABEL trap by investigating allophycocyanin (APC) proteins. These light-harvesting complexes from red algae and cyanobacteria are known to be highly sensitive to the conformation and dynamics of the protein subunits. This sensitivity is reflected by highly complex intensity trajectories in single APC studies. Moreover, results obtained from classical solid-host single-molecule studies were not consistent and significantly varied depending on the nature of the solid host. Using the ABEL trap, these inconsistencies could be compensated for and a plausible molecular model explaining the observed dynamics has been proposed. One remarkable outcome of these studies was the noncorrelation between radiative lifetime and fluorescence intensity. This suggests that the radiative lifetime depends on the local dielectric environment of the chromophore, which changes because of controlled shifts in the protein structure and conformational reordering processes. Accordingly, the protein tends to lose its native structure in a light-dependent manner. These findings would neither be possible in ensemble studies nor in a solid-host system where structural dynamics of a molecule are significantly constrained.

21.5.3
Single-Molecule Surfac-Enhanced Raman Scattering (SERS)

In the earlier sections, the capability of single-molecule studies has been demonstrated for different examples. However, as these investigations are all based on fluorescence measurements, the structural insight, which can be gained, is rather limited because of the broad and unstructured fluorescence spectra. Hence, an optical single-molecule spectroscopic technique, which provides access to structural information of, for example, distinct chemical bonds, is desirable. This requirement is met by Raman spectroscopic approaches, which utilize inelastically scattered light after monochromatic excitation of a molecule [97]. This radiation depends on the sampled material and reflects vibrations of distinct chemical groups of a molecule, which classifies Raman spectroscopy as an analytical spectroscopic technique.

However, Raman signals intrinsically suffer from a scattering cross section in the order of magnitude of $\sigma = 10^{-30}\,\text{cm}^2$, which is ∼12–13 orders of magnitude smaller than the absorbance cross section of typical fluorescence dye molecules ($\sigma_F = 10^{-16}\,\text{cm}^2$). As discussed in Section 21.2, this cross section is a limiting parameter for single-molecule detection as it defines the obtainable SNR and thus the ability of the target signal to extend over the background level. Hence, to apply Raman spectroscopy in single-molecule research, strategies to enhance the weak Raman signal have to be established.

The underlying principle of Raman scattering is the induction of a dipole moment within a molecule upon electromagnetic irradiation according to

$$\mu = \alpha \times E \tag{21.6}$$

where α is the molecular polarizability and E is the strength of the incident electromagnetic field.

Using $\alpha = \alpha_0 + \alpha_x \cos(2\pi(\nu \pm \upsilon_x) \times t)$, Eq. (21.6) reads

$$\mu = \alpha_0 E_0 \cos(2\pi \upsilon t) + {}^1\!/\!{}_2\alpha_x E_0[\cos(2\pi(\upsilon + \upsilon_x)t) + \cos(2\pi(\upsilon - \upsilon_x)t)] \tag{21.7}$$

where ν is the frequency of the excitation light and υ_x is the Stokes shifted frequency, respectively.

Equations (21.6) and (21.7) reveal that the induced dipole moment emerges to be dependent on only two parameters, the polarizability α of the molecule under investigation and the field strength of the external electromagnetic radiation $\vec{E}$. Accordingly, to enhance a Raman signal at least either of these parameters has to be increased.

One prominent approach to obtain Raman enhancement was introduced by Fleischmann *et al.* [98] in 1974 and is referred to as surface-enhanced resonance Raman scattering (SERRS). SERRS utilizes an enormous increase of up to 17 orders of magnitude of Raman intensity for molecules attached to rough noble metal surfaces. To explain the origin of this enhancement, we distinguish between an electromagnetic (EM) effect (Figure 21.20a), affecting the electrical field strength $\vec{E}$ and effects, which influence the polarizability α (Figure 21.20b,c) [99, 100].

The EM effect utilizes the field enhancement adjacent to defined nanostructures. To obtain a field enhancement, the versatile conduction band electrons of the metal particle must collectively follow the oscillation of incoming electromagnetic (light) waves, which is known as the *formation of surface plasmons*. These plasmons lead to noncompensated surface charges, which result in high local field strengths at the metal surface. For particles with a small radius compared to the light wavelength, $r \ll \lambda$, the occurrence of surface plasmons can be estimated from the polarizability

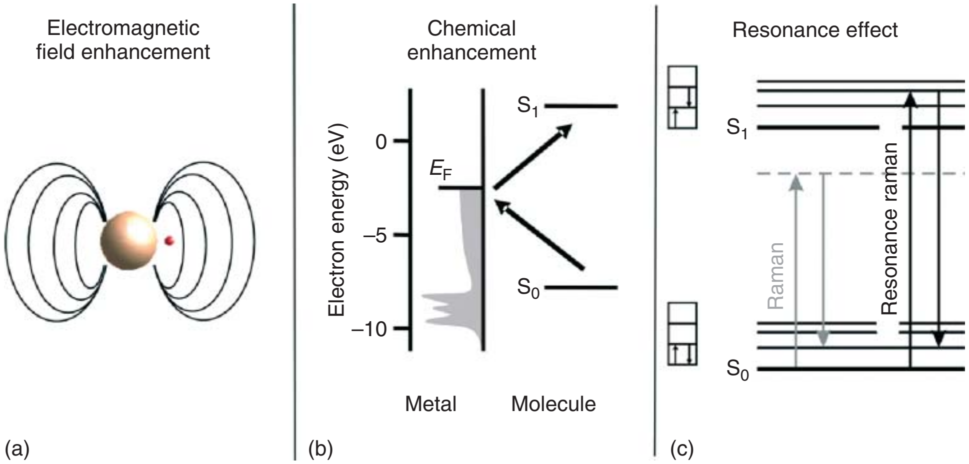

Figure 21.20 Raman enhancement effects. (a) Electromagnetic field enhancement in the vicinity of small metal particles. (b) Chemical enhancement due to the formation of charge-transfer complexes between metal and target molecule. (c) Resonance effect (black lines) with transition to a real electronic level versus conventional Raman (gray lines) to a so-called virtual level.

of the metal α_m given by Eq. (21.8)

$$\alpha_m = 4\pi r^3 \frac{\varepsilon(\upsilon) - \varepsilon_0}{\varepsilon(\upsilon) + 2\varepsilon_0} \tag{21.8}$$

where $\varepsilon(\upsilon)$ denotes the dielectric function of the metal for the respective field oscillation frequency υ and ε_0 describes the dielectric constant of the surrounding medium, which can be treated as a constant for transparent substances. For a maximal polarizability, the dielectric function of the metal must be $\varepsilon \to -2\varepsilon_0$. This condition for the appearance of surface plasmons is fulfilled in the regime of visible light for a couple of metals, the most prominent ones being the noble metals gold, silver, and copper.

Assuming a spherical metal particle, irradiation with light induces a dipole moment in the central point of the sphere, corresponding to the electrical field $E_{\text{ind}}(\upsilon_0)$ as described in Eq. (21.9)

$$E_{\text{ind}}(\upsilon_0) = r^3 \frac{\varepsilon(\upsilon_R) - \varepsilon_0}{\varepsilon(\upsilon_R) + 2\varepsilon_0} \times E_0(\upsilon_0) \times \frac{1}{(r+d)^3} \tag{21.9}$$

where d denotes the distance to the metal center. Hence, a molecule close to the metal particle experiences the superposition of the two fields E_{ind} and E_0.

The described effects are valid for the electromagnetic field emitted by the molecule $E_M(\upsilon_r)$ in an analog way. Hence, $E_M(\upsilon_r)$ induces a dipole moment in the metal particle, which leads to an increase in the detected Raman intensity. Accordingly, for big field strengths, the absolute electromagnetic enhancement factor Ω_{em} is given by the combination of the field enhancement factors for incoming and scattered light $\Phi(\upsilon)$ (Eq. 21.10)

$$\Omega_{\mathrm{em}} = |\Phi(\upsilon_0)|^2 \times |\Phi(\upsilon_\mathrm{S})|^2 = \frac{\varepsilon(\upsilon_0) - \varepsilon_0}{\varepsilon(\upsilon_0) + 2\varepsilon_0} \times \frac{\varepsilon(\upsilon_\mathrm{R}) - \varepsilon_0}{\varepsilon(\upsilon_\mathrm{R}) + 2\varepsilon_0} \times \left(\frac{r}{r+d}\right)^{12} \tag{21.10}$$

Equation (21.10) clarifies that the enhancement strongly depends on the distance between molecule and metal particle by an inverse 12th power law. However, for a monolayer of molecules with direct contact to the metal, this dependence drops to be d^{-10} (first-layer effect) [101]. Hence, molecules directly attached to the metal experience the highest electromagnetic enhancement. Signal enhancement due to the discussed EM effect can reach factors of up to 10^{10}. In addition, the fluorescence of luminescent molecules attached to a metal surface is effectively quenched as a result of excitation energy transfer to the metal electrons. Therefore, the strong fluorescence signal, which overlies the Raman signal in conventional resonant Raman measurements, is effectively reduced.

The second major approach to enhance the Raman effect by increasing the polarizability α can be met by what is referred to as the *chemical effect*. This enhancement factor is aroused by a direct interaction between the metal particle and the molecule under investigation. Although the chemical effect, which was introduced as a third dominant enhancement factor within SERRS, is widely accepted, its origin is still subject to ongoing controversial discussions. A prominent theoretical approach is given by Lombardi *et al.* [102] and Otto [103, 104], who postulate active sites at rough particle edges with localized state energies above the Ag-4d band, but well below the Fermi level. These states are understood as a starting point for a photoinduced electron transfer from the metal to the molecule. Within those charge-transfer complexes, the electron is shifted over a relatively big distance, resulting in an increased polarizability, because the electron is weakly bound to the molecule. With this chemical enhancement effect, enhancement factors of 10^2–10^3 can be obtained.

Resonance Raman scattering as a third approach to enhance the Raman effect is not directly connected to surface enhancement effects but is a commonly used effect for Raman enhancement at the single-molecule level [105]. Given that the irradiated light matches an electronic transition of the target molecule and does not excite the emitter into a virtual level (see Figure 21.20 for explanation), the molecule and its vibronic states experience a stronger interaction with the electromagnetic field, leading to a stronger charge displacement due to the electronic transition. As a result, the polarizability α is increased for resonance processes, allowing for an enhancement of the Raman signal by a factor of up to 10^2–10^4 or even, in exceptional cases, 10^6. However, merely exciting the molecule with a wavelength matching an electronic transition often involves fluorescence emission, which is still 8 orders of magnitude more intense and thus hides the Raman information. However, an excited molecule in close proximity to a metal can efficiently transfer its excitation energy to the metal and thus fluorescence emission is quenched.

A graphical illustration of the enhancement factors for Raman scattering is sketched in Figure 21.20a–c.

If the three reported enhancement factors discussed earlier, which are the resonance Raman effect, the electromagnetic, and the chemical effects, are combined, we obtain a resulting amplification factor of up to 10^{14} or even 10^{17}. Hence, the resulting scattering cross section σ can be calculated to reach values of up to 10^{-16} to 10^{-13} cm^2. Thus, it is possible to investigate the Raman signal of a single-emitting molecule with highly efficient detection techniques by SERRS.

Obviously, the metal substrate plays a decisive role in any single-molecule SERRS study. Therefore, many efforts were made to create suitable metal structures, providing highest Raman enhancement. These structures may be subdivided into three categories, pursuing different effect (Figure 21.21). The most common one is based on colloidal metallic nanoparticles, which can be produced chemically by redox reactions from aqueous solutions [106]. The various synthesis strategies reported in the literature have in common that the noble metal is utilized in its oxidized form and then carefully reduced to form nanoparticles. For that, micelle-building substances are added, which create a core–shell system on the metal surface. Thus, the particle growth can be controlled and the produced colloids are prevented from clustering.

Another approach to obtain SERRS-active substrates uses evaporation techniques. If a metal is evaporated onto a carrier substrate under high-vacuum conditions with a low deposition rate and the layer thickness is controlled to not extend a few nanometers, metal island films will form and homogeneously cover the substrate [107, 108]. By carefully controlling the evaporation conditions and layer thickness, these island films can be adjusted to consist of metal particles of a size, which matches the plasmonic resonance of the material.

The last approach uses lithographic techniques to produce highly ordered metal structures on a carrier substrate. Using this method, the size as well as the shape of the metallic nanoparticles can precisely be adjusted and the surface-enhanced Raman scattering (SERS) substrate can be designed to perfectly match the requirements of a specific measurement. For example, nanopillar structures

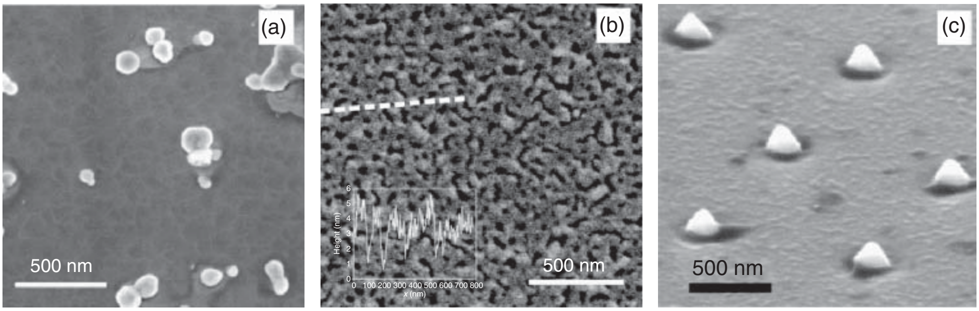

Figure 21.21 SERS substrates. (a) Silver colloids, (b) silver island film, and (c) lithographically produced silver cones.

can be built or even grating structures with highest SERS enhancement have been produced.

It is hard to judge which of the three approaches is most suited for SERS measurements; the colloidal approach does not depend on expensive equipment but can be carried out in any chemical laboratory. Moreover, working in an aqueous phase opens up the possibility to, for example, work in solution without the necessity of surface coatings and thus maintains physiological conditions for biological samples. On the contrary, the island films are easy and reliable to produce and provide a high reproducibility. Moreover, owing to the homogeneous covering of the substrate with structures well below the diffraction-limited focal spot of an optical microscope, SERS imaging is possible. Lithographically produced SERS substrates finally provide the most ordered structures and even high-performance particle arrangements such as bow-tie systems can be created. The latter ones use two particles in proximity to the molecule to enhance the Raman signal. In this way, outstanding SNRs can be obtained and thus the integration time per spectrum might be reduced, enabling the monitoring of fast molecular dynamics. However, these lithographically engineered substrates are challenging to produce and require specialized and expensive equipment. Moreover, SERS imaging is limited to the raster format of the produced substrates.

Similar to fluorescence studies, where the recorded spectra can be influenced either by the local molecular environment or by the internal properties of the individual emitter, for SERS spectra, we have to consider external and internal origins for spectral characteristics and dynamics [100]. Owing to the strong distance dependence of the SERS effect, scaling with an inverse 12th power law, even marginal variations in the distance between metal particle and the molecule or fluctuations of the morphology of the metal can cause dramatic changes in the overall Raman intensity. Moreover, as SERS spectra monitor the vibrational energy of distinct chemical bonds, any structural changes of the molecule must influence distinct Raman bands, whereas others remain unaffected. Accordingly, in SERS spectra, we can distinguish external influences, which appear as concerted fluctuations of the entire spectrum, from intrinsic structural changes within the molecule, which result in variations of the energies of distinct, isolated Raman bands. This is exemplarily shown in Figure 21.22. Figure 21.22a displays an SERRS spectra series of a single Rhodamine6G molecule, which exhibits intensity fluctuation of the entire spectrum, pointing toward a change in the enhancement efficiency caused by external factors. On the contrary, in Figure 21.22b, an SERRS spectra series of a Rhodamine6G molecule is shown, where distinct bands undergo fluctuations in their spectral position, while the overall Raman enhancement is maintained. This behavior is indicative of intrinsic dynamics of the molecule caused, for example, by the deformation of the molecule or slight conformational changes of distinct functional groups. As such spectral dynamics cannot be observed in the ensemble as a matter of principle, the observation of single SERRS band dynamics, whereas others remain fixed, is accepted as undoubted proof that SERRS provides single-molecule sensitivity [106, 109]. In Figure 21.22c, an interesting example of two SERRS spectra taken from a single Rhodamine6G molecule is

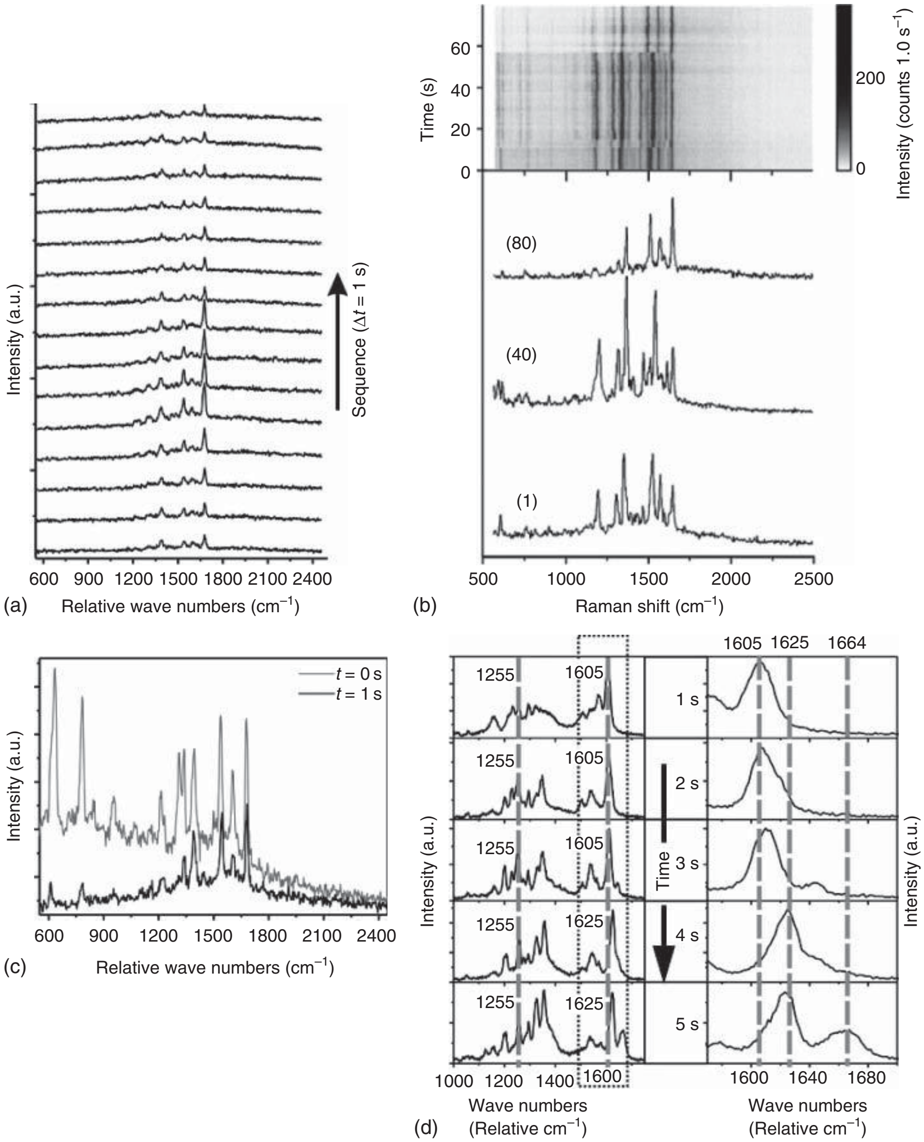

Figure 21.22 Spectral dynamics observed in SERRS spectra. (a) Intensity fluctuations of the entire Raman spectrum of a single R6G molecule point toward a change in the enhancement efficiency because of external factors rather than to a change in the target molecule. (b) Spectral changes and frequency jumps of distinct Raman bands of a single R6G molecule are definitive proof that single-molecule Raman spectroscopy is feasible. (c) Intensity changes of distinct Raman bands of a single R6G molecule reveal spatial fluctuations of molecular groups with respect to the enhancing metal particle [106]. (d) Spectral dynamics of distinct Raman lines of a single-fluorescent DsRed_N42H protein. The protein undergoes photodegradation and the Raman fingerprint switches from a red to a green signature [58].

presented. Here, a number of Raman lines exhibit intensity fluctuations, whereas others remain rather unaffected. Moreover, the spectral position of all bands is fixed. Obviously, no internal processes can cause this kind of dynamics as any changes in the molecular structure result in frequency changes of distinct Raman bands. Rather, these dynamics must be interpreted as a reorientation of distinct groups of the dye molecule with respect to the metal particle. Hence, some bonds of the molecule experience a weaker Raman enhancement and thus appear as less intense bands in the SERRS spectrum.

Figure 21.22d displays a spectrum series recorded from an AFP DsRed_N42H. As in DsRed, two different chromophoric species, with similar but slightly different chemical structures, can be present (Section 21.5.2.4), SERS spectra can show the Raman fingerprint of either of these species. It could be shown that the SERS spectra of the red- and the green-emitting chromophore can be distinguished by the anticorrelated presence of the Raman lines around 1565 and 1630 cm^{-1} [108]. The example shown in Figure 21.22d exhibits the 1565 cm^{-1} band, which is indicative of the observation of a red-emitting chromophore. During the course of the measurement, this band vanishes while a band at 1630 cm^{-1}, representative of the green-emitting chromophore, is detected. Accordingly, this protein underwent a conversion of the Raman fingerprint of the red to the green spectral form. This is of particular interest, as the red chromophore is known to be a dead-end product and no equilibrium between the two chromophores has been reported. This, in turn, yields that fluorescence studies cannot observe a transition from red to green species. However, the red chromophore can be degradated during intense irradiation, which leads to bond breaking and thus a reduction of the delocalized π system. In fluorescence measurements, these photodegradation products typically cannot be addressed as they are mostly nonfluorescent. However, SERS does not necessarily require an intact and emitting chromophore and hence even photodegradation products are accessible on the single-molecule level by this spectroscopic technique.

21.5.4
Recent Advances in Single-Molecule Spectroscopy

In the earlier sections, the underlying principle of single-molecule spectroscopic techniques has been demonstrated and distinct examples demonstrating the ability of these methods have been given. In the following, recent advances in single-molecule research shall shortly be presented.

21.5.4.1 Mode Density-Controlled Fluorescence

Although single-molecule fluorescence studies have become a valuable tool in life sciences, till date the inherent problem of low-signal intensities combined with a limited photostability is a problem. As a result, the duration of observation and the achievable brightness are critical as excitation powers are kept low enough to avoid excessive photodestruction. Accordingly, recent efforts explore strategies to enhance the fluorescence signal and the photostability of a given single molecule.

One prominent approach to this aim is metal-enhanced fluorescence, which, similar to SERS, utilizes plasmonic resonances of a metal particle in close proximity to a fluorescent molecule [110–112]. In principle, two competing effects have to be considered; on the one hand, a molecule experiences an increased local electromagnetic field next to a metal particle. On the other hand, fluorescence quenching is observed, where the excitation energy of the molecule can be transferred nonradiatively to the metal where it may dissipate. The interaction of the molecule and the metal is accompanied by a reduction of the excited-state lifetime of the molecule which in turn decreases the probability of photodestruction and hence enhances the photostability of the molecule. The underlying effects of metal-enhanced fluorescence are complex and only understood in parts. Moreover, a precise prediction whether the molecular fluorescence is quenched or enhanced is hard to make and the effects strongly depend on the nature and morphology of the metal particle [113].

However, while these effects incorporating plasmonic resonances are near-field effects, fluorescence properties, especially the fluorescence lifetime, of a molecule can also be effected by the far field of propagating electromagnetic waves [114]. In this regard, we may consider the metal particle acting as a mirror. Hence, we have to account for the electromagnetic field directly emitted by the molecule, which interferes with the field reflected by the mirror, that is, the mirror image of the molecule's emission. As a consequence, dependending on the distance between the molecule and metal particle we will find alternating constructive and destructive interferences. These interferences cause distance-dependent variations in the local photonic density of states, that is, the local mode density of the electromagnetic field. This mode density defines the probability for light of a given wavelength to propagate through space. In other words, an electromagnetic mode serves as a carrier for a photon [115].

All spectroscopic and most fluorescence studies have in common that they are investigative rather than manipulative. However, the fluorescence characteristic of a dye molecule depends on external parameters such as the (local) optical mode density. Hence, if we succeed in externally manipulating this mode density, for example, by the presence of a mirror, it is possible to control the light propagation properties and as a result the spectral characteristics of molecular emission. According to Fermi's golden rule, the probability for a transition between two states, for example, the S_1 and S_0 state ($P_{S_1 \rightarrow S_0}(t)$), depends on the mode density of the electromagnetic field [116]

$$P_{S1\rightarrow S0}(t) = \Gamma_{SpE} = \frac{1}{\tau_{SpE}} = \frac{2\pi}{\hbar^2}|\vec{\mu} \times \vec{\boldsymbol{E}}|^2 \times \rho(\omega) \tag{21.11}$$

where $\vec{\mu}$ is the transition dipole moment, $\vec{E}$ denotes the electromagnetic field vector, and $\rho(\omega)$ is the wavelength-dependent mode density of the electromagnetic field. Note that Eq. (21.9) only accounts for the electric part of the electromagnetic field, as the magnetic component can be neglected for optical transitions.

As discussed earlier, Eq. (21.11) reveals that a change of $\rho(\omega)$ directly affects the spontaneous emission rate Γ_{SpE}. As a consequence, we observe oscillations of Γ_{SpE}

and accordingly the fluorescence lifetime of a molecule for increasing distances to the metal interface [115].

While this approach already demonstrates the effect of a changed mode density by the interference of an incident and a reflected beam, the influence of the mode density on the fluorescence lifetime can even be enhanced when multiple interferences are considered.

One way to generate multiple interferences by controlling the mode density can be achieved by an optical Fabry–Perot interferometer setup with the dye molecules embedded between the plan-parallel resonator mirrors [117, 118].

As discussed earlier, Eq. (21.11) reveals that a change of $\rho(\omega)$ directly affects the spontaneous emission rate Γ_{SpE}. In the free space (i.e., no field confining components present), the mode density is represented by a continuum. On the contrary, for a Fabry–Perot microresonator $\rho(\omega)$ changes as a function of the mirror spacing L and has its maximum alteration amplitude in the first interference order m when exactly one-half of the light wavelength fits between the resonator mirrors according to the Fabry–Perot resonance condition

$$L\cos\theta = \left(m - \frac{\delta_{1,2}}{2\pi}\right) \times \frac{\lambda}{2n} \tag{21.12}$$

where $\delta_{1,2} = \sum_{i=1,2} \Delta\phi(d_i, \phi, \lambda)$ represents angle-dependent phase changes at the resonator mirrors and θ is the angle of incidence.

An experimental realization of such a microresonator is sketched in Figure 21.23 [118]. In short, a silver-coated microscope coverslip serves as a lower mirror. Here, spacer and protection layers are applied and a polymer layer with dye molecules embedded is spin coated on top. The upper mirror comprises a silver-coated plano-convex lens, which is connected to three piezo actuators. In this way, the mirror spacing L can be externally adjusted with high precision. To monitor the mirror spacing, it is suggested that white-light transmission measurements, which reveal concentric Newton rings in all colors of the rainbow, each of which represents a distinct resonance wavelength according to Eq. (21.12), be used.

In Figure 21.24, the microresonator effect on the emission spectrum of a single perylene imide (PI) molecule is depicted. Figure 21.24a–c shows spectra derived from one and the same dye molecule for different mirror spacings [119]. Clearly, the free space spectrum (gray-shaded area in Figure 21.24) is effectively redistributed to follow the mode characteristics of the microresonator.

The blue lines in Figure 21.24a–c denote theoretical simulations of the spectral shape based on a semiclassical approach and show a remarkable agreement with the experimental data (red dots). The simulations take into account that the coupling of the molecular emission to the electromagnetic modes inside the microresonator is strongly frequency dependent (Eq. 21.11). As the emission spectrum of a typical fluorescence dye is rather broad at room temperature, different spectral contributions experience different mode densities. Accordingly, distinct wavelengths have a high-coupling efficiency to the resonator modes. This results in an enhanced emission probability for these wavelengths, reflected by

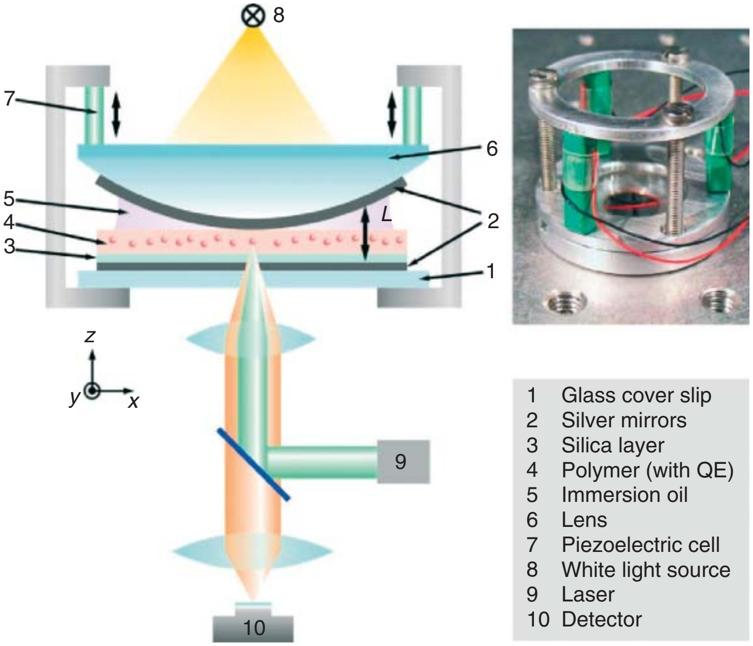

Figure 21.23 Schematic of an optical microresonator setup with tunable mirror spacing capable of single molecule detection.

an enhanced spontaneous emission rate (Eq. 21.11), while others are inhibited, an effect that is known as the *Purcell effect* [120]. The Purcell effect can also directly be visualized by measuring the fluorescence lifetime of a single molecule for different mirror spacings as shown in Figure 21.25. Clearly, the fluorescence lifetime changes according to the resonance condition of the microresonator (Figure 21.25a). However, Figure 21.25b reveals that the fluorescence lifetime variations, that is, the magnitude of the Purcell effect, are also dependent on the orientation of the molecular transition dipole moment. This is due to the fact that the resonator is composed of plan-parallel mirrors and thus the field confinement is anisotropic in space, resulting in a high confinement in the z-direction and a weaker confinement in the x,y plane. Thus, the effective resonator impact on the molecular emission is strongly dependent on the orientation of the transition dipole moment relative to the resonator mirrors.

As a result, the single-molecule emission experiences a significant and controllable spectral and temporal redistribution, making the microresonator a valuable tool to externally tailor molecular emission, for example, for new-generation single photon sources or quantum computing applications.

Besides these future applications, using the microresonator setup can also provide access to the fluorescence quantum yield of a single emitter [121]. The Purcell effect only influences radiative transitions. Accordingly, the amplitude of the microresonator length-dependent fluorescence emission rate variation is

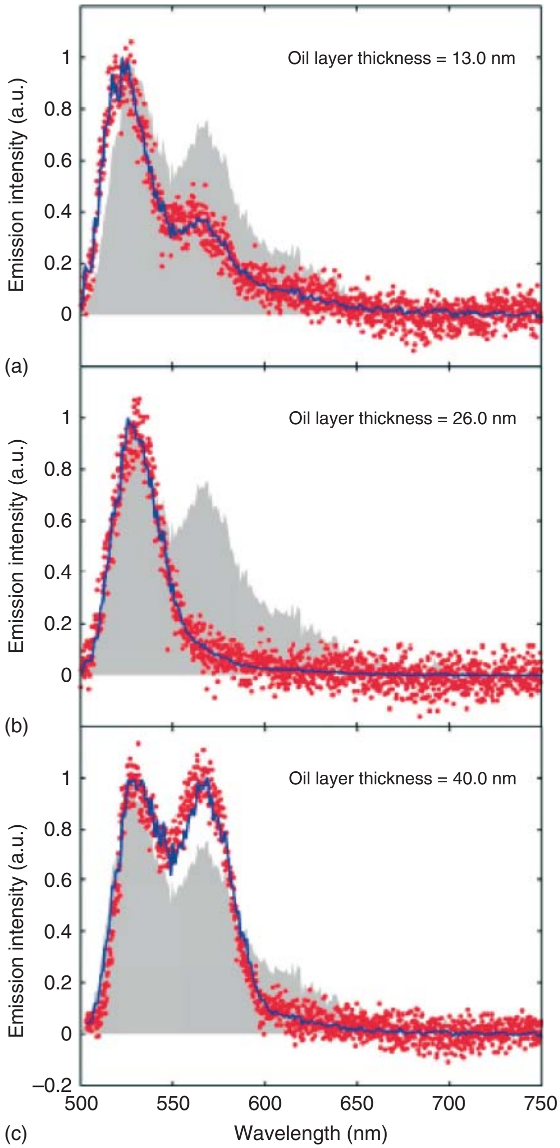

Figure 21.24 (a–c) Microresonator-controlled fluorescence spectra of one single PI molecule (red dots). The blue lines represent theoretical simulations of the spectral shape using a semiclassical approach. The gray-shaded area reflects the free space PI emission spectrum [119].

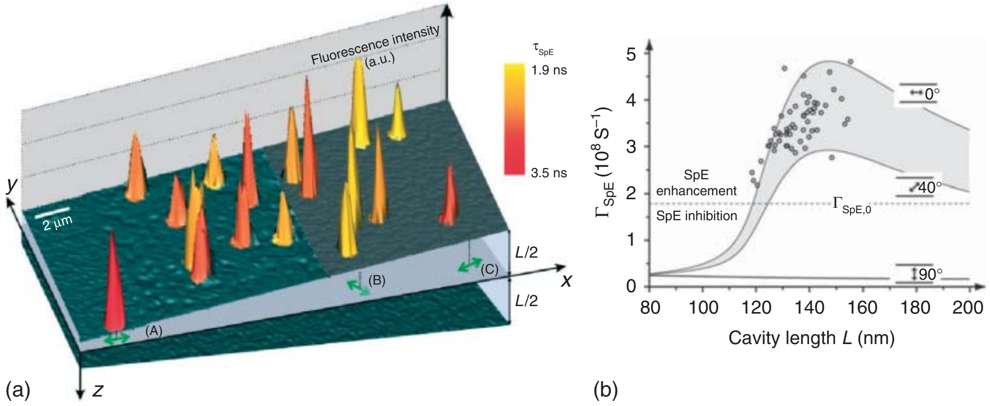

Figure 21.25 (a) FLIM (fluorescence lifetime imaging microscopy) Image of single perylene dyes embedded in a $\lambda/2$ microresonator and (b) fluorescence lifetimes of single perylene molecules for different mirror spacings [117].

maximal, if all relaxation processes are radiative, that is, the fluorescence quantum yield is 1, and decreases when nonradiative relaxation contributes. Hence, if it is possible to precisely determine the three-dimensional orientation of a single emitter embedded in the microresonator, the only free parameter to quantitatively describe the radiative rate is the fluorescence quantum yield. While the exact determination of the transition dipole orientation of a single emitter is critical using common excitation sources with a Gaussian intensity distribution, the use of doughnut-shaped higher order laser modes provides direct access to the 3D orientation of the emitter [122, 123]. A more detailed introduction in the generation, application, and data analysis of these laser modes is given in the respective section. The determination of single-molecule quantum yields revealed a broad scattering of the individual values, which reflect a strong nanoscopic inhomogeneity of the host environment of the single emitters [124].

21.5.4.2 **Single-Molecule Excitation Spectroscopy**

All the studies reported so far have in common that they rest on the analysis of the Stokes-shifted luminescence emission, either spectrally integrated or even with a spectral resolution. Indeed, it is desirable to get access to even more spectral parameters of a single molecule to further enhance the information content, which can be obtained from a single-molecule measurement,

For example, it is so far not possible to record a single-molecule absorbance spectrum for a couple of technical reasons. Thus, up to now, frequency-resolved monitoring of the electronic coupling of a quantum mechanical emitter (QME), such as a single molecule to an external electromagnetic field, is not possible. Fluorescence excitation spectroscopy, where the excitation wavelengths is swept over a broad spectral range while the fluorescence emission intensity is monitored in defined spectral window, is one approach, if certain presumptions (e.g., a constant fluorescence quantum yield over the excitation wavelength regime) are fulfilled.

While this is a standard technique in ensemble studies, it requires reasonable technical effort to adopt this spectroscopic method to single-molecule studies at ambient conditions and two major requirements have to be fulfilled. First, the excitation wavelength must be continuously tunable over a certain wavelength area. Second, the excitation source must be intense enough to ensure a sufficient number of excitation cycles of the single molecule to obtain a reasonable SNR. In very recent years, new-generation super-continuum laser sources providing white-light laser radiation over a broad wavelength regime, which meet these requirements, have become accessible. Combining these super-continuum lasers with a confocal microscope with single-molecule sensitivity then allows for excitation spectroscopy on individual emitters, if a dispersive element is introduced into the excitation path, which has a sufficient blocking efficiency combined with fast wavelength changing ability. For that, classical grating monochromators or, alternatively, new-generation acousto-optic tunable filters (AOTFs) can be utilized [125].

With a single-molecule fluorescence excitation spectroscopy setup as described earlier, a couple of open questions can be addressed. To name a few, a direct observation of FRET processes would be possible. Moreover, it is worth studying whether excitation spectra of individual emitters do slightly differ from each other because of different energy spacings per molecule. This, in turn, would help gain a deeper insight into the interaction between the chromophore and its local environment as, for example, the individual Stokes shift becomes accessible on a single-molecule level.

As an overview, results obtained from single-molecule excitation spectroscopy of individual semiconductor CdSe quantum dots (QDs) shall be briefly discussed. QD excitation spectra are known to exhibit a continuous slope toward short excitation wavelengths and are confined by a relatively sharp so-called excitonic peak close to the band edge of the material [21]. The spectral form can also be observed in single-molecule excitation spectra as depicted in Figure 21.26. Here, we also find features characteristic of single molecules such as instable emission due to blinking to various degrees. These blinking events are due to a transition of the QD to a nonemitting dark state and gets visible in the excitation spectrum as data acquisition is accomplished successively for each excitation wavelength. As a guide to the eye, the ensemble excitation spectrum is plotted as a dashed line. Along with

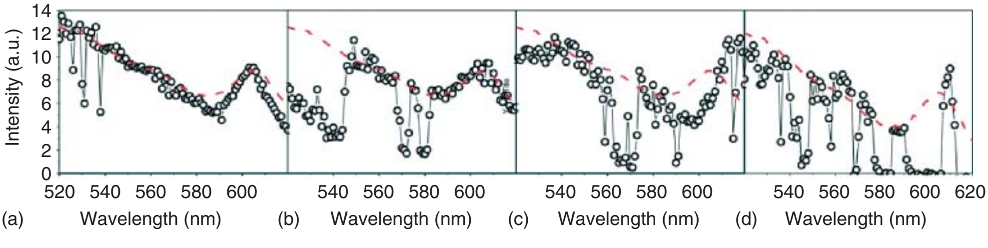

Figure 21.26 (a–d) Single QD fluorescence excitation spectra (open circles). Dashed lines are ensemble excitation spectrum [125].

the intensity fluctuations, photon antibunching curve measurements confirm the observation of single emitters (compare Section 21.4).

In addition to blinking, a number of QD dots revealed transitions to long-lasting dark states and did not recover until the end of the measurement. Interestingly, if the wavelengths where these transitions can be observed are histogrammed we find certain distinct wavelengths with a pronounced occurrence of these transitions. These wavelengths coincide with plateaus in a sum-spectrum derived from summing up all single QD excitation spectra. This finding is astonishing and has to be taken into consideration if high-performance setups with QDs as a (single-photon) light source are concerned. For such studies, the distinct excitation wavelengths derived from the single-molecule excitation spectra should be avoided as here the QD dot performance and stability is reduced.

21.5.4.3 **Single-Molecule Absorption Studies**

Even though it is not possible to record absorption spectra of individual molecules, there are some recent developments that enable spectrally integrated absorption studies at the single-molecule level. The most straightforward approach introduced by Celebrano *et al.* [126] directly detects the attenuation of irradiation light. Typically, the absorption cross sections of an individual molecule are as small as a few square angstroms and, hence, the attenuation of a focused laser beam is $\sim$0.0001%. Considering that inherent fluctuations in light sources are in the order of magnitude of 1%, the attenuation of the incident light by a single molecule is concealed. Celebrano *et al.* circumvented this restriction by using a dual-beam configuration, which essentially mimics the setup of a conventional absorption spectrometer. While one beam is tightly focused and probes the sample, the second one bypasses the sample volume before it is led to a detector. Thus, the second beam serves as a reference and by balanced detection even marginal intensity fluctuations, such as those provoked by a single-molecule absorption event, can be detected. If a polarization-sensitive detection scheme is introduced, the sensitivity can be further enhanced, thus allowing relatively short data acquisition times. However, as this approach monitors the attenuation of the incident light, discrimination between absorption and scattering processes is not intrinsically possible and a minimized surface roughness has to be ensured to scale the latter effect down.

A different approach to single-molecule absorption detection introduced by the Orrit group makes use of a two-color pump probe excitation schema in combination with a fast amplitude modulation to reduce measurement noise. Orrit *et al.* [127] detected the molecular absorption indirectly by monitoring the local heating, which is caused by the energy loss from the vibration of excited molecules. This photothermal effect can be probed with a second laser, which is not in resonance with an electronic transition of the sample (i.e., the sample appears transparent to this beam). Owing to the local heating, the refractive index experiences a slightly altered refractive index, which causes locally enhanced scattering. Using an amplitude modulation of the pump beam, these modulations also appear in the detection schema of the probe beam in case a molecule was excited by the pump beam. Providing a very good SNR, which outperforms the direct method, the main drawback of this photothermal technique is due to the inherent dependence on heat-induced changes in the refractive index and the level of heat conduction. These points especially become an issue for aqueous sample systems such as living cells, as here small changes in temperature only marginally affect the refractive index.

The third approach to single-molecule absorption has been established by the group of Sunny Xie, which probed an effect called *ground state depletion*. Using an experimental setup similar to the approach of Gaiduk *et al.* [127], the sample is excited with two laser beams of different wavelengths, both of which are in resonance with an electronic transition of the molecules under investigation. The first (pump) beam is used to prepare the molecules in their excited state. Accordingly, they are no longer resonant to the second (probe) beam and a fast on–off switching of the pump beam results in a modulated detection scheme of the probe beam [128]. While a high SNR is obtained and any restrictions concerning the temperature dependence of the local refractive index are circumvented by this approach, the technique requires high laser powers for the pump beam to drive the molecules into a saturated excited state, which highly strain the chromophores. Moreover, the excited-state lifetime is a crucial parameter as it defines the time evolution of the excited-state population after the pump pulse and the applicability to nonfluorescent molecules with short excited-state lifetimes remains to be demonstrated.

In conclusion, new techniques to approach single-molecule absorption measurements have been reported recently, driving single-molecule techniques to a new level. However, still a lot of effort has to be performed to make these approaches more sensitive, robust, and suitable for a broad range of sample systems. After these requirements have been fulfilled, even spectroscopic information might be gained from these absorption studies on individual molecules, further enhancing the information content of single-molecule studies.

Single-Molecule Interfacial Electron-Transfer Dynamics

Hong Peter Lu

22.1

Introduction

Interfacial electron transfer (ET) plays a critical role in catalysis, solar energy conversion, photosynthesis, environmental remediation technologies, and energy technologies. The fundamental information related to the energy flow between molecules and substrate surfaces as a function of surface site geometry and molecular structure are critical for understanding interfacial ET mechanism and dynamics. Specifically, interfacial ET processes involving dye molecules on titanium oxide (TiO_2) surfaces have been extensively investigated by ensemble-averaged studies [1–7]. As shown in Figure 22.1, in such studies, photoexcited dye molecules, such as organic dye molecules or porphyrin molecules, adsorbed on TiO_2 serve to inject electrons into the substrate conduction band (CB), where the excess electrons rapidly thermalize and relax to the CB minimum. The relaxed electrons may then diffuse into the bulk, becoming a part of the photochemical cycle, trap near the surface or in the bulk, or undergo back ET to an adsorbed molecule [4–20]. The forward electron transfer (FET) kinetics in various dye–TiO_2 ET systems are nonexponential or dispersive, with half-times disseminated in the femtoseconds to several hundred picoseconds range [6–20]. Following the FET, the thermalized-injected electron is localized to either subband states or surface states of the TiO_2 semiconductor [1–20]. Typically, a backward electron transfer (BET) from the semiconductor to the oxidized dye molecules will follow. In interfacial ET systems, a BET process is possible by thermal detrapping of the electrons from the total electron density of the reduced semiconductor and recombining the electrons with the oxidized dye molecules. When compared to ultrafast FET processes, BET processes take place at a longer timescale, ranging from subnanoseconds to several milliseconds, probably as a result of the existence of trap states and non-Brownian diffusion motions of the electrons in semiconductors. Furthermore, the dynamics of the BET processes are often nonexponential or dispersive [4–20]. Ensemble-averaged approaches, although valuable, cannot resolve important nanoscale aspects of interfacial ET. In particular, the geometry of the adsorption site, the orientation and the motion of the adsorbed molecule, and their relationship to the excited-state

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

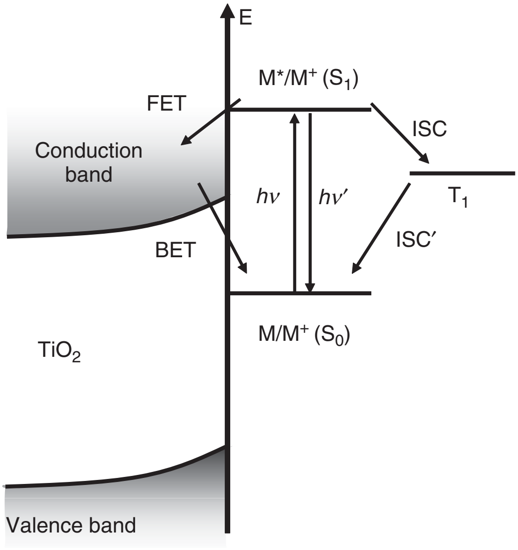

Figure 22.1 Schematic representation of a model of photoinduced processes in a dye-sensitized TiO_2 system. dynamics are often averaged out as the ensemble-averaged measurements cannot dissect complex interfacial ET processes at a site-specific level. The difficulty comes from both intrinsic spatial and temporal inhomogeneities of the interfacial ET dynamics, which can be identified, measured, and analyzed by studying specific one molecule at a time and a location at an interface.

Single-molecule spectroscopy was first demonstrated in 1997 [21]. Since then, the single-molecule spectroscopy has been a powerful approach for studying complex systems and inhomogeneous dynamics [21–39] and has also been applied to intramolecular [40] and interfacial ET investigations [21–39]. In this chapter, we will discuss on the single-molecule interfacial ET work carried out at our laboratory, and we will only briefly discuss the work carried out at a number of laboratories worldwide in recent years [39, 41–45].

22.2
Single-Molecule Spectroscopy Applicable for Studying Electron-Transfer Dynamics

22.2.1
Single-Molecule Time-Stamping Spectroscopy

A confocal microscope with a focused laser was typically used to image the individual molecules and measure the single-molecule fluorescence intensity trajectories. The output of the Coherent MIRA900 femtosecond laser at an 850–1000 nm wavelength and 75.7 MHz repetition rate was frequency doubled and coupled through a single-mode optical fiber (Figure 22.2). The beam was collimated after the fiber and passed through a polarizer, and the excitation light was attenuated to 0.1–1 μW. The beam was sent into the microscope from its epiport, reflected up by a dichroic beamsplitter, and focused by a 100× oil immersion objective lens (Zeiss Fluar numerical aperture (NA) 1.3) onto the upper sample surface of a microscope coverslip (Fisher Scientific, 0.17 mm thick). The sample can be raster scanned or moved to a particular position with respect to the laser focus using an x–y

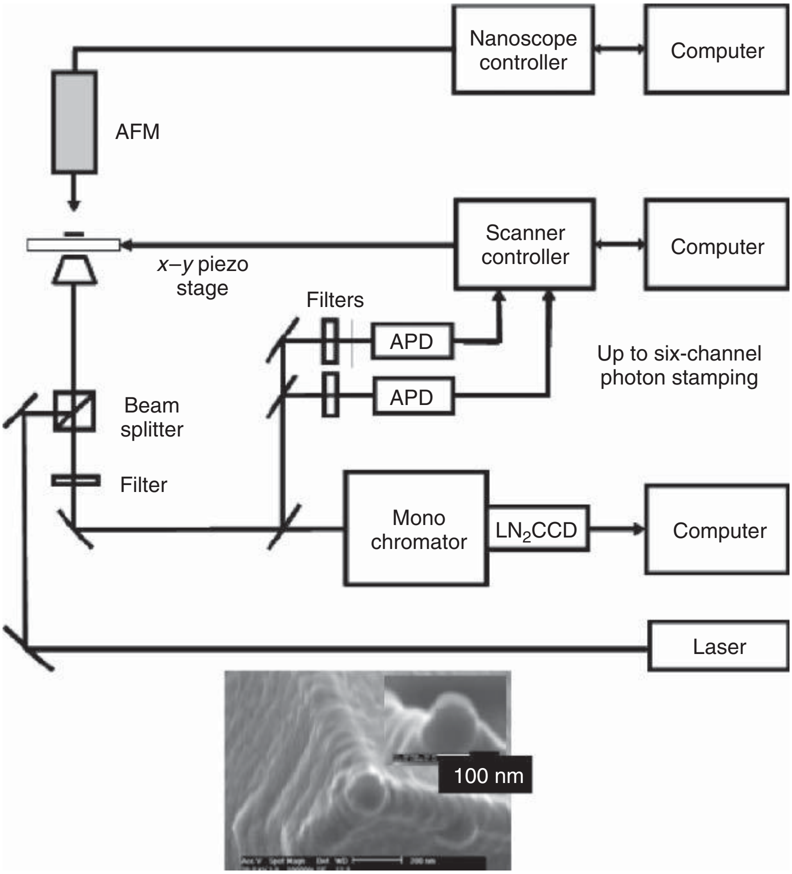

Figure 22.2 Schematic representation of the combined AFM tip-enhanced imaging and single-molecule fluorescence imaging experimental setup. Different continuous wave (CW) or pulse lasers and multicolor excitation are selected to improve the signal-to-noise ratio and the time resolution. A 2D piezoelectric closed-loop scanning stage is used to scan the sample in nanoscale precision for a 20 × 20 μm dynamic range and align the laser focal spot with the fluorescent molecule. APD, Avalanche photodiode; CCD (charged couple device camera). Inset: the AFM tip is typically coated with Au or Ag metal to facilitate tip-enhanced imaging and spectroscopy through surface plasmon enhancement and energy-transfer mechanisms.

piezoelectric closed-loop position scanning stage (Physik Instrumente, Germany). The fluorescence was collected by the same objective lens and was directed to the camera port of the microscope after going through the dichroic beamsplitter. The fluorescence signal was split by a polarizing beamsplitter or a color beamsplitter so that the two beams detected were the parallel and perpendicular components or the fluorescence resonant energy-transfer (FRET) donor and acceptor of the fluorescence, respectively. The two-channel (or four-channel) signals were imaged onto a (two pairs) pair of photon-counting detectors, either avalanche photodiodes (APDs; Perkin Elmer, SPCM-AQR-16 and SPCM-AQRH-14) or photomultiplier tube (PMT) (Hamamatsu H7522-40).

The detection electronics were derived from typical time-correlated single-photon counting. The two APD signals were directly sent to two time-to-amplitude converters (TACs) (Canberra, Model 2145) as a ‘‘start’’ signal. The photodiode signal from Mira 900 fs laser system was used as a ‘‘stop’’ signal for the TAC. The two TAC outputs were sent to a homemade two-channel digitizer instead of a multichannel analyzer. A recorded trajectory usually contains hundreds to thousands of photons

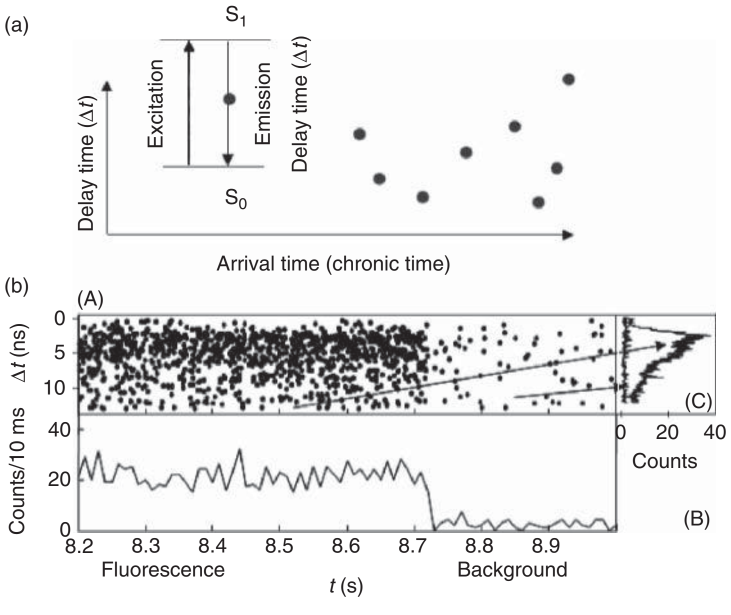

Figure 22.3 Schematic representation of a single-molecule confocal microscope with two-channel photon time-stamping spectroscopy. (a) It allows a study of the fluorescence intensity, lifetime, and anisotropy of a single molecule simultaneously by recording the arrival and delay time of each fluorescence photon. (b) An example of the raw data of the photon timestamping of a detector channel (A). Each dot corresponds to a photon-detected plot by its arrival time (t) and delay time (Δt). The fluorescence intensity trajectory (B) is calculated from the histogram of arrival time (t) with 0.01 s time bin resolution. The molecule was photobleached at 8.71 s. The nanosecond fluorescence decay curves (C) are the histograms of the delay time of the fluorescence photons ($t < 8.1$ s) and background photons ($t > 8.1$ s).

(Figure 22.3). For each photon, the detector identification, arrival time, and the delay time between laser excitation pulse and detected photon in nanoseconds or picoseconds were stored in the computer photon-by-photon for future data analysis. The recording of each photon is similar to receiving a mail with two stamps on the envelope showing when the mail was sent out and when the mail was received: this is where the name of the single-molecule photon-stamping spectroscopy originated from as an analogy to the mails [24, 27, 30, 39, 46, 47].

22.2.2
Tip-Enhanced Near-Field Fluorescence Lifetime Microscopy

A near-field optical imaging approach to correlate single-molecule optical spectroscopy with scanning tip topographic characterization [26, 28, 48–50] has been applied to studying interfacial ET, especially, to correlate the time-resolved spectroscopic temporal analysis and atomic force microscopy (AFM) topographic spatial analysis of the interfacial electron at a specific site (Figure 22.4). The method combines metallic tip scanning (either Au-coated AFM or STM metallic tips) with fluorescence lifetime imaging microscopy (FLIM) [48]. The AFM metallic tip was formed by sputter coating a Si tapping mode tip with Au, in a way that forms a globular tip apex (Figure 22.2, inset). The Au-coated tip generates high local electric field enhancement under laser illumination, which provides a strong electric field interaction between the AFM tip and the fluorescent molecule under

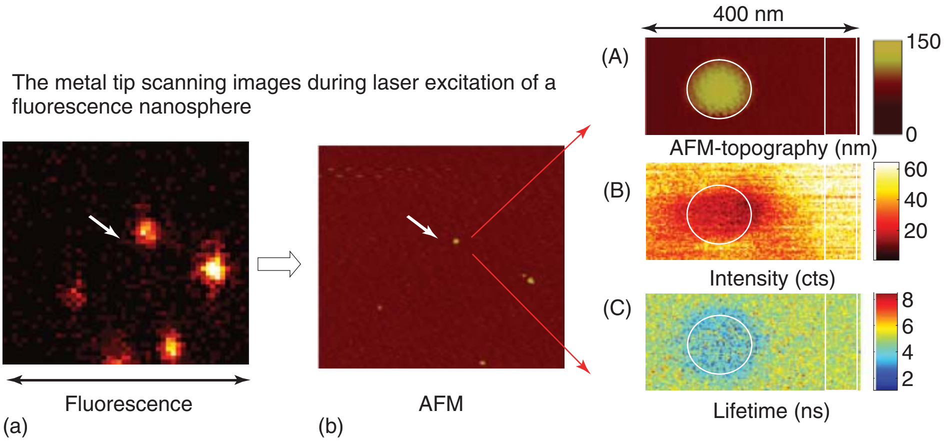

Figure 22.4 Proof-of-concept metallic tip-enhanced FLIM imaging. The fluorescence intensity image (a) and AFM image (b) of the same sample area containing 40 nm fluorescence nanospheres. The sample was first imaged by sample scanning confocal fluorescence microscopy and then by tip scanning AFM of the same area. The arrows on the images indicate the area zoomed-in for further high-resolution imaging shown in the three panels (A–C). The three nanosphere scanning probe images are obtained by (A) AFM; (B) the fluorescence intensity; and (C) the perturbation of the fluorescence lifetime [48].

the tip. The fluorescence lifetime is perturbed only when the tip is on top of the molecule within a nanometer range. The induced fluorescence lifetime changes provide the AFM–FLIM imaging contrast. Then imaging can be performed at an AFM spatial resolution typically defined by the tip diameter (Figure 22.4). Conceptually, an STM metallic tip can also facilitate correlated STM–FLIM imaging (Figure 22.5).

22.2.3
Tip-Enhanced Near-Field and Confocal Raman Spectroscopy Analysis of Vibronic Coupling of Interfacial Electron Transfer

AFM tip-enhanced site-specific resonance Raman microscopy studies on the interfacial ET of a dye-sensitization system has been applied to study interfacial ET energetics and dynamics [26]. A Raman excitation laser frequency resonant with the interfacial charge-transfer absorption band can be used in the Raman microscopic imaging measurements. For example, measuring the resonant-enhanced Raman signal associated with the chemical bonds that controls the interfacial ET dynamics [5, 47, 51, 52], we were able to observe the Raman peak intensity and peak-to-peak intensity ratio that are different from site to site at dye–TiO_2 nanoparticle (NP) layer. This approach allows quantitative analyses of vibrational relaxation energy barriers of the interfacial ET and surface chemical bonding and coupling between

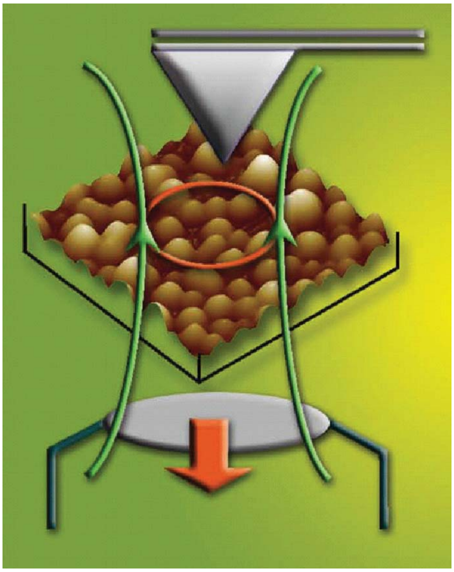

Figure 22.5 Schematic representation of AFM or STM metal tip-enhanced Raman spectroscopy of single TiO_2 nanoparticles. The optical detection and excitation are conducted using inverted confocal microscope coupled with monochromator-CCD or single-photon counting detectors (APD) [26, 28, 48, 49].

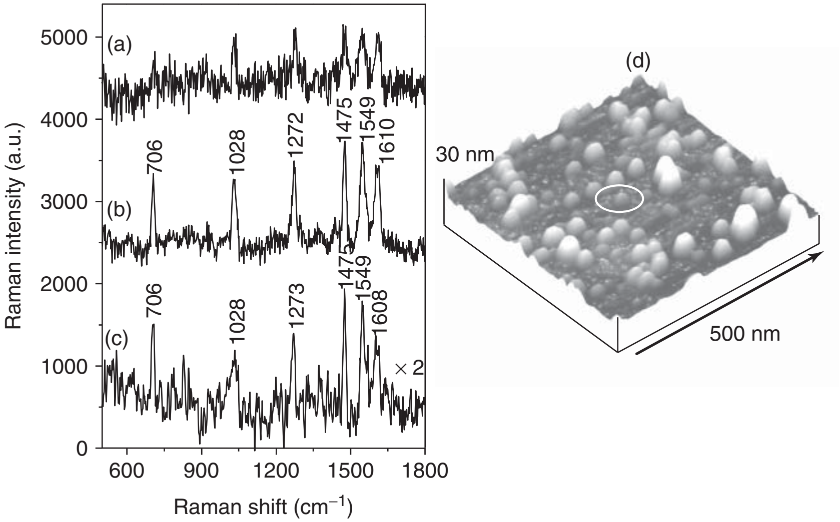

Figure 22.6 Tip-enhanced Raman spectroscopy and AFM characterization of N_3–TiO_2 interfacial electron transfer: (a) Raman spectrum without a tip, (b) Raman spectrum with a silver-coated AFM tip, (c) near-field Raman spectrum, and (d) an AFM image. The marked part in the AFM image corresponds to the nanoscale site where the near-field Raman spectrum was collected. In the near-field Raman spectrum, the most prominent bands, at 1475, 1549, and 1608 cm^{-1}, were assigned to the bipyridine ring stretching mode. The intense band at 1028 cm^{-1} was assigned to the ring breathing mode. The C–C interring stretch combined with the C–O stretching mode corresponds to the band at 1273 cm^{-1}. The 706 cm^{-1} band is attributed to an in-plan ring deformation mode [26].

the molecules and the substrates. A metallic-coated AFM tip can be used to enhance the Raman signals and help on achieving high spatial resolution beyond the optical diffraction-limited spatial resolution (Figure 22.6) [26, 53–55].

22.3
Intermittent Interfacial Electron Transfer in Organic Dye-Sensitized TiO_2 Nanoparticles

Here, we discuss a specific single-molecule spectroscopic study of photosensitized interfacial ET processes in Coumarin 343 (C343)–TiO_2 NP and Cresyl Violet (CV^+)–TiO_2 NP systems, using time-correlated single-photon stamping coupled with scanning confocal fluorescence microscopy. In this work, fluorescence intensity trajectories of individual dye molecules adsorbed on a semiconductor NP surface showed fluorescence fluctuations and blinking, with time constants distributed from milliseconds to seconds. The fluorescence fluctuation dynamics were found to be inhomogeneous from molecule to molecule and from time to time, showing significant static and dynamic disorders in the interfacial ET reaction dynamics. We attribute fluorescence fluctuations to the interfacial ET reaction rate fluctuations, associating redox reactivity intermittency with the fluctuations of molecule–TiO_2 electronic and Franck–Condon coupling. The intermittent interfacial reaction dynamics that likely occur among single molecules in other interfacial and surface chemical processes can typically be observed by single-molecule studies but not by conventional ensemble-averaged experiments.

With single-molecule spectroscopy, this study of interfacial ET dynamics of individual molecules avoided interference from (i) molecular aggregation, (ii) multiple electron injection to a single particle, and (iii) multiple electron–cation recombinations on the surface of a single particle.

C343–TiO_2 NP, CV^+–TiO_2 NP, and porphyin–TiO_2 systems were chosen for the studies of single-molecule interfacial ET (Figure 22.7). These systems exhibit a number of amenable properties for such research: (i) TiO_2 semiconductor being an essential substrate in many solar cells, interfacial ET processes in dye–TiO_2 NP systems have a potential industrial importance [1, 2]; (ii) the high fluorescence quantum efficiencies of C343 ($\Phi_f = \sim 0.7$) [56] and CV^+ ($\Phi = \sim 0.545$) [40] make it feasible to use single-molecule fluorescence spectroscopy to study interfacial ET processes; (iii) it has already been demonstrated that C343 [40, 56, 57] and CV^+ [58] adsorbed on semiconductor surfaces are efficient electron donors under photoexcitation; (iv) the systems can be used to validate single-molecule spectroscopy as a way to study interfacial ET processes involving chromophores that absorb in the near-UV (C343) and visible region (CV^+); (v) the oxidized dye molecules have different charge densities, +2 charges on CV and +1 charge on C343, making them an informative comparison; and (vi) STM and AFM can be applied to obtain single-molecule topographic images of single porphyin molecules on a single-crystal surface of TiO_2, rutile, or anatase.

Interfacial ET processes involving C343 have been explicitly proved by probing the ultrafast ET processes and ET products (cation radical of C343 and trapped electron in TiO_2 colloidal particles) in thorough ensemble-averaged studies of the C343–TiO_2 system [35, 40, 57]. Interfacial ET processes involving monomers or aggregates of CV^+ as electron donor have been reported in a previous single-molecule ET study [36] and in other ensemble-averaged ET studies [1–20, 40, 57, 58].

We examined the single-molecule interfacial ET processes by recording and analyzing the fluorescence intensity trajectories of individual C343 and CV^+ molecules adsorbed on the surface of TiO_2 NPs. In our experiments, a thin layer of TiO_2 NPs was spin coated on a glass coverslip (Figure 22.7) followed by spin coating a solution (0.1 nM) of C343 or CV^+. The dye molecules were covered using a thin film of poly(methyl methacrylate) (PMMA) by spin coating a toluene solution of PMMA (1 mg ml^{-1}). Fluorescence intensity trajectories of C343 and CV^+ single molecules adsorbed on bare glass surfaces and the surfaces of TiO_2 NPs were measured by single-photon time stamping (Figure 22.8) [24]. Uninterrupted fluorescence states, that is, no fluorescence blinking or fluctuation, were observed for both C343 and CV^+ molecules in the absence of TiO_2 NPs on insulating glass surfaces. Figure 22.8a shows a typical fluorescence intensity trajectory of a single C343 molecule

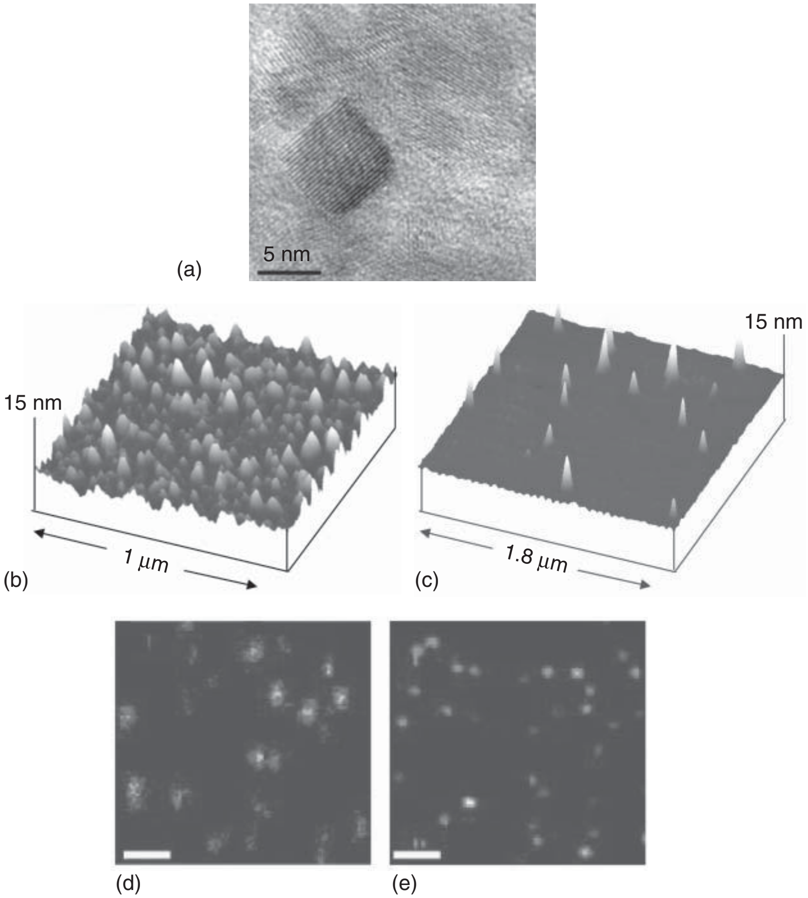

Figure 22.7 (a) A high-resolution TEM image of TiO_2 NPs obtained under 300 kV acceleration and 600 k magnification. (b) AFM images obtained for a 0.8 μM colloidal TiO_2 NP solution spin coated on a glass coverslip (samples prepared under this condition were overcoated with C343 or CV^+ dye molecules and used in single-molecule fluorescence studies) and (c) a 40 nM colloidal TiO_2 NP solution spin coated on a freshly cleaved mica surface. Fluorescence images of single molecules of (d) C343 and (e) CV^+ spin coated on TiO_2 NP-coated glass coverslips (topographies of these samples are identical to those in (b)). The scale bar in (a) is 5 nm and in (d) and (e) are 2 μm [24].

on a glass surface. Dye molecules at the singlet excited states exhibit different excited-state electronic deactivation processes: internal conversion, fluorescence emission, and intersystem crossing (ISC) to a dark triplet state (Figure 22.1). Under ambient conditions and millisecond temporal resolutions, it is rare to observe fluorescence blinking of these molecules as a result of ISC to the dark triplet-state and ground-state recovery. These processes usually occur in a much shorter timescale, for example, quenching of the triplet state by oxygen is in submillisecond timescale [24, 59]. In our experiments, we used submillisecond temporal resolution

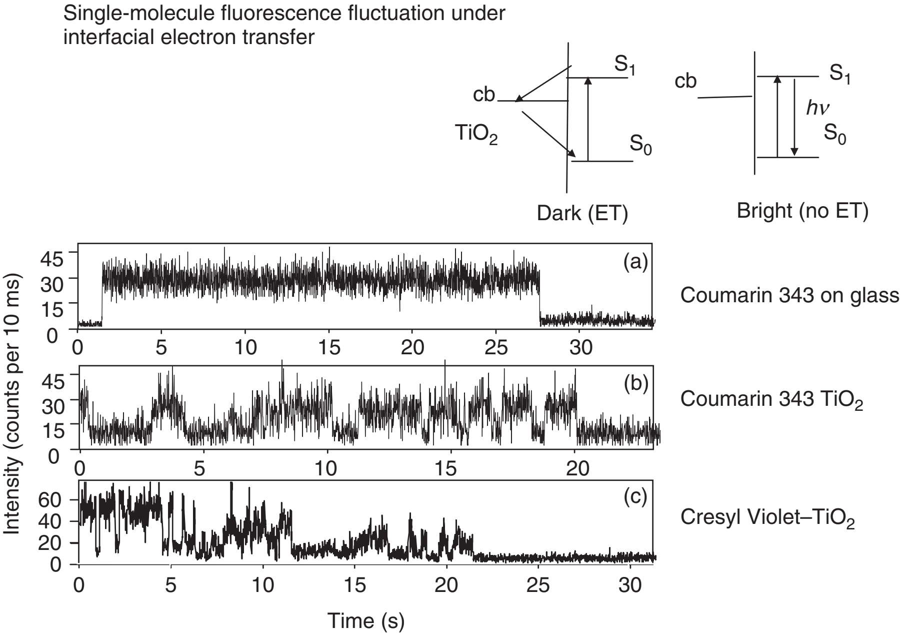

Figure 22.8 Fluorescence intensity trajectories collected in air for single molecules of C343 or CV^+, with samples prepared by spin coating aqueous dye solutions (0.1 nM) on glass coverslips or on TiO_2 NP-coated glass coverslips and overlaid with thin film of PMMA: (a) trajectory of C343 in the absence of TiO_2 NP; (b) trajectories of C343 in the presence of TiO_2 NPs; and (c) trajectory of CV^+ in the presence of TiO_2 NPs. The binning time for the trajectories was 10 ms. The fluorescence intermittency and blinking characteristics observed (b,c) are as a result of intermittent interfacial ET reactivity.

for single-photon counting and a 10 ms bin time for recording and analyzing single-photon arrival time. These timescales allowed any fast fluorescence intensity fluctuations or blinking of the dye molecules to be averaged out within our measurements.

A typical fluorescence intensity trajectory obtained for a single C343 molecule, adsorbed on the surface of TiO_2 NPs and recorded in air, is shown in Figure 22.8b. Figure 22.8c shows a typical fluorescence intensity trajectory of a single CV^+ molecule adsorbed on the surface of a TiO_2 NP and recorded in air. Under these conditions, fluorescence intensity trajectories of both C343 and CV^+ single molecules showed fluctuation behavior. The single-molecule fluorescence intensities stochastically dropped to either a lower or the background level. For both the C343 and CV^+ single molecules, the timescales of fluorescence intensity fluctuations ranged from several milliseconds to several seconds and also the fluctuation behavior was found differed among the single molecules.

On the basis of our experimental results and the literature, we are able to attribute the fluorescence intensity fluctuation behavior of single molecules adsorbed on TiO_2 NP surfaces to interfacial ET reactions for the following reasons: (i) the oxidized state of the dyes is essentially nonfluorescent, in contrast to their bright reduced forms; [24, 60] (ii) ensemble-averaged fluorescence and transient absorption studies have demonstrated that photoexcited C343 molecules inject electrons to the CB or energetically accessible surface states of the TiO_2 semiconductor, and both ensemble-averaged and single-molecule studies have identified interfacial ET reactions of CV^+ on semiconductor surfaces; (iii) fluorescence intensity trajectories of single molecules of C343 (Figure 22.8a) and CV^+ (not shown) in the absence of TiO_2 NPs in our control experiments showed essentially continuous fluorescence until the molecules were irreversibly photobleached; (iv) ET between the dye molecules and a PMMA film is unlikely, based on our control experiment (Figure 22.8a) in which the dye molecules were directly deposited on a glass surface and followed by covering with a PMMA layer; and (v) the fluorescence intensity fluctuations are not due to triplet states or the rotation of the transition dipoles of the dye molecules (see reference [24] for details).

We have investigated the possibility that transient changes in the transition dipole orientations of the single molecules, as a result of molecular rotational or translational motions, are responsible for the observed fluorescence fluctuations and blinking in subseconds to seconds (Figure 22.8b,d). Dye molecules adsorbed on TiO_2 NP surfaces may change their orientations as a result of the collective motions of the molecular environment or rotational and translational motions of the dye molecules. Under linearly polarized laser excitation, changes in the excitation cross section as a result of changes in molecular orientation result in fluorescence intensity changes. In our single-molecule control experiments, we recorded single-molecule fluorescence photon-stamping time trajectories using an orientation angle-modulated linear polarized laser excitation.

We determined the transition dipole orientation angles of single molecules by analyzing the fluorescence intensity trajectories. We identified that more than 80% of the single-molecule fluorescence intensity trajectories showed that the transition dipole orientations of single molecules do not change significantly. However, the intensity fluctuated along the trajectory. These observations substantiate the conclusion that molecular rotation or translation is not primarily responsible for the fluorescence fluctuation and blinking in the intensity trajectories (Figure 22.8b,c).

The nature of the lower fluorescence intensity levels has been further investigated. One possibility is that emission from the oxidized states of the dye molecules ($C343^+$ and CV^{2+}) may be responsible for lower fluorescence intensity levels. However, it is known in the literature that the oxidized states of the dye molecules ($C343^+$ and CV^{2+}) produce no fluorescence or extremely weak fluorescence that would not be significant compared to background. Another possibility is the fluorescence quenching by ET process. The timescale of the FET processes are known to be from femtoseconds to subnanoseconds [40, 57], whereas the fluorescence lifetimes of C343 and CV^+ are in nanoseconds. On the basis of the rates of FET and fluorescence, extremely low fluorescence quantum efficiency is expected.

It is an apparent paradox that single-molecule fluorescence is observed along with ET processes. We investigated this intriguing observation by analyzing the fluorescence lifetimes of single molecules. In this experiment, the arrival and the delay times of every detected photons were recorded using time-stamping technique [61]. The arrival time was used to construct an intensity trajectory and the delay time to analyze single-molecule fluorescence lifetimes. Figure 22.9a shows the intensity trajectory of a typical single CV^+ molecule constructed from the photon arrival time. The photon delay time of the same single molecule can be used to derive the fluorescence lifetime correlated to the intensity trajectory. For this, the trajectory was separated into higher and lower levels, based on a photon count threshold of 30 per 10 ms. Then, the nanosecond fluorescence decay curves were plotted, based on delay time of photons in each group (Figure 22.9). The curves were fitted to single exponential decays with time constants of 2.6 ns (for the profile "a" in Figure 22.9b) and 3.4 ns (for the profile "b" in Figure 22.9b). We found that the fluorescence lifetimes of the higher and the lower intensity states are very close

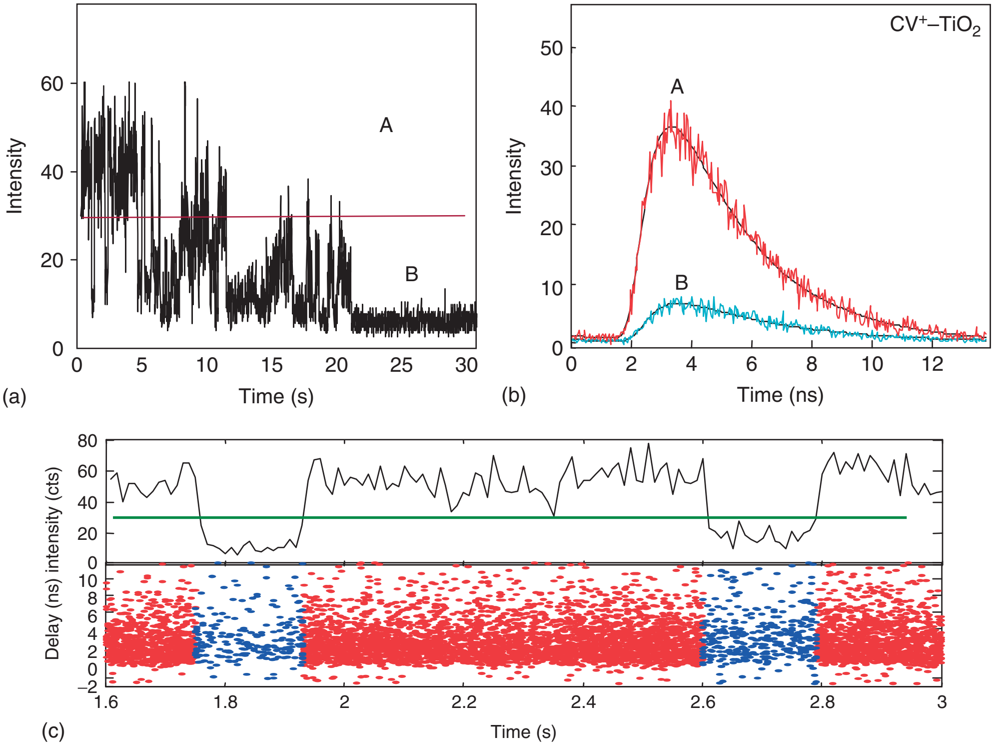

Figure 22.9 Fluorescence decay profiles of a single CV^+ molecule, whose intensity trajectory is provided in Figure 22.4d. The trajectory (Figure 22.4D) is separated into higher and lower levels based on a photocount threshold of 30 per 10 ms: (a) and (b) are the nanosecond fluorescence decay curves of the photons emitted within the higher and lower intensity periods, respectively. The curves are fitted to single exponential decays with time constants of 2.6 ns for (a) and 3.4 ns for (b). Both the curves are normalized based on their total accumulation time. The ratio of the preexponential amplitudes of the higher and the lower intensity curves is 6.

for the molecule, as shown in Figure 22.9. However, the preexponential amplitude of the higher intensity state was six times higher than that of the lower. Therefore, the intensity difference between the profiles (traces "a" and "b" in Figure 22.9) was attributed to the difference in the preexponential amplitudes. On the other hand, quenching of the singlet excited state as a result of interfacial ET reactions occurs at hundreds of picoseconds or below and is much faster than our instrument response time. The observed timescale of this fast quenching process of single molecules agrees with the reported fast FET rates in general. Similar behavior was observed in the analyzes of the intensity trajectories of other single molecules.

The fluorescence intensity level is determined by the fraction of time during which the intermittent ET process takes place. The fluctuations in the fluorescence intensity trajectories are as a result of high and low ET reactivities of the single dye molecules with TiO_2 NPs. It is unlikely that interfacial ET processes are completely turned "on" and "off" during the periods of the lower and higher fluorescence intensity states, respectively. On the other hand, each lower and higher intensity states likely include occurrences of multiple FET and BET events. Therefore, only the time-binning-averaged intensities were recorded in the single-molecule trajectories. The fluorescence intensity fluctuations reflect that interfacial ET reactivity changes from time to time stochastically, resulting different time span of the lower and higher intensity states. When the interfacial ET reactivity is high, the ultrafast redox reactions dictate the fate of the singlet excited state of the dye molecules, and the fluorescence quantum efficiency is low or close to zero. In contrast, when the redox reactivity is low or nonexistent, the fluorescence quantum efficiency is high and the fluorescence intensity is high. This concept is illustrated in Figure 22.10.

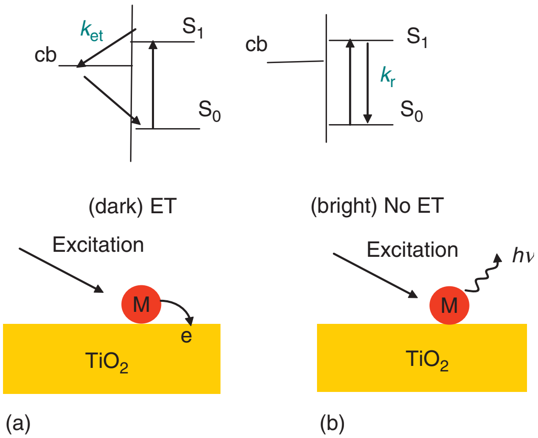

Figure 22.10 The ET activity is intermittent in nature and does not always dominate the excited-state process of the dye–TiO_2 NP system. (a) The dark state in the fluorescence trajectory is due to ET process with high activity quenching the fluorescence, (b) and the bright state is due to natural fluorescence emission cycles from $S_1 \rightarrow S_0$ and low activity in ET process.

Our control experiments support the conclusion that (i) the single-molecule interfacial ET is ultrafast and not directly time resolved by our single-molecule photon-stamping measurements; (ii) the single-molecule fluorescence intensity fluctuation reflects the single-molecule interfacial ET reactivity fluctuation; (iii) when the interfacial ET activity is low, the $S_1 \rightarrow S_0$ radiative emission dominates the signal, and the detected fluorescence intensity is high giving the bright states; (iv) whereas, when the interfacial ET activity is high, the ET quenches the $S_1 \rightarrow S_0$ radiative transition, and the detected fluorescence intensity is low giving the dark states; and (v) therefore the variations of the dark times represent the single-molecule ET reactivity fluctuation; statistically, a longer dark time represents a higher reactivity, and vice versa.

The molecular fluorescence intensity is typically characterized by the fluorescence quantum yield (Q) of the molecules. The value of Q is determined by the ratio of the number of emission photons to the number of excitation photons absorbed. As the intensity of the CW laser is stable and has almost no drift with time, the excitation photon flux is thereby held stable. Furthermore, the rotation motions of dye molecules are rare events within seconds as shown in Figure 22.2; the absorbed photon number is also held stable. Therefore, the single-molecule fluorescence intensity fluctuation, reflected by Q value fluctuation, is due to the emission photon number density fluctuation. Once an excitation photon is absorbed, a single-molecule dye is excited from S_0 ground state to the S_1 excited state (Figure 22.11). The probability of an emission transition from the S_1 excited state depends on both radiative decay rate constant k_{rad} and nonradiative decay rate constant, k_{nr}, and is given by the relation, $Q = k_{\mathrm{rad}}/(k_{\mathrm{rad}} + k_{\mathrm{nr}})$. If there is no nonradiative decay

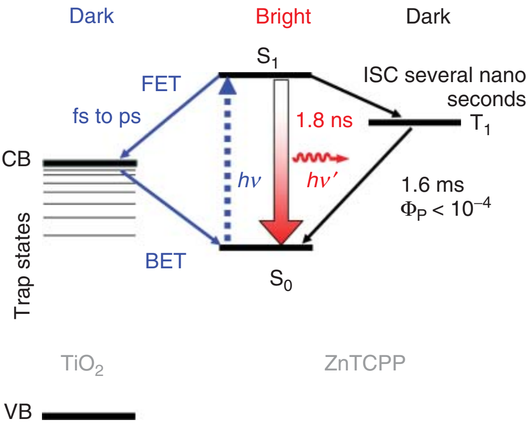

Figure 22.11 Schematic representation of energy levels and basic photoinduced process in dye–TiO_2 system. In this case, the dye molecule is a zinc porphyrin molecule (ZnTCPP); [39] nevertheless, the concept is generally applied to other interfacial electron dynamics discussed in this section. CB, conduction band; VB, valence band; FET, forward electron transfer; BET, backward electron transfer; and ISC, intersystem crossing. The dark state on the left is due to that the high ET reactivity quenches the photon emission and the dark state on the right is due to the triplet state of dye molecule.

process ($k_{nr} = 0$) or the nonradiative decay is much slower than the radiative decay ($k_{nr} \ll k_{rad}$), then the $Q = 1$ and the chromophore is bright. If the nonradiative decay is much faster, then the $Q \to 0$ and the chromophore are dark. As there is always a nonradiative decay process, and the decay time can be comparable to the radiative decay time, the Q has a finite value between 0 and 1. In a dye–TiO_2 NP system, the k_{rad} is the reciprocal fluorescence lifetime of nanosecond, and k_{nr} is dominated by FET time of femtoseconds to picoseconds as both the internal conversion from S_1 to S_0 (nanoseconds to microseconds) and the intersystem cross from S_1 to T_1 state (several nanoseconds) are much slower (Figure 22.4). The natural fluorescence lifetime is unlikely to fluctuate at milliseconds to seconds under the single-molecule experimental condition; therefore, it is the k_{nr} fluctuation that contributes to the Q fluctuation, which in turn contributes to the fluorescence intensity fluctuation (for example, Figure 22.4).

It is still not technically possible to measure the subpicoseconds and femtoseconds single-molecule ET dynamics directly, although measurements of the ultrafast single-molecule excited-state dynamics has been demonstrated [29]. In our single-molecule fluorescence spectroscopy experiments, what has been measured is the nanosecond emission photons from the $S_1 \to S_0$ radiative transition, which is related to the quantum efficiency of the excited state involving in FET as a dominated nonradiative transition, radiative transition, and intersystem cross transition from the singlet S_1 excited state to the triplet state (Figure 22.4). In other words, it is the $S_1 \to S_0$ nanosecond transition that serves as a clock to regulate the decay pathway of the excited state of dye molecule: the FET time apparently fluctuates in a wide timescale from femotoseconds to nanoseconds or even slower. This is because that if the FET as a nonradiative decay is constant in a femtosecond to picosecond timescale, the excited-state radiative emission efficiency at nanosecond timescale should be as low as 10^{-3} to 10^{-6}, and the single molecules should be essentially nonfluorescent or not observable by photon detection. However, we have observed that the single-molecule fluorescence intensity is blinking between the dark and bright states. When the nonradiative FET process is much faster than the nanosecond radiative decay, the single molecule is dark; when the nonradiative FET process is much slower than the nanosecond radiative decay, the single-molecule is bright; when the nonradiative FET time is comparable to the nanosecond radiative decay, the single-molecule fluorescence state is in between bright and dark states. The comparative nonradiative and radiative decay processes determined the fate of the excited states, and in turn determined the brightness of the single molecules. The fluctuation of the single-molecule emission intensity is a reflection of the rate fluctuation of the nonradiative FET process; and the fluctuation of the FET dynamics is practically probed by the nanosecond radiative decay process in determining the fluorescence quantum efficiency.

The single-molecule interfacial ET processes in C343–TiO_2 and CV^+–TiO_2 systems were found to be inhomogeneous, both dynamically and statically. The static inhomogeneity originates from different interfacial ET reactivity fluctuations from molecule to molecule, whereas dynamic inhomogeneity is associated with the ET reactivity fluctuations from time to time for the same individual molecules, resulting fluorescence fluctuations. On the basis of extensive literature on ensemble-averaged ET dynamics and mechanisms, we attributed the origins of these static and dynamic inhomogeneities in the single-molecule interfacial ET processes to fluctuation of the molecular properties, including donor–acceptor distance, redox potentials of the donor and the acceptor, Frank–Condon factors, donor–acceptor electronic coupling, and the solvent reorganization energy [5, 12, 24, 39, 62, 63]. Among these critical parameters, the changes in Frank–Condon coupling and associated nuclear motions are most likely to determine the ET rate fluctuation of a single molecule, assuming that other parameters do not change considerably for a single molecule overtime. However, limited by the sensitivity of the single-molecule fluorescence spectroscopy, we are not yet able to detect the changes of these parameters. There are two possible origins: (i) the changes in molecule–surface vibronic coupling as a result of nuclear motions, and (ii) the changes in Frank–Condon coupling as a result of fluctuations of the energy gap between the reactants and products are responsible for the dynamic inhomogeneity of the interfacial ET processes. We observed the dynamic inhomogeneity of the interfacial ET reactions by obtaining and analyzing autocorrelation functions (insets of Figure 22.12a,b) of single-molecule fluorescence intensity fluctuations and blinking. The autocorrelation decays are typically dispersive and fitted using

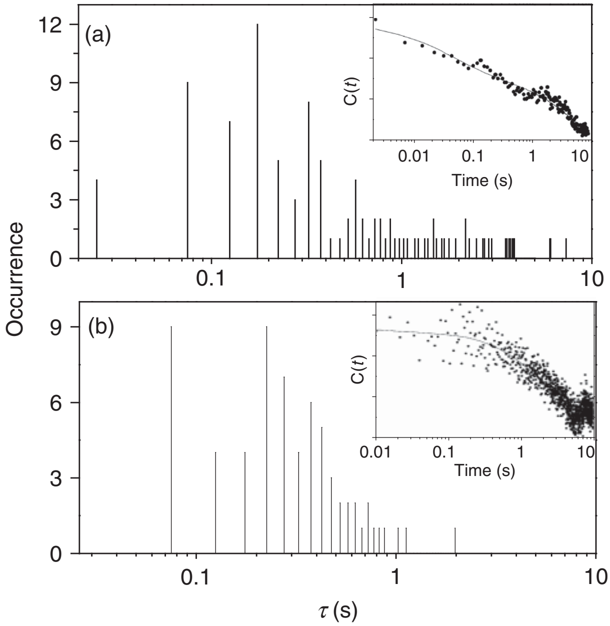

Figure 22.12 Histograms of fluorescence intermittency time constants, obtained from intensity trajectory autocorrelations, for >100 single molecules of C343 (a) and CV^+ (b) adsorbed on TiO_2 NP surfaces. The insets in (a) and (b) are typical fluorescence intensity trajectory autocorrelation traces for single C343 and CV^+ molecules, respectively.

biexponential decays, with the decay times ranging from 10 ms to 30 s. The dispersive and power-law behavior [64–68] of the autocorrelation function decays, which stretched across wide timescales, from submilliseconds to minutes, shows the dynamic inhomogeneity of the single-molecule interfacial ET reactivities. The cutoff at submilliseconds of the power-law decay is due to our measurement system response limitation, and it is highly likely that the dynamic inhomogeneity extends to shorter timescales.

Single-molecule interfacial ET dynamics has also been studied for zinc-tetra (4-carboxyphenyl) porphyrin (ZnTCPP)–TiO_2 NP system. The single-molecule fluorescence trajectories show strong fluctuation and blinking between bright and dark states. The intermittency and fluctuation of the single-molecule fluorescence are attributed to the variation of the reactivity of interfacial ET. The nonexponential autocorrelation function and the power-law distribution of the probability density of dark times imply the dynamic and static inhomogeneities of the interfacial ET dynamics. On the basis of the power-law analysis, the variation of single-molecule interfacial ET reactivity is analyzed as a fluctuation according to the Lévy statistics. We will focus on discussing the statistical analysis of the interfacial ET dynamics fluctuations in the following part of this section, and so far, the analysis approach has been applicable to the interfacial ET dynamics fluctuations in various dye–TiO_2 systems [24, 39].

To analyze the single-molecule interfacial ET dynamics that is associated with the fluctuation of the single-molecule fluorescence trajectories, a histogram of emission intensity is first constructed and then a threshold is determined. The

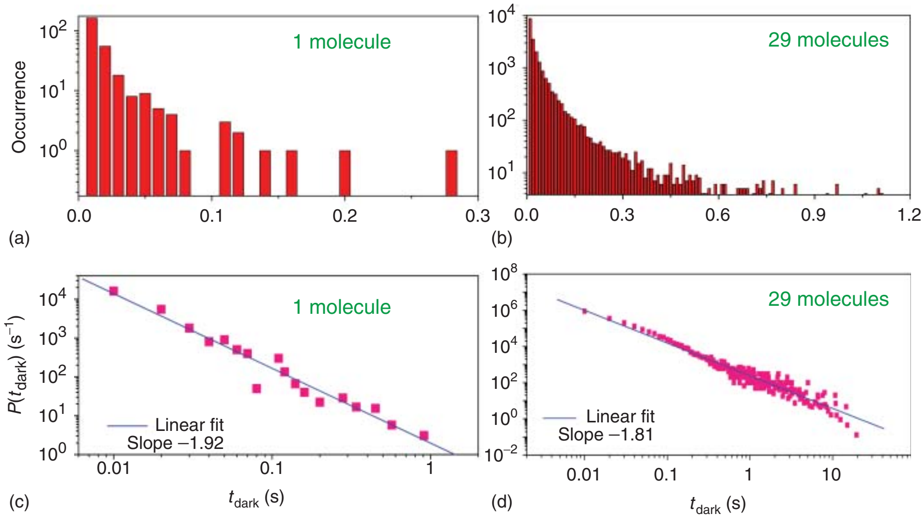

Figure 22.13 Distributions of occurrence (a,b) and probability density (c,d) of dark state for 1 molecule and 29 molecules. In (a) and (b), the occurrence and dark time are plotted in a semilog to linear scale. There are about 240 and 20 K dark states recorded for single molecule (a) and 29 molecules (b), respectively.

time durations of the dark or bright states are then obtained. Figure 22.13a,b shows the distributions of the time durations of the dark states for a single molecule and 29 molecules, respectively. The duration of the dark states spans a broad range from subseconds to seconds. It is interesting that, for the single molecules, non-Poisson behavior is observed evidenced by a nonexponential dark time distributions, as shown in Figure 22.13. This non-Poisson dark time distribution suggests that the intrinsic physical mechanism is not originated from a single Poisson event under an exponential rate dynamics, which reflects that the interfacial ET involves complex rate process that cannot be defined by a static rate constant and the rate changes from time to time. This fluctuation behavior has been characterized as dynamic disorder [24, 39, 69, 70], which is beyond the conventional scope of chemical kinetics.

To analyze the ET reactivity fluctuation dynamics associated with the non-Poisson dark time distributions, we have constructed the probability density [71] distributions of the dark states ($P\ (t_{\text{dark}}) = \text{Occurrence}\ (t)/\Delta t$). Each data point of the histogram is weighted by the average time between nearest neighbor events. The calculated log–log plots (Figure 22.13c,d) of the single-molecule dark time probability density distributions show typical power-law behavior, which can be mathematically described as $P(t_{\text{dark}}) \propto t_{\text{dark}}^{-m_{\text{dark}}}$. This power-law kinetics quantitatively demonstrates that the dark time probability density distributions are nonexponential and should correspond to non-Poisson dynamics associated with dynamically inhomogeneous ET activity, that is, the ET reaction activity fluctuates from time to time. Power-law behaviors have been extensively investigated in emission blinking dynamics of quantum dots and other single emitters [71, 72]. Distributed-traps model and diffusion-controlled models have been proposed to rationalize the power-law behavior of quantum dots [73, 74]. The former model proposed the quantum dots that enter dark state once it loses an electron into the surface traps and become bright again after a nonradiative Auger recombination. The latter model suggests that the blinking is controlled by the diffusion of the energy of electron or trap state, and the model agrees well with the experimental results. For the power-law behavior in single-molecule blinking, power-law-distributed dark states are found to be the main pathway of photobleach for single organic molecules, and it has been suggested that the power-law blinking of organic molecules seems to require dynamic disorder dynamics. Connected with experiment, the origin of power-law distribution in single-molecule conformation dynamics has been theoretically studied [72, 75]. In our experiment, the power-law statistical behavior is intrinsically determined by the interfacial ET dynamics. For ZnTCPP–TiO_2 system, the power-law behavior reflects the disorder of the ET reactivity, and the power exponent m_{dark} represents nonexponential distribution nature of the probability of the dark times.

We have calculated the power exponents, m_{dark}, for 28 molecules and obtained a distribution of m_{dark} (Figure 22.14a). The value ranges from 1.02 to 2.68, which reflects the inhomogeneity of the ET activity fluctuation from molecule to molecule. The mean value of the power exponents $<m_{\text{dark}}>$ is 1.79. To further understand the ET reactivity fluctuation and the dark state properties, we calculated the autocorrelation functions of the single-molecule fluorescence intensity trajectories.

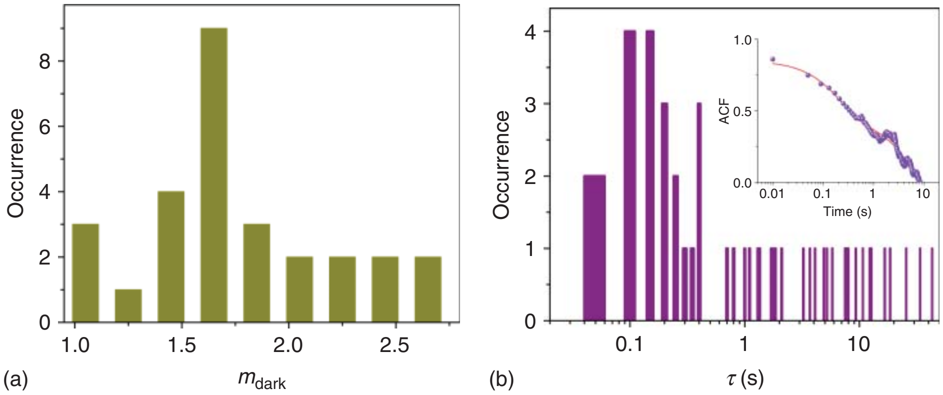

Figure 22.14 (a) Histogram of power-law exponents for 28 ZnTCPP molecules. (b) Histogram of fluctuation times derived from the autocorrelation function of the fluorescence intensity for 29 ZnTCPP molecules. Inset: a typical nonexponential autocorrelation function calculated from a single-molecule fluorescence intensity time trajectory. For autocorrelation function of emission intensity, $1/\tau$ represents the fluctuation rate, that is, interfacial ET reactivity fluctuation rate in the ZnTCPP–TiO_2 system.

Most of the autocorrelation functions show nonexponential decays, which is consistent with our previous findings on single-molecule Coumarin 343–TiO_2 and CV–TiO_2 interfacial ET dynamics [24]. The nonexponential autocorrelation function indicates the dynamic disorder of the interfacial ET reactivity, that is, the reactivity fluctuation rate changes from time to time during a single-molecule measurement.

Both the autocorrelation function decay time τ and the power-law exponent m_{dark} are critical factors characterizing the interfacial ET reactivity fluctuation dynamics. These two parameters correspond to the basic properties of single-molecule fluorescence fluctuations. The autocorrelation function fluctuation time τ represents the ET reactivity fluctuation time, and the power-law exponent m_{dark} represents nonexponential distribution nature of the probability of the dark times. The τ determines the fluctuation timescale for a single molecule to shift from a bright state to a dark state statistically. Although power-law exponent m_{dark} indicates the relative probability for the dark state duration: a larger m_{dark} suggests a relatively higher distribution probability for a shorter dart time states. As we have discussed earlier, the single-molecule fluorescence fluctuation as well as the dark states are as a result of the interfacial ET dynamics fluctuation, and the longer a dark state lasts, the longer the interfacial ET process dominates the ZnTCPP excited-state dynamics.

For a power-law distribution expressed as $P(t_{\text{dark}}) \propto t_{\text{dark}}^{-m_{\text{dark}}}$, the distribution is dominant by Lévy statistics at $1 < m_{\text{dark}} = 1 + \alpha < 2$ [76]

$$P(t_{\text{dark}}) \propto 1/t_{\text{dark}}^{1+\alpha}, \qquad 0 < \alpha < 1$$

Lévy statistics is usually observed in complex systems with nonlinear interactions, such as in physics and biology. Its typical characteristic is the diverging variance and a broad distribution expressed by power-law rule. In single-molecule spectroscopy, Lévy statistics has been extensively investigated in the blinking dynamics of quantum dots [61, 67]. Some abnormal properties due to Lévy statistics, such as statistical aging and ergodicity breaking, have been deduced by calculating the evolution time of on (off) state or time-averaged correlation function or power spectra [61, 68].

Figure 22.13a shows that there are 21 power-law exponents met with $1 < m_{\mathrm{dark}} < 2$, suggesting that the distribution of the dark states of 75% molecules examined obey Lévy statistics. We have calculated the evolution time of a ZnTCPP–TiO_2 system that spends in the dark states, that is, the total time spent in the dark state in the first N dark periods. For a single-molecule trajectory, the evolution time of the dark state is defined as [61]

$$\theta(N) = \sum_{i=1}^{N} t_{dark}^{i}$$

where $\theta(N)$ is the total evolution time, t_{dark} is the duration of a dark state, and N is the state index in a single-molecule fluorescence intensity trajectory. Figure 22.15 shows the evolution time trace for two single-molecule trajectories with m_{dark} of 1.39 and 2.68. Obviously, the Lévy type evolution performs a nonlinear increase with N, and the sum $\theta(N)$ is almost dominated by few long-time events of the order of $\theta(N)$ itself, which unambiguously shows the diverging variance in Lévy statistics. The Lévy statistics of dark states quantitatively reveal the fluctuation mode of the interfacial ET reactivity in ZnTCPP–TiO_2 system. We suggest that Lévy statistics of the interfacial ET can be ascribed to the complex interfacial site- and time-specific interactions between single ZnTCPP molecules and nanoscale local environments.

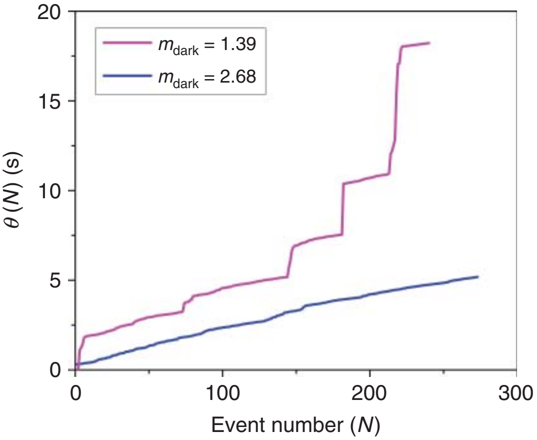

Figure 22.15 Evolution of total time spent in dark states $\theta(N)$ with the event index N. The curve with $m_{\mathrm{dark}} = 1.39$, which obeys Lévy statistics, shows rapid and nonlinear increase. The evolution is dominated by few events of the order of $\theta(N)$ itself.

Nevertheless, complex interfacial ET dynamics has been reported over the last 30 years from ensemble-averaged experiments, and it is often that different ET times (from femtoseconds to nanoseconds for FET time and nanoseconds to milliseconds for BET time) were reported for the same dye-sensitization system but from the different spectroscopy approach at different time resolutions. Our observation of the static and dynamic disordered interfacial ET dynamics fluctuating across a wide timescale is consistent with the ensemble-averaged results and reveals partially the origin of the complexity of the interfacial ET dynamics.

According to this work and our previously reported work [24, 39], the highly inhomogeneous ET dynamics is most likely common for the interfacial chemical reactions that are strongly regulated by the molecular interaction between adsorbed molecules and substrate surfaces. The spontaneous thermal fluctuations of the local environment and the molecular interactions occur at a wide timescale at room temperature, resulting in the interfacial ET reaction rate fluctuation and inhomogeneous dynamics. Our single-molecule spectroscopy analysis provides detailed information about the inhomogeneity of the interfacial ET, which is consistent but not obtainable from the conventional ensemble-averaged experiments.

22.4
Probing Inhomogeneous Vibrational Reorganization Energy Barriers of the Interfacial Electron Transfer

The complex fluctuations of the interfacial ET dynamics show characteristic dynamic and static disorders. We have attributed that the fluctuations are primarily originated from the rate fluctuation in a wide range across from ultrafast to nanoseconds and to even longer timescales. It is well known that the interfacial ET rate is highly sensitive to the molecular interactions between the adsorbed dye molecules and the TiO_2 substrate in a TiO_2-based dye sensitization system. The primary parameters of the molecular interaction are, for example, the ET driving force of free energy gap between the excited state of molecule and the CB of TiO_2 semiconductor, the vibrational relaxation energy of the adsorbed molecules and the surface vibrational modes of TiO_2, the electronic coupling between the molecules and the TiO_2, and so on. Among these parameters, the electronic coupling parameter is the most critical one on the interfacial ET rate from the excited state of dye molecules to the CB of TiO_2. The inhomogeneous surface state distribution and specific surface states that in contact with the single-molecule dye molecules play a critical role in the electronic coupling parameter. Specifically, the formation, stability, and rupture of surface bonding to TiO_2 may change and perturb electronic coupling significantly, and the electronic coupling can be energetically perturbed by local environment thermal fluctuation at room temperature. A powerful approach to analyze these energetic parameters is the electron transfer resonant Raman spectroscopy and microscopy [5, 25, 26, 47, 51, 52, 77]. We have applied an AFM-tip-enhanced Raman spectroscopic approach to analyze the surface vibrational modes and the vibrational relaxation energies of the relevant molecular vibrational modes and the TiO_2 surface vibrational modes. In this section, we will discuss our work on revealing that for alizarin–TiO_2 interfaces, the vibrational reorganization energy barriers of interfacial ET are inhomogeneous from TiO_2 NP to NP and from molecular site to site [25, 26].

Applying a microscopic AFM–Raman characterization and Heller theory (time-dependent wave packet scattering theory) analysis, we revealed that for alizarin–TiO_2 interfaces, the vibrational reorganization energy barriers of interfacial ET are inhomogeneous at a submesoscale (~250 nm). We found that (i) the total vibrational reorganization energy was inhomogeneous from site to site; (ii) the alizarin–TiO_2 bridging normal modes were the primary contributor to the total vibrational reorganization energy and its inhomogeneity; (iii) the mode-specific analyses indicated that the energy distributions were inhomogeneous for bridging normal modes and homogeneous for nonbridging normal modes, especially for modes far away from the alizarin–TiO_2 coupling hydroxyl modes; and (iv) the vibrational reorganization energy inhomogeneity was closely associated with the local environmental heterogeneity of the alizarin–TiO_2 interface (Figure 22.16). It is most likely that the vibrational reorganization energy inhomogeneities contributed to the inhomogeneous dynamics of the interfacial ET processes. Our results demonstrated that correlated AFM–confocal Raman microscopy is a promising approach for a quantitative understanding of inhomogeneous interfacial charge transfers.

Our spectral analysis was based on the Heller theory, that is, the resonance Raman and absorption cross sections were calculated using the following time-dependent wave packet propagation formalism: [5, 25, 26, 58, 78, 79]

$$\sigma_{Ri\to f}(\omega_L) = \frac{8\pi(\mathrm{eM})^4\,\omega_L\omega_S^3}{9\hbar^2c^4}\sum_i P_i\left|\int_0^\infty dt\langle f\right| i(t)\rangle\exp\left[i(\omega_\mathrm{L}+\omega_i-\omega_0)t-\gamma t/2\right]^2 \tag{22.1}$$

$$\sigma_A(\omega) = \frac{4\pi(\mathrm{eM})^2\omega}{3\hbar^2c}\sum_i P_i\ \mathrm{Re}\int_0^\infty dt\langle i|i(t)\rangle\exp[i(\omega+\omega_i-\omega_0)t-\gamma t/2] \tag{22.2}$$

where ω_L and ω_S are the incident (laser) and scattered photon frequencies, respectively; (eM) is the electronic transition dipole moment; $|i\rangle$ and $|f\rangle$ are the initial and final vibrational states on the ground-state potential energy surface, respectively; P_i is the Boltzmann population of initial vibrational state; ω_i is the vibrational frequency at the vibrational level of $|i\rangle$ or $|f\rangle$; ω_0 is the electronic zero–zero energy; γ is the inverse lifetime of the excited state; and $|i(t)\rangle$ is the vibrational wave packet function propagating in time t on the excited-state potential surface. In our treatment, the $\langle i|i(t)\rangle$ and $\langle f|i(t)\rangle$ overlaps are dependent on the displacement, Δ, in dimensionless normal coordinates between ground- and excited-state equilibrium geometries along each normal coordinate. The initial guesses for Δ were given from the relative resonance Raman intensities, assuming that the intensity ratios

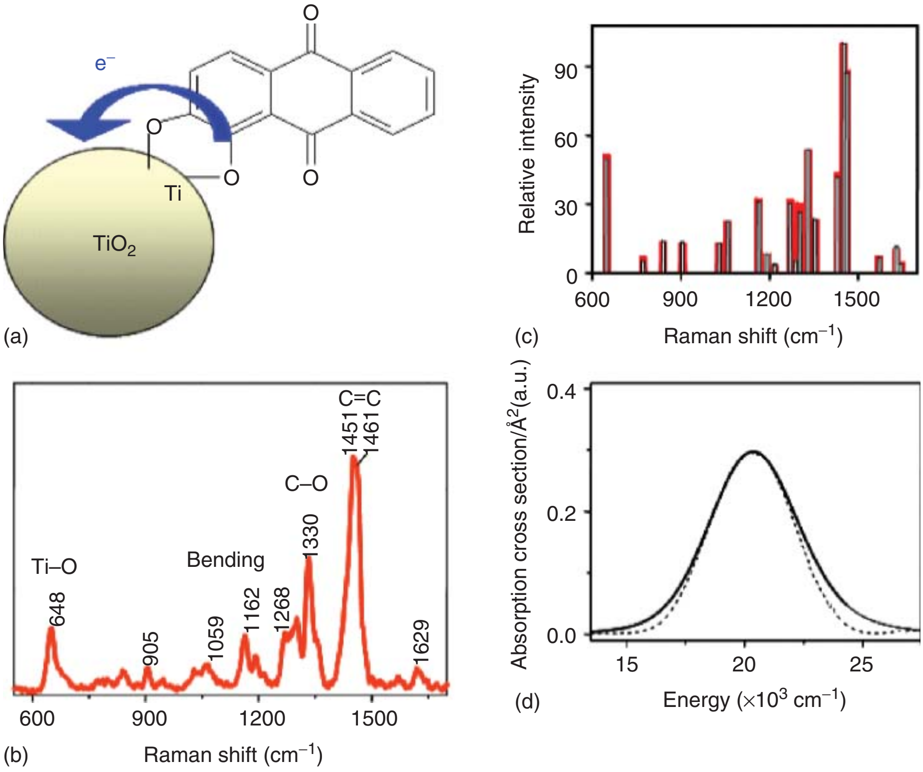

Figure 22.16 (a) Sketch of alizarin–TiO_2 nanoparticle surface adsorption of alizarin via the hydroxyl group bonding to the TiO_2 nanoparticles. (b) Resonance microscopic Raman spectrum of alizarin–TiO_2 nanoparticles. (c) Time-dependent wave packet analysis of Raman spectra. Comparison of experimental (white) and calculated (red) resonance Raman intensities of all observed modes for a specific microscopic site. (d) Time-dependent wave packet analysis of absorption spectra. The absorption cross section of experimental (solid) and calculated (dotted) charge-transfer-associated excitation band of the alizarin–TiO_2 complex in solution.

were proportional to $\Delta^2\nu^2$ ratios, where ν is the vibrational frequency. The homogeneous broadening (Γ) was calculated from the homogeneous line width function. The inhomogeneous broadening (Φ), a standard deviation of the normalized inhomogeneous Gaussian distribution function, was determined by the absorption band shape and resonance Raman intensity. The energy gap between potential surfaces, ω_0, was initially determined by the wavelength of the absorption spectrum maximum arising from the ET reaction. The parameters were optimized iteratively until the calculated and experimental absorption spectrum and resonance Raman intensities were in agreement. Finally, the mode-specific reorganization energy (λ_ν), assuming the vibrations to be harmonic, was calculated by

$$\lambda_\nu = \frac{1}{2}\nu\Delta^2 \tag{22.3}$$

The resonance Raman spectra in the alizarin–TiO_2 complex (Figure 22.16) exhibited 20 vibrational bands, consistent with the ensemble-averaged Raman measurement [25, 26]. The most prominent bands, at 1450 and 1461 cm^{-1}, were assigned to the ring C=C stretches. The C–O stretch combined with the ring C=C stretch mode corresponds to the intense bands at 1330 cm^{-1} and in the region of 1268–1300 cm^{-1} (Figure 22.16b). The 648 cm^{-1} band was attributable to a Ti–O stretching mode from a bridging Ti–O–C bond. On comparing with free molecules, the increased Raman intensity in the C–O stretching at 1330 cm^{-1} revealed that the hydroxyl groups provided the primary bridging bonds to the interfacial charge transfer.

To specify and characterize such an inhomogeneity, we used the time-dependent wave packet calculations to analyze correlatively the Raman and absorption spectra, obtaining the vibrational reorganization energy of individual normal modes of the alizarin–TiO_2 complex under interfacial charge-transfer reaction at each microscopic site. We analyzed the resonance Raman cross sections, the charge-transfer absorption spectrum (to determine the spectral broadening and Raman damping parameters), and the electronic transition energy. The analysis provided detailed information about changes in nuclear equilibrium geometry for both the electron donor–acceptor and the surrounding local environment in the interfacial charge-transfer processes. Figure 22.16c,d shows a typical fitting of the experimental Raman intensities for the observed Raman peaks from a specific spot. Figure 22.16d presents the corresponding experimental and fitting absorption spectral band at 496 nm, a strong charge-transfer interaction band [25, 26]. The model generates a good fit to both the relative intensities of the Raman peaks and the charge-transfer absorption spectrum with the parameters of electronic zero–zero energy ($\omega_0 = 20010\ cm^{-1}$), homogeneous broadening ($\Gamma = 550\ cm^{-1}$), inhomogeneous broadening ($\Phi = 1600\ cm^{-1}$), and frequencies and intensities of the 20 resonant Raman modes (Figure 22.16c). From the time-dependent wave packet analysis of the Raman and absorption spectra, we obtained unitless normal-coordinate displacements, Δ, for each electron-transfer-associated resonant Raman mode. The vibrational reorganization energies along each of the observed Raman modes were calculated from the unitless normal-coordinate displacement by Eq. (22.3). Our spectral analysis yielded a total vibrational reorganization energy of 0.045 eV for this specific spot, which is consistent with the result obtained from the ensemble-averaged Raman excitation profile [25, 26].

The most significant finding from our experiments is that the vibrational reorganization energy is inhomogeneous, that is, different from microscopic site to site of this alizarin–TiO_2 interfacial ET system. Correlating the topographic AFM imaging, we measured the resonance Raman spectra at different microscopic spots and found that relative Raman intensities of the Ti–O, C–O, and ring stretching modes were significantly different from site to site. These relative Raman intensity changes presumably resulted from properties intrinsic to interfacial charge transfer. The reorganization energy for the C–O bridge mode changes was measured from 63 to 97 cm^{-1}, the Ti–O bridge mode gave measurable vibration reorganization energy from 12 to 28 cm^{-1}, and the ring C=C stretching mode yielded a range from 30 to 65 cm^{-1}. Consequently, the total vibrational reorganization energy, λ_{total}, was obtained from values between 242 and 380 cm^{-1}. The λ_{total} was predominately contributed from the bridging modes at the alizarin–TiO_2 interface. We observed that not all of the vibrational modes associated with ET had inhomogeneous energies. The vibrational reorganization energy distributions of the specific normal modes in the alizarin–TiO_2 complex were homogeneous for those modes located away from direct bonding with the TiO_2. For example, the vibrational reorganization energy distributions of two C–H in-plane bending modes, revealing the distributions to be within the measurement error bars and significantly narrower than distributions of bridging modes.

It is desirable to obtain a correlated topographic and spectroscopic characterization with high chemical sensitivity, high spatial resolution, and spectroscopic selectivity for ET systems. The correlated metallic tip-enhanced near-field Raman spectroscopy and AFM technique was applied to measuring the tip-enhanced Raman spectrum for characterizing the vibrational relaxation energy barrier of dye-sensitized TiO_2 NPs. We have obtained the near-field Raman spectra that are associated with the photoinduced charge-transfer reaction in Ru(4,4′-dicarboxy-2,2′-bipyridine)$_2$(NCS)$_2$-sensitized TiO_2 single NPs. This method demonstrates that tip-enhanced near-field Raman spectroscopy is an effective approach for understanding inhomogeneous interfacial ETs with nanoscale spatial resolution. Near-field scanning optical scanning microscopy makes use of the strongly enhanced electric field around a sharp metal tip under laser illumination [26, 28, 48, 49, 53–55]. The spatial resolution achievable with this technique is determined primarily by the metallic tip size and shape, and the signal-to-noise is defined by the strength of the field-enhancement effect.

Correlated AFM images were obtained for the microscopic Raman spectral collection at optical diffraction-limited imaging sites. In contrast, as a result of the high fluorescence background and off-resonant excitation, no Raman bands were detected from an alizarin-alone sample under the same experimental conditions (Figure 22.16) because there were no contributions from the electron-transfer resonance Raman enhancement.

Figure 22.6 shows the correlated near-field Raman spectrum and the topographic AFM image of a larger area around the Raman measurement site at a single TiO_2 NP. In this measurement, a far-field Raman spectrum without a metallic tip for a specific microscopic site was first collected (Figure 22.6a), and then under the same microscopic site, the tip-enhanced Raman spectrum was detected when a silver-coated AFM tip was engaged over an N_3-sensitized TiO_2 NP (Figure 22.6b). The Raman signal with the near-field contribution caused by the tip was a factor of 2.1 higher than the signal measured without the tip. The near-field Raman spectrum (Figure 22.6c) was obtained after subtracting the far-field component from the tip-enhanced Raman spectrum. Figure 22.6d shows the topography of the dye-sensitized TiO_2 NPs on a nanoscale site (<50 nm) where the near-field Raman spectrum (Figure 22.6c) was collected. In the near-field Raman spectrum, the most prominent bands, at 1475, 1549, and 1608 cm^{-1}, were assigned to the bipyridine ring stretching mode. The intense band at 1028 cm^{-1} was assigned to the ring breathing mode. The C–C interring stretch combined with the C–O stretching mode corresponds to the band at 1273 cm^{-1}. The 706 cm^{-1} band is attributed to an in-plan ring deformation mode.

In this work, we achieved a Raman measurement from a single N_3 dye-loaded TiO_2 NP. Near-field Raman scattering enhancement is confined within the vicinity of the metallic tip axis, which provides a higher spatial resolution beyond the optical diffraction limit. Tip-enhanced Raman spectroscopy combined with simultaneous AFM measurement extends our ability to characterize the spatial inhomogeneity of interfacial ET dynamics at a spatial scale comparable to the AFM imaging scale.

We have moved forward to achieve higher spatial resolution and spectral sensitivity in order to obtain nanoscale site-specific characterization of the inhomogeneous vibrational reorganization energy barriers. The most needed technical and scientific advances include the following: (i) AFM-tip-enhanced near-field Raman spectroscopic measurements for dye-sensitized semiconductor NPs; (ii) higher measurement sensitivity to measure a small number of molecules or even single molecules at nanoscale sites; and (iii) a molecule-level understanding of the relationship between topographical nanoscale structures and surface chemical bonding structures.

22.5
Single-Molecule Triplet-State Photon Antibunching Analysis of Back Charge-Transfer Dynamics

Using photon antibunching measurements under CW laser excitation, nonclassical photon statistics, and excitation power-dependent measurements, we were able to selectively measure the single-molecule metal-to-ligand charge-transfer (MLCT) state lifetime that is a direct measurement of MLCT back charge-transfer time. This work demonstrated the single-molecule photon antibunching of triplet excited state and presented a step forward in studying single-molecule ET in proteins using MLCT complex as an ET donor or acceptor. Photon antibunching, a type of nonclassical photon statistical behavior, is the signature of phosphorescence from a single quantum system and can reveal information about transition rates between the photophysical states [80, 81]. Photon antibunching has been demonstrated for organic dye molecules [81, 82], polymer molecules [83], and quantum dots [84, 85].

Transition-metal complexes such as ruthenium complexes, having MLCT states, are being extensively investigated for their involvement in solar energy conversion [76], interfacial ET [86], and ET in biological systems [87–90]. The dynamics of this process can be highly complex and inhomogeneous, especially when molecules are involved in interactions and perturbations with heterogeneous local environments such as at interfaces or in covalent interactions with electron-transfer proteins. In this section, we discuss the use of photon antibunching to measure triplet-state lifetimes at room temperature at a microsecond timescale. We apply this approach to the studies of the MLCT state dynamics of a ruthenium complex, with the potential application of studying ET processes in biological systems at the single-molecule level.

In our experiments, $Ru(dpp)_3$ (Aldrich) was diluted to 3×10^{-10} M in methanol and was spin coated on polymethylmethacrylate-coated glass coverslips. The single-molecule sample was under constant nitrogen gas purge during the experiments, and all experiments were conducted at room temperature. A CW HeCd laser with 442 nm wavelength was used for photoexcitation. The intensity was modulated by a Pockel cell (Lasermetrics 3079) with a specific frequency and wave form controlled by a function generator. The laser was coupled through single-mode optical fiber and brought to the epiport of an inverted microscope (Zeiss Axiovert 200). The laser was reflected by a dichroic beamsplitter (Chroma 460DCLP) and focused by an objective (Fluar, 100×, NA1.3). The phosphorescence from a single-molecule $Ru(dpp)_3$ was collected by the same objective and passed through an emission filter (Chroma E470LP). The emission photons were detected by an APD (Perkin-Elmer SPCM-AQR-15). The detected photon time was recorded by a home-built time-stamping device based on the National Instrument data acquisition card (multiple-channel digital I/O Board (PCI-DIO)-32HS). The arrival time of every photon was digitized with the increment of 0.1 μs.

Single $Ru(dpp)_3$ molecules typically produce a kilohertz-level detected photon flux and several hundreds of thousand photons total before an irreversible photobleaching. The excitation laser intensity was modulated by a square wave function. Within every 0.1 s, there is a 0.03 s period of high power and a 0.07 s period of low power. The power ratio is 3.0 (high and low at 1.2 and 0.4 μW, respectively). The detected photons were separated into two groups according to the power level at their arrival time. Both the histogram of the interphoton time and the autocorrelation of the photon arrival time trajectory reveal the antibunching phenomena by showing the decreased probability of two photons arriving within the MLCT state lifetime. The autocorrelation was calculated for each group of photons under both high and low excitation powers (Figure 22.17b,c). Both autocorrelation curves show a dip near time zero, suggesting that there is less probability of two photons arriving at the same time or within the excited-state lifetime. This is a signature of photon antibunching, a characteristic property of emission photons from a single molecule.

The photophysical process of $Ru(dpp)_3$ can be considered as the hopping of a two-level system because the ISC in an excited state is much faster than the excitation and excited-state relaxation due to heavy metal effect on spin–orbit coupling in our experiments. The analytical relations between the transition rates of the photophysical states and the autocorrelation for a two-level system are presented in Eqs. (22.4) and (22.5). The autocorrelation $g(t)$ is an exponential rising curve [27]

$$g(t) = A[1 - \exp(-kt)] \tag{22.4}$$

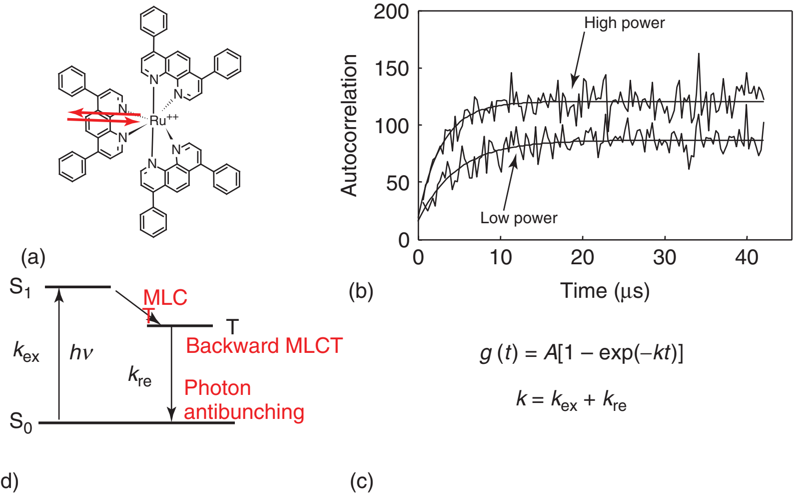

Figure 22.17 (a) The molecular structure of Ru(dpp)$_3$, tris(4,7-diphenyl-1,10-phenanthrolin)ruthenium(II) dichloride; forward and backward MLCT are depicted by the arrows. (b,c) The autocorrelation of the photon trajectory. The upper one is the molecule under high excitation power, and the lower is the same molecule under low excitation power. They are both fitted by single exponential curves. (d) The three-state energy diagram of the MLCT dynamics.

where the exponential decay rate constant k is the sum of the excitation rate k_{ex} and excited-state relaxation rate k_{re}

$$k = k_{\text{ex}} + k_{\text{re}} \tag{22.5}$$

To determine the individual rate of k_{ex} and k_{re}, we analyzed the results of excitation power modulation experiment, assuming that k_{re} is not affected by the excitation power and k_{ex} is proportional to the excitation power. The autocorrelation rates at high and low excitation power were measured, with k_{ex} and k_{re} then calculated [27]. Both autocorrelation curves of Ru(dpp)$_3$ in Figure 22.17b were fitted by a single exponential. The rate constants are $k_{\text{(high)}} = 3.0 \times 10^5\ \text{s}^{-1}$ and $k_{\text{(low)}} = 1.7 \times 10^5\ \text{s}^{-1}$ for high- and low-power excitations, respectively. By assuming an excitation rate ratio of 3.0, we obtained the excitation rate and excited-state relaxation rate by solving linear equations (Eq. (22.5)) at high- and low-power excitations. The results were $k_{\text{re}} = 1.1 \times 10^5\ \text{s}^{-1}$, $k_{\text{ex(low)}} = 6.2 \times 10^4\ \text{s}^{-1}$, and $k_{\text{ex(high)}} = 1.9 \times 10^4\ \text{s}^{-1}$. Thus, we derived the MLCT excited-state lifetime from photon statistics under CW laser excitation.

For further confirmation and characterization of the antibunching photons [27], we have calculated the photon statistics using Mandel's parameter [91] to verify the sub-Poisson or super-Poisson statistics of the detected photons at different timescales. The time-dependent Mandel parameter $Q(T)$ is defined as

$$Q(T) = \frac{\langle I^2 \rangle - \langle I \rangle^2}{\langle I \rangle} - 1$$

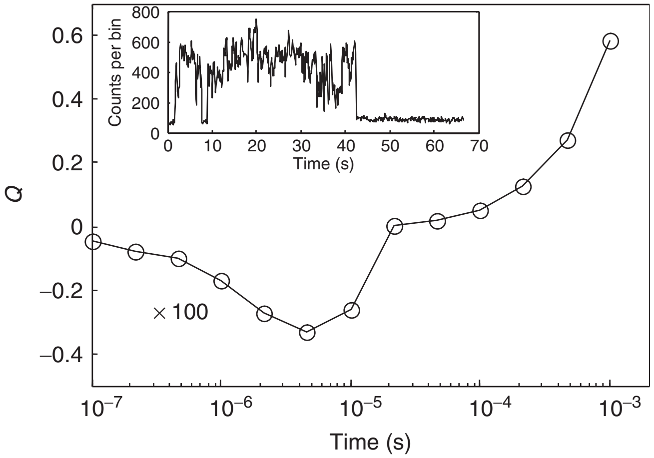

Figure 22.18 The Mandel parameter of a single molecule. The negative values are magnified by a factor of 100 to enhance the view. This single-molecule's phosphorescence intensity trajectory in the 0.1 s bin is shown in the inset.

where I is the intensity counts at the bin time T. A negative Q indicates sub-Poisson statistics (antibunching), while a positive Q indicates super-Poisson statistics (bunching). We have analyzed the Mandel parameter of a single $Ru(dpp)_3$ molecule's phosphorescence. The Mandel parameter result of a typical molecule is illustrated in Figure 22.18. The excitation power is at constant level without modulation. In the timescale of $<10\,\mu s$, the Mandel parameter is negative, which indicates photon antibunching dynamics. In contrast, at the longer timescale of milliseconds, the Mandel parameter is positive, indicating photon bunching due to the "blinking" of the single-molecule emission intensity.

Transition-metal complexes have been widely used as an electron donor or acceptor in studying conformational gated ET in redox electron-transfer proteins. Single-molecule photon antibunching studies will be particularly effective in resolving the ET dynamics in such complex systems. In this single-molecule photon antibunching study of MLCT state excitation and relaxation dynamics of $Ru(dpp)_3$ at room temperature, we provide a new method of probing single-molecule triplet-state dynamics. Using an excitation modulation measurement, we were able to obtain both single-molecule excitation and emission rate constants associated with MLCT dynamics.

22.6
Concluding Remarks and Perspective

Single-molecule spectroscopy has already changed the landscape of studying interfacial ET dynamics that often involve complex mechanism and spatial heterogeneity. The nonexponential ET rate processes can now be interrogated one molecule at one specific nanoscale site at a time. In an earlier study [21], the single-molecule ET dynamics shows single exponential for each individual molecules, but at different rate constants from molecule to molecule in a system of CV–indium tin oxide (ITO) interfacial ET; in recent years, a number of dye–TiO_2 interfacial ET systems have shown rate fluctuation in interfacial ET dynamics [24, 39, 45]. The intermittency of the single-molecule interfacial ET dynamics associated with single-molecule fluorescence blinking is one of the most significant discoveries made by single-molecule spectroscopy. In an ensemble-averaged measurement, these types of intermittency are not observable and are often averaged out as typical nonexponential or dispersive dynamics because the interfacial ET time constants involve fluctuations ranged from femtoseconds to microseconds. Since the intermittent single-molecule interfacial ET dynamics first reported in 2004 [24], similar intermittent interfacial ET dynamics has been observed for a few other interfacial systems and reported in 2008 [43–45]. Since 2004, significant efforts have been made to reveal the physical origins for the interfacial ET rate fluctuations, and AFM-correlated Raman spectroscopic analysis has revealed the inhomogeneous surface bonds, bonding energy, and vibrational relaxation energies at a single-TiO_2 NP level [25, 26], which suggests that thermal-induced conformational motions of adsorbed molecules may contribute to fluctuations of electronic and vibrational couplings between the dye molecules and the TiO_2 NPs, and these energetic fluctuations result the interfacial ET rate fluctuations. This new discovery suggests that the non-exponential and complex dynamics observed in ensemble-averaged experiments are most likely intrinsic for the interfacial ET dynamics, and the interfacial ET time constants contain in typical ensemble-averaged results may be widely ranged from femtoseconds to nanoseconds. The single-molecule analyses on both dynamics and energetics will be critical. The dynamics analysis will include application of femtosecond single-molecule spectroscopy, and the energetics analysis will involve analyzing of the fluctuations and inhomogeneity of the driving force, electronic and vibrational coupling, solvent and vibrational relaxation energy, and local electronic work function. It is anticipated that the single-molecule spectroscopy will provide more profound and fundamental understanding of the interfacial ET dynamics related to catalysis, surface redox reaction dynamics, environmental sciences, and solar energy sciences.

Acknowledgments

The author gratefully acknowledges Yuanmin Wang, Vasudevanpillai Biju, Donhai Pan, Dehong Hu, Micky Micic, Xiefei Wang, and Sujit Ghosh for their crucial contributions to the work discussed here. The work was supported by the Office of Basic Energy Sciences within the Office of Science of the US Department of Energy (DOE). A number of experiments were conducted in the Environmental Molecular Sciences Laboratory (EMSL) at Pacific Northwest National Laboratory (PNNL). The EMSL is a national scientific user facility and supported by the US DOE's Office of Biological and Environmental Research. PNNL is a multiprogram national laboratory operated for the US Department of Energy by Battelle Memorial Institute under contract number DE-AC06-76RLO 1830. After 2006, the work was conducted at the Center for Photochemical Sciences, Department of Chemistry of the Bowling Green State University in Bowling Green, OH. Part of the text appeared in our previous publications referenced.

Scanning Near-Field Gap-Mode Microscopy

Dai Zhang and Alfred J. Meixner

23.1

Introduction

The central part of scanning near-mode microscopy (SNGM) is a nanometer gap between the apex of a sharp metallic tip and the sample surface that is optically excited. A metallic tip focuses the electric field of the incident radiation into the sub-diffraction volume of the gap via the coherent light-induced oscillation of the conducting electrons in the metal tip. Dieter Pohl, a pioneer in near-field optical microscopy, pointed out the analogy of this configuration to the radio antenna. Such a configuration serves to collect energy from an electromagnetic wave and to deliver it to an oscillator circuit that has dimensions much smaller than the wavelength; or vice versa to emit an electromagnetic wave that has an additional signal imprinted onto it, that is, the information to be broadcasted. This gap-mode configuration is strikingly similar to the first antennas constructed by Heinrich Hertz, which he used to experimentally verify the generation of electromagnetic radiation. This comment is by no means to diminish the achievements in the developments of SNGM. We will see in the pace of this chapter that the electric field and emission enhancement in near-field optics has many similarities to radio antennas, however there is much more to it than simply downscaling the wavelength from centimeters to nanometers. The reader who is interested in a more in-depth treatment on nanoantennas is referred to an excellent recent review article and the references therein [1].

In the following sections, we will mainly focus on the aspects of electromagnetic enhancement important to high-resolution SNGM. In the visible frequency range, the phenomenon of electromagnetic enhancement has been introduced since 40 years ago to explain the tremendously enhanced Raman signals observed from organic molecules deposited on roughened noble metal surfaces or particles [2–4]. Today, surface-enhanced Raman spectroscopy, or surface-enhanced Raman scattering (SERS), has developed to a well-established surface-sensitive spectroscopic technique [5]. The enhancement factor can reach several orders of magnitude, which allows the technique to be sensitive enough to detect single molecules [6, 7].

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

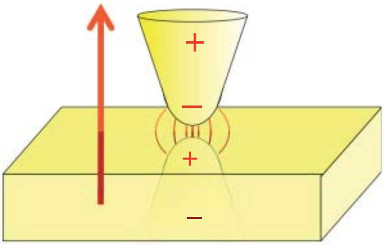

Figure 23.1 The gap width is on the order of some nanometers, that is, much smaller than the optical wavelength. The tip is polarized by the electric field of the incident beam, which is indicated by the red arrow. Electromagnetic radiation leading to a surface charge at the tip apex and its mirror on the sample surface. The surface charges establish a strongly enhanced electric field (indicated by the curved red lines) in the gap.

In Figure 23.1, we sketch the fundamental configuration of the optical antenna used in SNGM, consisting typically of a sharp gold or silver tip approaching the sample surface as close as a few nanometers and illuminated by incident laser radiation. Toward the end of the conical tip, its lateral diameter becomes smaller than the penetration depth of the incident optical field into the metal, and the electric field component of incident radiation induces a coherent oscillation of the conduction electrons – a so-called plasmon oscillation. The energy quanta of the charge oscillation are called *plasmon* in analogy to the photon as energy quanta of an oscillating electromagnetic field or wave. As the plasmon oscillation is always coupled with an optical field oscillation, it is termed as *plasmon polariton*. If the incident electric field is oriented along the tip axis, the freely moving charge in the metal is periodically driven up and down along the tip shaft bouncing periodically against the tip apex. It leads there to an oscillating surface charge with a maximum at the tip apex and, as a consequence, to a greatly enhanced local field. The response of the sample to the tip-enhanced field can be easily explained with the concept of mirror charges and leads to a local polarization that acts back on the tip. Hence, the tip and the sample form a system of coupled oscillators influencing each other via the electric field in the gap as sketched in Figure 23.2, and the magnetic field outside. The oscillating surface charges of the tip-sample system again emit radiation, with most of it at the incident laser frequency, that is, elastic or Rayleigh scattering. A small fraction resulting from inelastic processes [e.g., Raman scattering, photoluminescence (PL), or fluorescence] that is frequency-shifted. The emission pattern has radial symmetry about the antenna axis and the emitted power must constantly be refed to the antenna by the incident radiation; else the charge oscillation of the antenna would quickly fade away. From the optical reciprocity theorem, it remains clear that the antenna is most efficiently excited by an incident wave that is the time reversal of the emitted wave. Such excitation conditions can conveniently be realized by focusing a radially polarized laser beam by an objective lens with high numerical aperture (NA) or by a high NA parabolic mirror, an important issue to which we come back in Section 23.2.

In a simple way, we can view the electromagnetic field emitted by this system as the superposition of the fields created by two aligned and coupled dipoles that are separated by a short distance, one being from the oscillating charges at the end of the tip and the other being from the induced mirror dipole at the sample beneath the tip. The strength and the phase of these dipoles depend on the illumination conditions, polarizability of the tip, and local polarizability or the responsiveness of the sample to the locally enhanced field at the tip apex. Hence, it is easy to understand that the local variations of the dielectric properties of the sample can be probed by recording the optical signal point by point with a resolution and signal intensity limited by the tip radius, the tip-sample distance, and the polarizability of tip and the sample.

Furthermore, if we consider now a molecule in the gap, it can contribute to the optical signal via different processes, such as (i) tip-enhanced Rayleigh- and Raman scattering, (ii) tip-enhanced fluorescence or luminescence excitation under resonant condition, or (iii) tip-induced molecular fluorescence quenching by transferring energy to the tip as a result of absorptive losses of the metal. All three processes have been observed and the balance of the branching ratio between the signal enhancement and quenching depends on the spectral overlap between the molecule's emission and the tip absorption, the orientation of its emission dipole moment with respect to the local field in the gap and the distance with respect to the tip, the quantum yield of the molecule, and so on.

In summary, the laser-irradiated tip close to the sample surface leads to locally enhanced scattering and excitation as a result of the enhanced field in the gap. In addition, it leads to enhanced emission as a result of the enhanced optical mode density close to the gap offering a molecule more degrees of freedom to emit photons via the near-field to the far-field as compared to the situation without a tip. Finally, absorptive losses from an excited molecule to the tip could lead to luminescence quenching at very short distances between the molecule and the tip.

23.1.1
Enhancement Factor

An important measure for the local signal enhancement in the gap is the phenomenological enhancement factor. As there is no standard way for its definition in the literature that allows comparing data measured under different experimental conditions, we dedicate the following section to the definition of such a term that will allow us to compare different measurements.

First of all, we note that all photons are recorded in the far-field, that is, a macroscopic distance away from the gap. Second, a confocal optical configuration is used both for illuminating the tip-sample gap and for collecting the scattered photons from there. Hence, we can distinguish between the signals recorded from the far-field detection volume when the tip is at close distance to the sample such that a nanometer gap is formed and near-field phenomena play a role, from the optical signal when the tip-sample separation is so large that near-field effects can be neglected. Such measurements can easily be performed by recording spectra

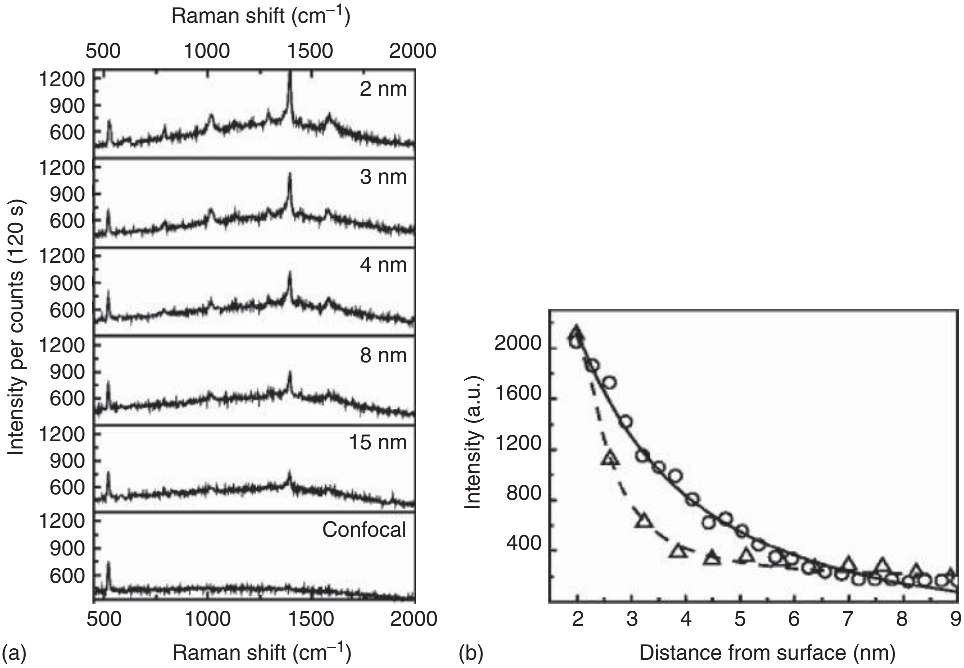

Figure 23.2 (a,b) Tip-enhanced Raman spectra of BTA on a smooth gold layer for decreasing tip–surface distances. Every spectrum was taken with an integration time of 120 s. The line at 520 cm^{-1} originates from the Si substrate under the gold layer and serves as an internal standard. (Copyright (2008) by Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim. Reprinted from [8].)

for decreasing gap widths. An example is demonstrated in Figure 23.2, where a series of tip-enhanced spectra is shown that were taken from a monolayer of benzotriazole (BTA) molecules adsorbed on a smooth gold film when a sharp gold tip approaches to the sample surface [8]. The spectra show the appearance of a smooth luminescence background that originates both from the sample surface and from the gold tip, and in addition, the appearance of distinct Raman lines of BTA with decreasing tip-sample distances. The Raman line at 520 cm^{-1} is present in all spectra independent of tip–sample distance. It originates from the Si substrate below the Au film and is too far away from the tip to experience the near-field enhancement. This signal can, hence, conveniently serve as a reference to prove that the z-position (parallel to the optical axis of the microscope) of the sample in the focus stayed constant while the sequence of spectra was recorded.

Obviously, the increase in signal arises from the increasing optical near-field in the gap between the tip apex and the sample as they approach each other. Hence, the optical signal recorded at the detector is the sum of photons emitted from the confocal detection volume consisting of those arises from the near-field effect at close tip–sample distance, and the rest from the far-field focus illuminated area that can be considered as the confocal far-field background.

At a close tip–sample distance, the enhanced signal, $\int S_{\mathrm{enh}}(\omega)\mathrm{d}\omega$, can formally be divided into three fractions: the signal that originates only from the gap, $\int S_{\mathrm{gap}}(\omega)\mathrm{d}\omega$, and a confocal far-field background signal that originates from the sample, $\int S_{\mathrm{sample}}(\omega)\mathrm{d}\omega$, and the tip, $\int S_{\mathrm{tip}}(\omega)\mathrm{d}\omega$

$$\int S_{\mathrm{gap}}(\omega)\mathrm{d}\omega = \int S_{\mathrm{enh}}(\omega)\mathrm{d}\omega - \int S_{\mathrm{sample}}(\omega)\mathrm{d}\omega - \int S_{\mathrm{tip}}(\omega)\mathrm{d}\omega \tag{23.1}$$

The fraction of the background that originates from far-field illumination of the sample can be determined straightforwardly by retracting the tip and performing independent confocal measurements of the sample. Similarly, the contribution of the tip-emitted photons to the background signal can be evaluated by recording a confocal spectrum from the tip alone.

Since the near-field-enhanced signal originates from the sample surface and the tip apex within the tip–sample gap, it hence makes sense to define a near-field spot area A_{gap}, for example, given by the waist diameter of the enhanced field in the gap. The phenomenological spectral integrated enhancement factor (G) can thus be defined as the ratio between the spectral-integrated enhanced signal from the gap divided by A_{gap} and the confocal background divided by the diffraction-limited confocal far-field-illuminated area A_{conf}:

$$G = \frac{\dfrac{\int S_{\mathrm{gap}}(\omega)\mathrm{d}\omega}{A_{\mathrm{gap}}}}{\dfrac{\int S_{\mathrm{sample}}(\omega)\mathrm{d}(\omega) + \int S_{\mathrm{tip}}(\omega)\mathrm{d}\omega}{A_{\mathrm{conf}}}} \tag{23.2}$$

We would like to note that the enhancement factor accounts for the total spectral-integrated enhanced signal that is the sum of the enhanced luminescence background arising both from the sample surface and from the metallic tip as well as the tip-enhanced Raman signal from the adsorbed molecules at the metallic surface.

23.1.1.1 Physical Interpretation of the Enhancement Factor

23.1.1.1.1 Tip-Enhanced Photoluminescence (TEPL) Tip-enhanced photoluminescence (TEPL) results from the radiative decay of molecules or excitons electronically excited in the optical near-field between the tip apex and the sample. To explain the origin of the PL enhancement, we must take into account the enhancement of the excitation rate as well as the PL quantum yield. While the excitation rate is determined by the local optical field and, thus, follows directly the enhancement of the energy density in the optical near-field, the emission rate depends on the balance between the radiative decay rate Γ_{r} and the nonradiative decay rate Γ_{nr} leading to

$$I_{\mathrm{PL}} \propto \Gamma_{\mathrm{exc}} \times \left[1 - \frac{\Gamma_{\mathrm{nr}}}{\Gamma_{\mathrm{r}} + \Gamma_{\mathrm{nr}}}\right] \tag{23.3}$$

where the term in brackets represents the quantum yield in terms of the radiative and nonradiative rates. The excitation rate of a molecule or the rate for generating an exciton is proportional to the square of the transition dipole moment $\vec{D}$ between the electronic ground state and the excited state as well as the spectral energy density $\rho(\omega_{\mathrm{exc}}) = \frac{1}{2}\varepsilon_0 \vec{E}_0^2$ of the incident radiation at the location of the dipole as

$$\Gamma_{\mathrm{exc}} = \frac{\pi}{\varepsilon_0 h^2} |\vec{D}\vec{n}|^2 \rho(\omega_{\mathrm{exc}}) \tag{23.4}$$

where $\vec{n}$ is a unit vector along the direction of the electric field component with the amplitude $\vec{E}_0$. If we assume that the transition dipole is not affected by the presence of the tip, the excitation enhancement of the excitation process G_{exc} is given by

$$G_{\mathrm{exc}} = \frac{\rho(\omega)_{\mathrm{gap}}}{\rho(\omega)_{\mathrm{conf}}} \tag{23.5}$$

where $\rho(\omega)_{\mathrm{gap}}$ is the spectral energy density at the position of the transition dipole moment in the gap and $\rho(\omega)_{\mathrm{conf}}$ is the spectral energy density in the focus at the same position when the tip is infinitely far way. Hence, it is easy to understand that the enhanced optical near-field in the gap leads to an enhanced excitation rate. With respect to the confocal far-field situation, the enhancement of the optical near-field in the gap depends on the details of the tip and the sample, such as the materials they consist of and their geometries. Field enhancement factors of more than two orders of magnitude have been reproducibly achieved, giving excitation enhancement factors of up to five orders of magnitude.

The reasons for the enhancement of the emission process are less obvious to spectroscopists used to work with classical systems. According to Fermi's golden rule, the spontaneous radiative decay rate per frequency interval is

$$\frac{\partial \Gamma_{\mathrm{r}}(\omega_{\mathrm{em}})}{\partial \omega} = \frac{2\omega_{\mathrm{em}}}{3\hbar\varepsilon} |\vec{D}_{\mathrm{em}} \times \vec{n}|^2 \rho(\omega_{\mathrm{em}}) \tag{23.6}$$

where $\vec{D}_{\mathrm{em}}$ is the transition dipole for emission, the same definition as that of formular (23.4)? which is excited by the emission dipole, and $\rho(\omega_{\mathrm{em}})$ is the photonic mode density surrounding the emission dipole. In classical spectroscopy, usually samples with an ensemble of molecules homogeneously dispersed at high dilution in a transparent, dielectric solvent, or matrix are investigated, with an observation volume much larger than the optical wavelength. Under these conditions, the optical mode density is given by $\rho(\omega) = \frac{n^3\omega^2}{\pi^2 c^3}$ with n as the refractive index of the medium and has no spatial variation [9].

The situation is different for molecules in a resonator or for those very close to metallic nanoparticles. There $\rho(\omega)$ can vary dramatically within half a wavelength.

In order to determine the emission enhancement for a molecule in a gap, we have to compare the signal of an emitting dipole placed on or close to a surface adjacent to open space with the same situation, however with an additional tip pointing from the free space toward the surface such that the emitting dipole is enclosed in the small cavity between the surface and the tip apex. Both situations are rather complex when compared to a dipole emitting in free space and a quantitative analysis requires substantial numerical simulations.

The tip increases locally the photonic mode density in the gap between the apex and the sample surface when compared to a surface adjacent to open space and thus increases the radiative recombination rate Γ_r. Also absorptive losses from the emitting dipole to a metal surface increase the nonradiative decay rate at nanometer distances [10] and lead to complete fluorescence quenching for a molecule at an infinitely extended metal surface. However, as the radius of the tip apex gets smaller (e.g., some nanometers), the increase in the radiative rate may outweigh absorptive losses at short tip–sample distances as a result of the giant near-field enhancement. On the basis of this analysis, the PL enhancement G_{PL} can be expressed as the product of the excitation enhancement $G_{\mathrm{PL,exc}}$, and the emission enhancement $G_{\mathrm{PL,em}}$:

$$G_{\mathrm{PL}} = G_{\mathrm{PL,exc}} \times G_{\mathrm{PL,em}} = \left(\frac{\rho_{\mathrm{gap}}}{\rho_{\mathrm{conf}}}\right) \times \left(\frac{1 - \frac{\Gamma_{\mathrm{nr,gap}}}{\Gamma_{\mathrm{r,gap}} + \Gamma_{\mathrm{nr,gap}}}}{1 - \frac{\Gamma_{\mathrm{nr,conf}}}{\Gamma_{\mathrm{r,conf}} + \Gamma_{\mathrm{nr,conf}}}}\right) \tag{23.7}$$

As we will see in $G_{\mathrm{PL,exc}}$ and $G_{\mathrm{PL,em}}$, sensitivity depends on the tip and the sample properties such as their wavelength-dependent susceptibilities; the geometrical parameters such as the tip–sample distances and the tip geometries, in particular, apex radius, the illumination conditions; and on the optical properties of the molecules under consideration.

23.1.1.1.2 **Tip-Enhanced Raman Scattering (TERS)** The electromagnetic enhancement in TERS can in principle be analyzed in the same manner as for the PL enhancement. Estimating the local enhancement of Raman scattering would require solving the problem of a radiating dipole that is coherently driven by the gap field and comparing this with the solution for the same radiating dipole on the sample substrate under far-field excitation conditions, for example, in a diffraction-limited spot. This is a challenging task, being a matter of current research [11, 12]. In the following section, we discuss the intuitive arguments borrowed from the theory developed to explain electromagnetic enhancement in SERS [13, 14]. If we consider a single molecule located in the gap, the Raman enhancement factor, G_{R}, can be expressed as

$$G_{\mathrm{R}} = G_{\mathrm{R,exc}}(\omega_{\mathrm{L}}) \times G_{\mathrm{R,rad}}(\omega_{\mathrm{R}}) \tag{23.8}$$

where the excitation enhancement $G_{\mathrm{R,exc}}(\omega_{\mathrm{L}})$ is proportional to the enhancement of the local energy density of the excitation field at the position of the molecule versus the energy density at the same molecule under confocal far-field excitation. Other experimental conditions are kept constant

$$G_{\mathrm{R,exc}}(\omega_{\mathrm{L}}) = \frac{\rho_{\mathrm{gap}}}{\rho_{\mathrm{conf}}} = \frac{|\vec{E}_{\omega_{\mathrm{L}},\mathrm{gap}}|^2}{|\vec{E}_{\omega_{\mathrm{L}},\mathrm{conf}}|^2} \tag{23.9}$$

where $|\vec{E}_{\omega_{\mathrm{L}},\mathrm{gap}}|^2$ and $|\vec{E}_{\omega_{\mathrm{L}},\mathrm{conf}}|^2$ are the squared electric field amplitudes in the gap and confocally, respectively. A very simple approximation for the enhancement factor often used in SERS is motivated by the optical reciprocity theorem and assumes that the frequency difference between the Raman-scattered photons and the incident laser radiation has a minor effect and can be neglected. Also, neglecting polarization effects and absorptive losses by the metal and the radiative enhancement factor can be approximated as

$$G_{\mathrm{R,rad}}(\omega_{\mathrm{R}}) \approx \frac{\rho_{\mathrm{gap}}(\omega_{\mathrm{R}})}{\rho_{\mathrm{conf}}(\omega_{\mathrm{R}})} \approx \frac{\rho_{\mathrm{gap}}(\omega_{\mathrm{L}})}{\rho_{\mathrm{conf}}(\omega_{\mathrm{L}})} = \frac{|E_{0,\mathrm{gap}}|^2}{|E_{0,\mathrm{conf}}|^2} \tag{23.10}$$

Assuming similar enhancement levels for the incident and the scattered light, the total enhancement factor can be approximated by

$$G_{\mathrm{TERS}} \approx \frac{|E_{0,\mathrm{gap}}|^4}{|E_{0,\mathrm{conf}}|^4} \tag{23.11}$$

This result states that the tip-enhanced Raman signal increases with the fourth power of the local field enhancement. This expression is very popular in the SERS literature, where it is referred to as the $|E|^4$-*approximation* for the SERS enhancement. It must be kept in mind, however, that it is an approximation hiding an important part of the physics of TERS, namely, the enhancement in the scattering process is also strongly influenced by the magnitude of the local field enhancement.

23.2
Instrumentation

23.2.1
Tip Antenna

23.2.1.1 Tip Material

As has been explained in the introduction section, tip material is one of the crucial factors for an excellent SNGM performance. Metals with negative real permittivity can support collective oscillations of free charges (surface plasmon propagation) in the materials at an applied electromagnetic field. However, metals are plagued by large losses, especially in the visible and UV spectral ranges, arising partly from interband electronic transitions [15]. Even the metals with the highest conductivities suffer from large losses at optical frequencies [16–18]. Therefore, in practical applications, there are not many metallic materials that can be good candidates for tip fabrication. For example, Pettinger *et al*. [19] had reported that the Raman intensity of malachite green isothiocyanate (MGITC) adsorbed on Au (111) was increased by a factor of 2 when a He–Ne laser-illuminated Ir tip was approached at a distance of 1 nm away from the molecules. Under the comparable experimental condition, when the Ir tip was replaced by an Au tip, the average increase in the Raman intensity was ~8000. The explanation of the poor enhancements from an Ir tip was that a significant damping of the confined electric field occurred despite the excitation of localized surface plasmon in the Ir/Au (111) crystal cavity.

Among the metallic elements, Ag has the smallest total damping rate and the lowest loss in the visible and near-infrared spectrometer (NIR) ranges. Au, which has a larger damping rate than Ag, is often the metal of choice at lower NIR frequencies. However, Au has high interband losses in the visible spectrum for wavelengths below ~500 nm. Cu has an excellent conductivity (only less than Ag) among metals; hence, it is expected to exhibit promising plasmonic properties. Indeed, the imaginary part of the permittivity of Cu is comparable to that of Au from 600 to 750 nm. However, Cu has large interband losses over most of the visible spectrum. Al has not been an attractive plasmonic material because of the low-energy threshold (around 800 nm, 1.5 eV) of its interband transition, resulting in a large imaginary part in the visible wavelength range. However, in deep UV, the real part of its permittivity is negative while the imaginary part is still relatively low. Therefore, Al is a better plasmonic material than either Au or Ag in the blue and UV range [20].

An important issue concerning tip antenna is its chemical stability. Ag, Cu, and Al all form oxides at atmospheric conditions, leading to a complete loss or deteriorated antenna effect [21]. Concerning this practical problem, Au has a stable chemical stability and, therefore, is of an excellent candidate for tip antenna fabrication. Freshly prepared Ag tips are also used because of its attractive plasmonic properties [22]. To minimize the oxidation, the prepared sharp Ag tips can be stored and used either in a vacuum condition or under inert atmosphere protection.

23.2.1.2 **Tip Fabrication**

Different fabrication techniques exist for producing suitable tips for SNGM. In this section, we will shortly review some of the most employed methods for tip preparations.

23.2.1.2.1 **Metal Evaporation on Atomic Force Microscopy (AFM) Tip** SNGM combines scanning probe microscopy and optical microscopy. The manipulation of the tip antenna, such as approaching it to the vicinity of the sample surface, based on atomic force, is one of the most popular methods. As the AFM cantilever tips are typically made from Si, the tip apex needs to be coated by Au or Ag to create surface plasmon in the visible or near-UV regime. A simple manufacturing method is to evaporate a 20–50 nm thick metal layer over the cantilever, which results in a final tip radius in the range 20–50 nm [23]. A thinner film is promising for giving sharper tip apex, but is mechanically less stable. The advantage of this method is that we can easily employ the commercially available AFM sharp tip as a base, coating with various metals, for tip fabrication. Notably, the main disadvantage of such a method is the ill reproducibility of the tip apex geometry, which often leads to a large fluctuation in the near-field enhancement among different tips.

23.2.1.2.2 **Nanostructure at Different Tip Bases** Other techniques include attaching individual gold particles to the end of an optical fiber tip and using ion beam milling to fabricate tailored plasmonic structures.

For example, the antennas were fabricated at the apex of the pyramidal Si_3N_4 AFM cantilever tips (Figure 23.3a). The electric field, in this case, is confined by the

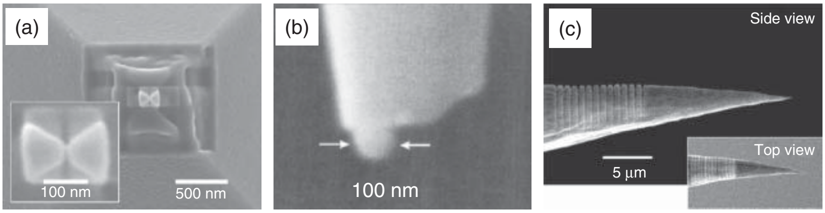

Figure 23.3 (a) Optical antenna at the apex of an AFM tip. (Copyright (2005) by the American Physical Society. Reprinted from [24].) (b) SEM images of an Au nanoparticle was fixed to a fiber tip. (Copyright (2001) by the Royal Microscopical Society. Reprinted from Ref. [25].) (c) Grating-coupling of surface plasmons on a tip. (Copyright (2010) by the American Chemical Society. Reprinted from [27].)

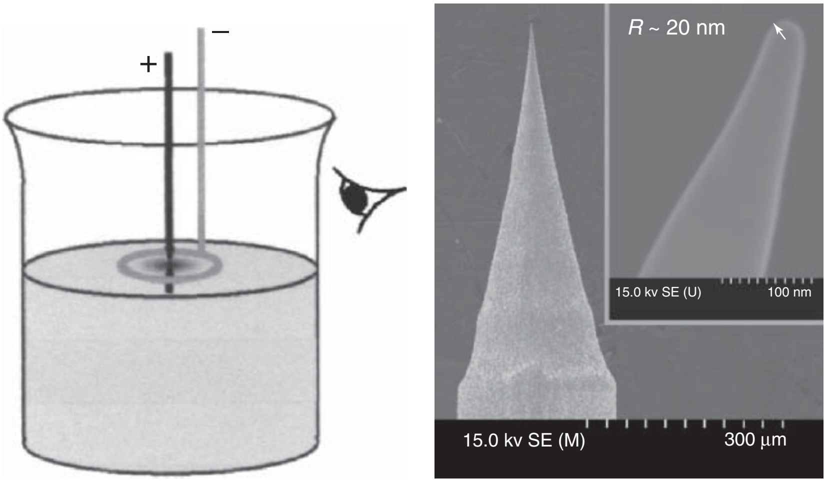
excitation of the antenna gap. After evaporating a homogeneous 40 nm thickness aluminum film to the AFM tip, a bowtie-shaped metallic structure was sculptured from the film by means of focused ion beam (FIB) milling. This includes, in a final step, cutting of a narrow gap between the two arms of the antenna right at the apex. The flare angle, radius of curvature of the antenna arms at the feed gap, and the feed gap width are 40°, 30 nm, and approximately 50 nm, respectively. The overall antenna length is 170 nm, which is in between the length of the half-wave dipole, estimated to be near 120 nm under consideration of the average dielectric properties of the environment, with the first minimum of the antenna responsively at about twice that length [24]. Figure 23.3b illustrates another approach that an Au nanoparticle can be attached to the end of a glass fiber tip as a local electric field confiner [25]. The advantage of such method lies in the fact that the size and geometry of the nanoparticle are well confined. However, the reproducibility and the flexibility of handling are under debate. Recently, a new type of tip of fabricating grating structure at the tip shaft is introduced [26, 27], as shown in Figure 23.3c. This local light source is based on spatially focusing surface plasmon polariton (SPPs) on nanofabricated, three-dimensionally tapered conical tips with apex radii of a few tens of nanometers. One-dimensional grating was written onto the tip shaft by FIB sputtering, which is more than 10 µm away from the apex. Illumination of the grating with a broadband femtosecond laser leads to resonant excitation of SPPs, which travel to the tip apex and radiates. This sort of tip is potentially very plausible for significant reduction of background illumination in SNGM.

23.2.1.2.3 **Electrochemical Etching of Au or Ag Wires** Electrochemical etching of Au or Ag wires to generate sharp tip apex is often used in fundamental research laboratories [28]. The setup for etching the Au tip is based on a commonly used configuration, as shown in Figure 23.4, placing a gold ring of ~8 mm diameter made from 1 mm gold wire on the surface of the solution (about 3/4 height of the ring is immersed in the solution).

A gold wire of 0.25 mm diameter after a quick flame annealing was immersed in the center of the ring. The immersed length is normally 2–3 mm. The etching solution was prepared using analytical grade fuming hydrochloric acid and ethanol



(a) (b)

Figure 23.4 (a) The schematic diagram of the setup for preparing the gold tip. (b) The smooth, pencil-shaped Au STM tip produced by electrochemical etching. (Copyright (2006) by the American Institute of Physics. Reprinted from [28].)

from Merck. The chemical reactions occurred during the tip etching procedure are

$$\mathrm{Au} + 4\mathrm{Cl}^- \rightarrow \mathrm{AuCl}_4^- + 3\mathrm{e}^-, E_0 = 1.002\ \mathrm{V}$$

$$\mathrm{Au} + 2\mathrm{Cl}^- \rightarrow \mathrm{AuCl}_4^- + \mathrm{e}^-, E_0 = 1.154\ \mathrm{V}$$

$$\mathrm{AuCl}_2^- + 2\mathrm{Cl}^- \rightarrow \mathrm{AuCl}_4^- + 2\mathrm{e}^-, E_0 = 0.926\ \mathrm{V}$$

According to authors' observation, a stable current oscillation only occurs at DC voltage more positive than 1.4 V with respect to a saturated calomel electrode. Notably, when the etching voltage is too high, side reactions such as the bubble evolution of Cl_2 and O_2 may occur, leading to severely roughened surface. The addition of ethanol is suggested in their method to reduce the bubbling and hence to produce a smooth surface during the etching process. After systematic comparisons of the different mixture ratios between ethanol and HCl, as well as the etching voltages, the authors suggested a series of optimized-electrochemical etching parameters: ethanol and fuming HCl are mixed with equal amount and the etching voltage is selected as 2.4 V. Although they did not rule out that other combinations of etching voltage and solution composition can produce better tips, they can achieve, with the earlier-mentioned parameters, well-defined tip shape and very smooth surface structure (a typical tip picture, as shown in Figure 23.4).

23.2.2
Microscope Configurations

The commonly used experimental configurations for SNGM, based on the arrangements of the optical paths for laser illumination and signal collection, can be divided into three main streams: transmission, side illumination, and top illumination.

23.2.2.1 Transmission Configuration

Laser illumination and signal collection in a transmission configuration is mostly employed to perform near-field optical microscopy. In such a configuration (Figure 23.5), the laser beam is delivered from below the sample and is focused by a lens at the apex of an AFM tip coated with metal. The scattered signal will be collected by the lens and be delivered to the detector. There are several advantages of working with such a configuration. (i) It can be a relatively convenient setup by integrating commercial available confocal optical microscope and scanning probe microscope, such as AFM. So far, most SNGM instruments on the market are based on this configuration. (ii) High NA oil immersion lens can be used in this configuration, which allows a tight laser focusing for minimizing the background signal and an efficient signal collection for achieving higher sensitivity.

Concurrently, there is a prerequirement that the sample substrates have been restricted to be transparent in order to let the laser illuminate the sample and the signal being collected through the substrate [29, 30, 23]. Transparent substrates such as mica and glass or ultrathin metal films have to be used, which limits the applicability of this technique. As shown later, for nontransparent samples, side illumination and top illumination were employed [31–34].

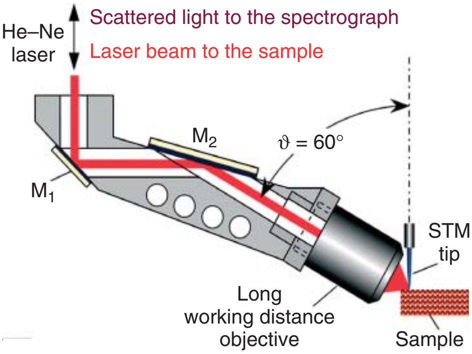

Figure 23.6 A schematic representation of a side-illumination configuration. (Copyright (2009) by the Elsevier B.V. Reprinted from [35].)

23.2.2.2 Side-Illumination Configuration

In this configuration, the laser illumination and signal collection are carried out at the side of the tip antenna with a certain angle (Figure 23.6).

In order to maximize the electric enhancement at the tip apex, the electric field of the incident light should be aligned along the tip axis, which is similar to the case of optimizing the electric enhancement in an elliptical metal particle. Such sort of requirement is difficult for the bottom-illumination method, especially when nontransparent sample is used; side-illumination configuration where a *p*-polarized laser beam [36] is directed to the tip antenna from a tilted angle versus the sample surface is proved to be an effective solution regarding this problem. The tilted angle has been suggested theoretically as between 45° and 60°. Practically, 60° [33] or 65° tilting angle is commonly used. The tip can be approached to the sample surface at a desired distance via tunneling current [35] and force [32].

Such an SNGM configuration allows a broad choice of samples, and no limitation regarding the sample transparency need to be taken account of. On the other hand, the limited NA of the air objective inevitably leads to some signal lose. In addition, the signal produced from the sample is collected only at ~60° from one side of the tip shaft, which may lead to artificial picture when using side-illumination configuration to do microscopic imaging.

23.2.2.3 Top-Illumination Configuration

In this reflection-type configuration (Figure 23.7), a high NA ($\mathrm{NA} = 0.998$) parabolic mirror is placed above the sample for laser focusing and signal collection [37]. Instead of commonly used lineally polarized beam, higher order laser beam such as radially polarized beam has been intensively employed. Compared to the focus of a linearly polarized beam, the radial symmetry of the field vectors in a radially polarized beam leads to a perfectly symmetric focus with a strong longitudinal component centered on the optical axis [38, 39]. When focused by the high NA

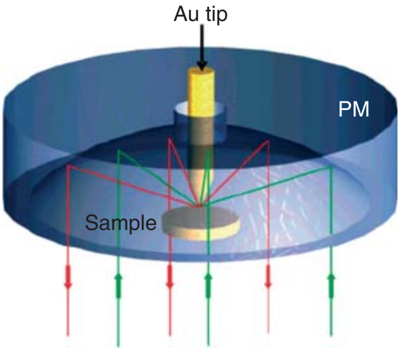

Figure 23.7 Sketch of a parabolic mirror situated above a sample and the tip antenna approached through an axial hole into the focus of a radially polarized laser beam. Green arrows indicate the incoming laser beam and the red arrows indicate the outgoing laser beam and optical signals. (Copyright (2010) by John Wiley & Sons, Ltd. Reprinted from [42].)

parabolic mirror, the electric field distribution along the longitudinal direction is ∼14.6 times stronger than that of the transverse direction and has a decay constant on the order to λ [40]. The tip is brought into the center of the focus through an axial hole at the center top of the parabolic mirror and is kept at a defined distance from the sample surface by shear force control [41, 42] or tunneling current [43, 44].

Similarly to the side-illumination configuration, top-illumination also has no limitation regarding the sample transparency. Besides this, on comparing with common air objective, a NA of nearly 1 can be achieved by a parabolic mirror, allowing an efficient and symmetric signal collection over a solid angle of π above the sample surface. Only a minor fraction of the signal is lost as a result of the small axial hole opened at the top of the parabolic mirror and the blockage of the tip shaft. In addition, a tighter focus that is slightly smaller than $\lambda/2$ can be achieved by a parabolic mirror, which helps to minimize the background signals from the far-field focus illuminated sample area [45]. A further advantage is that parabolic mirror focusing is based on reflection and is free from chromatic aberration, and thus, adaptable to different laser wavelengths. Notably, different from objective lens that has wide field of view and high degree of correction function; parabolic mirror has limited off-axis imaging property. Slight deviation of the incident beam from the optical axis or parallelism leads to large aberrations [40]. Therefore, the quality and the precise alignment of parabolic mirror are critical in such sort of configuration.

23.3
Applications

23.3.1
Materials Science

23.3.1.1 Carbon Nanotube and Graphene

Semiconducting single-walled carbon nanotubes (SWNTs) are photoluminescent quasi-one-dimensional quantum wires with great promise for application in photonics as well as opto and nanoelectronics. The unique optical and electronic properties observed in SWNTs are largely because of the one-dimensional confinement of electronic and phonon states, resulting in the so-called van Hove singularities in the nanotube [46]. Raman spectroscopy has been popularly employed to characterize SWNTs [47, 48]. The diameter and chirality of an SWNT can be determined by the shift of the radial breathing mode (RBM) at 100–400 cm^{-1} [49]. The detect defects in the nanotube structure can be detected by the disorder-induced D band at $\sim$1350 cm^{-1} [50], whereas the types of the SWNTs, be it semiconductor or metallic, can be distinguished from the shape of the tangential stretching G band ($\sim$1590 cm^{-1}) [51].

Near-field Raman and PL imaging of SWNTs have been performed by several groups [52–54]. Hartschuh *et al.* [55, 56] reported the TERS investigation of SWNTs with a spatial resolution of better than 15 nm. Highly localized excitation is used to visualize the spatial extent of the contributing excited states. Figure 23.8 shows the simultaneously near-field PL, Raman, and topographic imaging of micelle-encapsulated SWNTs on mica. The PL image and the Raman image were formed by detecting the light intensity that is transmitted by the band-pass filters centered at 950 nm (PL from the (8,3)-nanotubes) and 700 nm (G-band Raman scattering), respectively [57].

Recently, Maciel *et al.* [58] have shown the use of TERS and TEPL to detect spatially local charged defects along individual doped SWNTs. They observed a high degree of spatial localization of the PL along the SWNT, which is related to trapped excitons. They also reported a new peak in the G′ peak in the Raman spectra from the defect sites. This new peak can be shifted to lower or higher frequencies relative to that of the pristine tubes. They suggested that this additional G′ peak originates from the charged defects (dopants), having its frequency up/downshifted for p/n dopants.

As the basic structural element of carbon nanotube, graphene is one-atom-thick planar sheet of sp^2-bonded carbon atoms that are densely packed in a honeycomb crystal lattice [59]. The carbon–carbon bond length in graphene is $\sim$0.142 nm. Graphene sheets stack to form graphite with an interplanar spacing

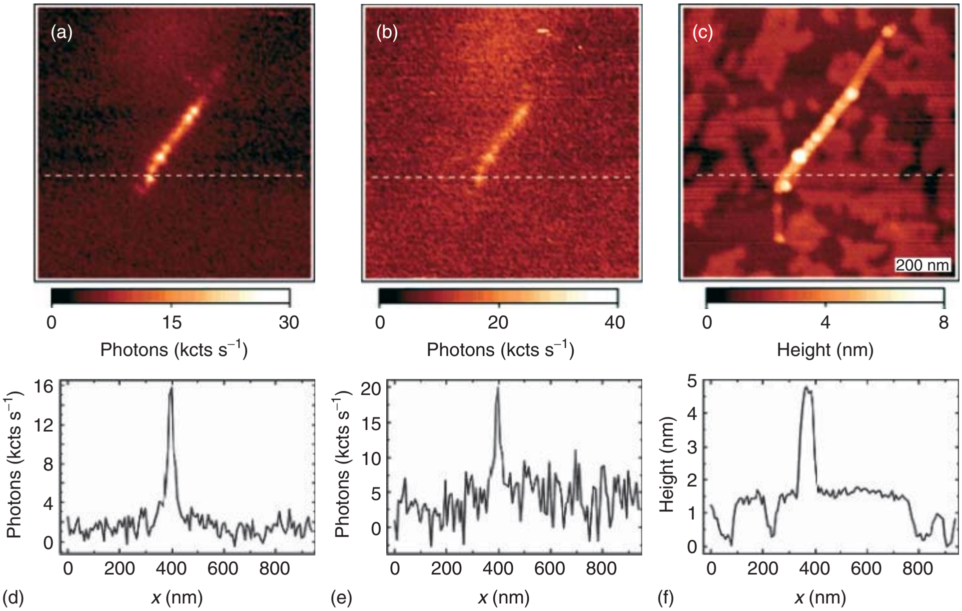

Figure 23.8 (a) Near-field PL, (b) Raman, and (c) topography image detected simultaneously for micelle-encapsulated SWNTs. (d–f) Optical and topographic cross sections taken along the dashed lines in (a–c), respectively. (Copyright (2005) by American Chemical Society. Reprinted from [55].)

of 0.335 nm. The extraordinary electronic and optical properties of graphene have attracted tremendous interests these days. In 2010, the Nobel prize in Physics was awarded to Andre Geim and Konstantin Novoselov "for groundbreaking experiments regarding the two-dimensional material graphene." Spectroscopic methods have been proved to be effective to identify the number of graphene layers, as well as to study the intermolecular interactions, molecular orientations, and symmetry distortions of graphene [60]. Saito *et al.* [61] has reported TERS analysis of n-graphene layers. Continuous change of intensity and peak shift of the G-band and the second-order overtone of the defect mode 2D band across the layer boundaries has been observed. They have suggested a near-field optical method to estimate the number of graphene layers and the thickness distribution in ultrathin graphite flakes. Snitka *et al.* [57] presented the TERS imaging of single-layer and multilayer graphene flakes with tips fabricated by flattering Au microwires. They reported an enhancement up to 10^6 of the D- and G-band of graphene, and by careful control of the tip, sample pressure, the shift in G-band wavelength was produced. In addition, the peak fluctuation in the 2D band also suggests the local stress distribution produced as a result of graphene–tip interaction. The number of layers and stress analysis in 2D imaging allows nondestructive identification of graphene layers critical for the evaluation of this material in future device applications.

23.3.1.2 **Inorganic Semiconductor**

Technology based on strained silicon has been widely used in semiconductor devices fabrications because it boosts the speed and reduces the power consumption of electronic devices [62–64]. For example, the strain introduced in active regions of complementary metal-oxide-semiconductors (CMOSs) devices can modify the electronic band structure and improve the mobility of charge carriers, hence enhancing the speed of high-performance microprocessors [65]. The device performance depends strongly on the level and the spatial distribution of the stress that is artificially imposed on the silicon lattice. Therefore, nondestructive characterization techniques of local stress with a lateral resolution below 100 nm are required for the quality control of high-performance electronic devices using silicon substrate [66]. Raman spectroscopy is one of the popular characterization tools to monitor the Si strain because of the linear dependence of the Si–Si phonon mode Raman shift on the strain level [67, 68]. The deviation from this peak position shows the amount of strain. Depending on the property of the strain, whether it is compressive or tensile, the Raman frequency of the Si–Si phonon mode shifts to either blue or red with respect to that of the nonstrained Si. A frequency change of at least 0.02 cm^{-1} can currently be detected [69]. Although Raman spectroscopy is in principle a powerful tool to characterize Si strain, this technique is less satisfactory regarding the sensitivity and the diffraction-limited optical resolution, that is, at a scale of several hundreds of nanometer.

TERS investigations of the Si strain have been performed by some research groups to cope with the earlier-mentioned problems. As shown in Figure 23.9, Ogawa *et al.* [70] have reported the nanometer-scale mapping of Ge/Si ODs that were grown on a Si substrate using TERS with a spatial resolution of less than 100 nm comparable with the dot sizes. In order to create a concentrated near-field, they deposited a gold particle at the apex of a fiber tip. On the basis of their TERS imaging, they discussed the strain in the Si substrate and the intermixing of single quantum dots (QDs). It was found that Ge–Ge and Si–Ge modes in the Raman spectra are significantly enhanced only when the AFM tip with a gold nanoparticle is positioned on the dots. It is also found that the Si substrate peak at 520 cm^{-1} is shifted considerably in the neighborhood of the dots. This implies that a large stress acts on the Si substrate around the dots. The Ge content reduces at the center of the dots. This result suggests that the dots consist of a Si-rich core and a Ge-rich shell. The Ge content decreases and the strain in the Si substrate increases with an increase in the dot height. Their work shows that the TERS technique is fully applicable to evaluation of the lattice structure and electronic properties of nanomaterials. Hanafusa *et al.* [71] studied the strain distribution of sputter-formed strained Si by TERS. A transparent cantilever tip with a gold nanoparticle deposited on top was used as the TERS probe. They carried out simultaneous measurements of the strain and surface undulation distribution for strained Si layers at a quadruple-$\mathrm{Si}_{1-x}\mathrm{Ge}_x$-layer. Their results show a strong relationship between the surface flatness and the strain distribution uniformity. The TERS analyses suggest that the compositional fluctuation of the underlying

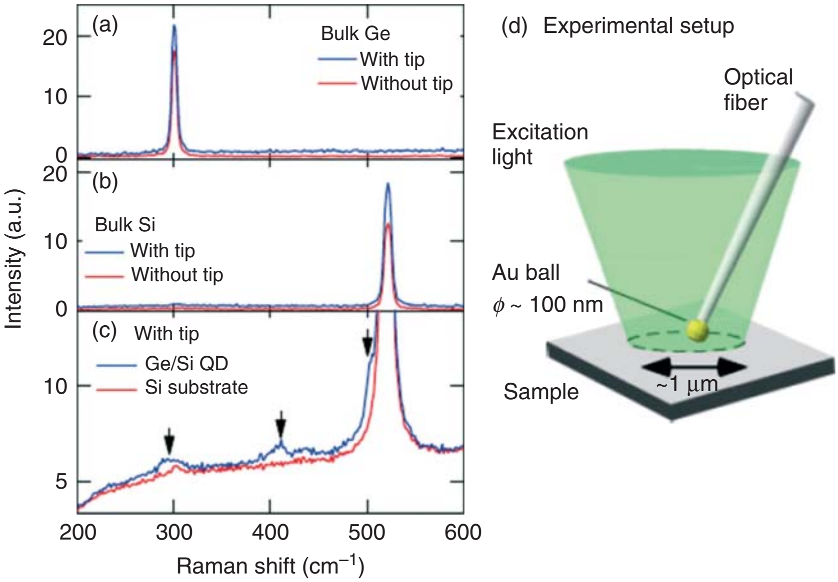

Figure 23.9 Raman spectra of bulk (a) Ge and (b) Si with tip [blue (black) line] and without tip [red (gray) line]. (c) Tip-enhanced Raman scattering (TERS) spectra of Ge/Si quantum dots (QDs) [blue (black) line] and Si substrate [red (gray) line]. The 2TA mode of the Si substrate is observed at 300 cm^{-1}. The three peaks of Ge/Si QDs observed at 294, 410, and 500 cm^{-1} belong to the Ge–Ge, Si–Ge, and Si–Si modes, respectively. (d) Experimental setup for TERS measurement. The TERS probe was made up of glass fibers and single gold nanoparticle with a size of ~100 nm attached to it; this particle was positioned on the samples in the focal spot during the measurements and was controlled by using a tapping-mode atomic force microscope. (Copyright (2011) by the American Physical Society. Reprinted from [70].)

$Si_{1-x}Ge_x$ is largely related to the weak Si strain fluctuation, which may also be related to the multidirectional lattice plane slips, which cause the surface flattening.

In addition to the Raman signal from the nanometer-sized area excited by the tip-induced near-field, an even overwhelming optical signal from the sample volume illuminated by the diffraction-limited focus (as discussed in Section 23.1.1) contributes as well to the collected TERS spectrum. This leads to the well-known problem of far-field signal interference when using TERS to characterize thin-strained Si layer. To minimize such a far-field interference without sacrificing the Raman signal from the strain Si, two major alternatives have been suggested. (i) UV illumination can be employed as the excitation source because of its thin penetration depth into the unstrained bulk Si substrate [72]. Owing to the frequency-dependent dielectric constant, Al has been recommended for the TERS measurement using UV light. Poborchii *et al.* [73] have optimized the tip materials and its shape for near-UV TERS of Si structures. They show both theoretically and experimentally that Al is a good Raman enhancer at the excitation of 363.8 nm. Employing an inclined Al-coated Si AFM tip, they succeeded in detecting weak

TERS signal of strained Si. (ii) The second alternative is based on the manipulation of the well-defined polarization properties of the Si crystalline sample relative to the polarization and propagation of the incident light. Such a method has been implemented by the reflective type side-illumination TERS configuration [74, 75]. They also proposed far-field suppression by depolarization configuration [76]. In this configuration, the tip depolarizes the incident beam from *p*-polarized light to *s*-polarized light or vice versa. The resulting depolarized light will incur a depolarized Raman signal that can be detected through an analyzer while blocking the Raman signal from the originally polarized light to minimize the far-field Raman signals. Ossikovski *et al.* [77, 78] proposed a simple model that describes polarized TERS to characterize the tip enhancement process. The model is based on a tip amplification tensor describing the interaction of the tip with both the incident and scattered optical field. The interference signal from the underlying bulk Si substrate can be reduced by appropriately setting the polarizer and analyzer relative to the material crystalline axis.

23.3.1.3 **Semiconductor Organic Thin Film**

Semiconducting organic materials have been studied intensively because of their interesting optoelectronic properties, giving rise to a broad range of applications such as organic field-effect transistors [79], organic light emitting diodes, or organic solar cells. The electronic properties of thin film semiconductors are usually different from the monomer or bulk crystal properties; moreover, they depend strongly on the microscopic film morphology, such as grain boundaries.

Zhang *et al.* [80] had reported the near-field imaging of a diindenoperylene (DIP) thin film based on the plasmon–polariton coupling between the excited gold tip and the semiconductor film. A near-field optical image of the DIP film and the simultaneously recorded topographic image are shown in Figure 23.10a,b. A sharp optical resolution of $\sim$17 nm at one molecular boundary is demonstrated. The DIP molecular domain boundaries being one to four molecular layers (1.5–6 nm) high are resolved topographically by a shear force scanning tip and optically by the 6×10^5 times enhanced PL (Figure 23.10c). The excitation is four magnitudes enhanced and the intrinsically weak PL yield of the DIP film is 15-fold enhanced by the tip. The enhanced PL contrast results from the local film morphology via stronger coupling between the tip plasmon and the exciton–polariton in the DIP film. The increasing and redshifted PL intensity with the tip approaching closer to the DIP sample indicate a stronger plasmon–polariton coupling (Figure 23.10d). The boundary of the DIP thin film appears to be brighter because of a stronger tip–sample coupling when compared to that of inside the thin film (Figure 23.10e).

On the basis of conjugated semiconductor polymers, organic solar cell is a promising candidate for new generation of low-cost and flexible photovoltaic devices. With blends of poly(3-hexylthiophene) and [21]-phenyl-C_{61} butyric acid methyl ester (P3HT:PCBM) that have been intensely used as electron donor and acceptor in organic solar cells devices. One of the main factors affecting the power conversion efficiency of P3HT:PCBM solar cells is the nanoscale morphology issue [81, 82].

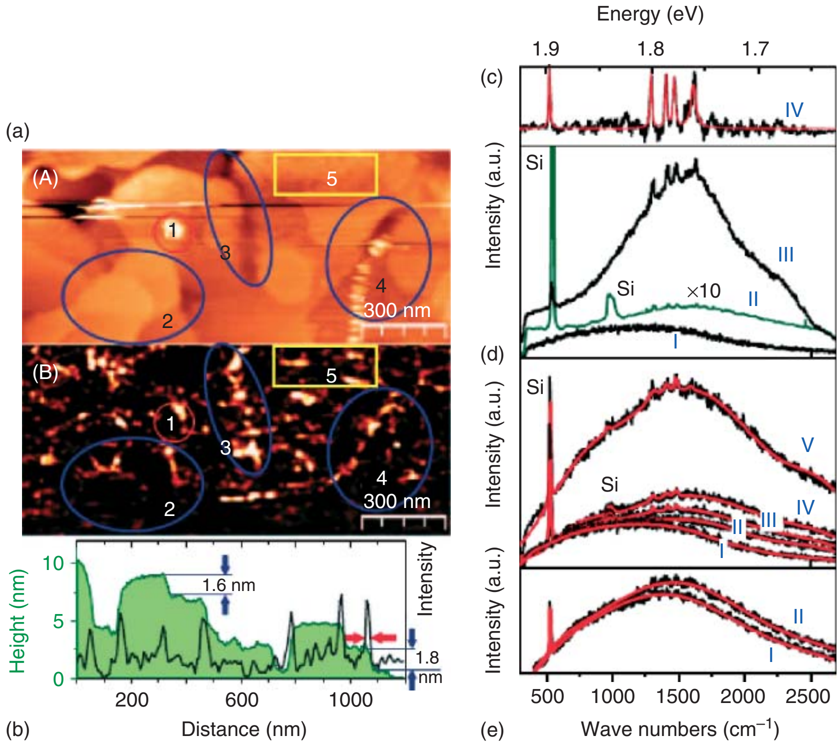

Figure 23.10 (a) Simultaneously recorded topographic (A) and near-field optical images (B). Scan area of 1.5 × 0.7 µm^2, laser power at the focus is 170 µW, tip–sample distance is 3 nm. (b) Line profile through the topographic image with its correlated optical intensity. (c) Confocal far-field PL spectrum (I) of a tip alone integrated for 10 s, (II) DIP film integrated for 900 s, and (III) tip-enhanced spectrum integrated for 10 s at a tip–DIP distance of 3 nm. Excitation power is 170 µW. (IV) tip-enhanced Raman spectrum obtained from (III) after subtraction of PL background with fitted spectrum (red curve). Wang *et al.* [83] had reported the correlated topographical and near-field spectroscopic mapping images obtained from the blend film, which has been thermally annealed for 30 min (Figure 23.11). The PL intensity variation reflects the efficiency of charge generation at the P3HT:PCBM interface. Raman spectroscopy that is very sensitive to the degree of π-electron delocalization along the chain axis of conjugated polymers, studies nanoscale changes in morphology by monitoring the vibrational modes of P3HT polymer chains that are involved in electronic transitions.

Figure 23.11a shows the AFM image of a sample area. The corresponding near-field mapping image (Figure 23.11b), obtained by summing the total spectral

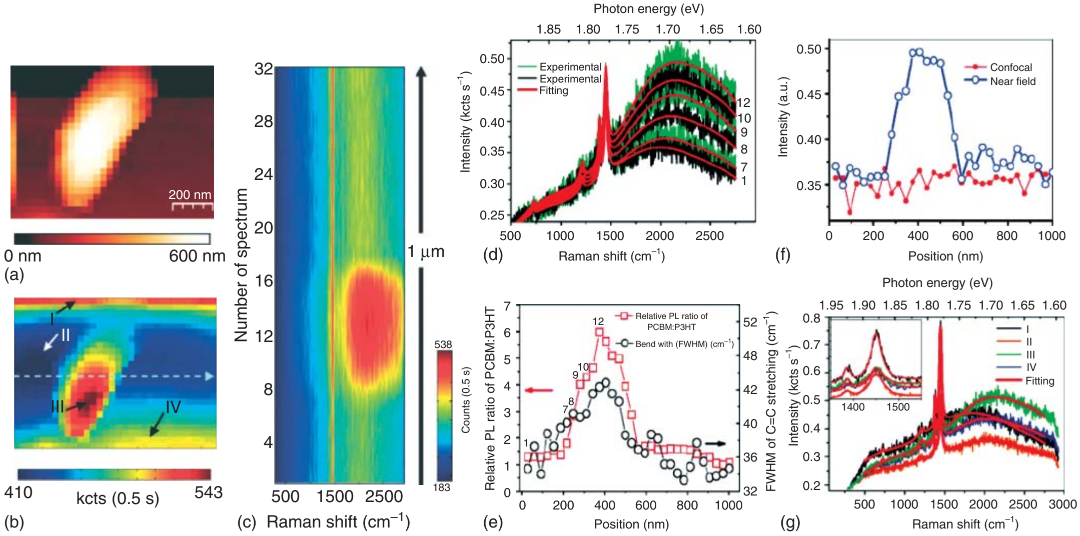

Figure 23.11 (a) Topographical image. (b) Near-field spectroscopic mapping images obtained by summing the total spectral pixel intensity from 283 to 2926 cm^{-1}. (c) Thirty-two spectra extracted from a line scan (1 μm) the position of which is indicated in (b) with an arrow. (d) Comparisons of several spectra extracted from the Raman line mapping sequence are shown in (c). The green and black spectra are the experimental data while the red curves are the fitted spectra. (e) The relative PL ratios between PCBM and P3HT (curves labeled with red open rectangles) and the FWHM changes of the P3HT C=C stretching Raman peaks (curves labeled with black open circles) along the line indicated in (b). (f) Comparison of the near-field and confocal spectroscopic mapping along the same line indicated in (b). The optical signals plotted here are derived from the PCBM PL intensities. (g) Near-field spectra collected at positions I, II, III, and IV as indicated in (b). The red curves are the fitting spectra. The inset figure shows the enlarged spectra from 1350 to 1550 cm^{-1}. Sample is thermally annealed at 140 °C for 30 min. Scan area is 1 × 0.75 μm. Laser power is 250 μW. Acquisition time is 0.5 s per spectrum. (Copyright (2010) by Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim. Reprinted from [83].)

intensity from 283 to 2926 cm^{-1}, shows intense optical signals at the places where the island is located. Gradually decreasing optical intensity from the maximum height of the island to the flat area is clearly resolved. Figure 23.11c stacks 32 Raman spectra taken from a one-line near-field spectroscopic map (1 μm) along the arrow indicated in Figure 23.11b. Although the P3HT Raman peak at 1450 cm^{-1}, represented by the red line across Figure 23.11c, indicates the presence of P3HT molecules throughout this region, a clear optical signal evolution in the range from 1600 to 2600 cm^{-1}, corresponding to PCBM PL, is observed following the one-line scan. Figure 23.11c shows that from spectra No.7–12, PCBM tends to aggregate more and more severely as supported by the PCBM PL increase and the topographically obvious clustering. The full-width-at-half-maximum (FWHM) of the C=C stretching Raman peaks is broadened where the PL ratio of PCBM against P3HT is larger (Figure 23.11e). From spectra No.1–12, the PL ratio of PCBM against P3HT increases six times. Correspondingly, the FWHM of the P3HT C=C stretching Raman vibration peak increases by ~10 cm^{-1}, indicating that the increasing clustering of PCBM induces reduced crystallinity of the P3HT domain. The fine optical information given earlier cannot be revealed by the conventional far-field microscopy because of its resolution limitation (Figure 23.11f).

23.3.1.4 **Life Science**

To apply TERS to studying biological structures is of greatly interesting as a result of its high sensitivity, nanometer spatial resolution, and no need for complicated labeling [84]. Many biological molecules, such as DNA or RNA, have large cross sections and allow extremely sensitive detection, even down to single-molecule level. Domke *et al.* [85] have reported the distinctively different TER spectra of DNA bases (adenine, thymine, guanine, and cytosine) adsorbed on Au (111) crystal surface (Figure 23.12a). The pronounced near-field enhancement induced by the tip–Au crystal coupling realized the detection of even picomolar amount of adenine, which is ~400 molecules. Zhang *et al.* [86] have investigated the hydrogen bonding between adenine and thymine molecules using TERS. Hennemann *et al.* [87] has immobilized calf thymus DNA strands on a Au crystal surface. Using the top-illuminated parabolic mirror setup, the authors have reported the TERS spectra from a fraction of the DNA strands. A Raman enhancement factor of at least 1400 has been achieved when compared to the measurement without tip enhancement (Figure 23.12b).

Despite of its promising potential, the practical implementation of TERS in the biology field encounters several distinctive problems that may not appear in the solid-state physics. For example, a biological structure bearing its characteristic biological functions and compositions requires most often in its presence in a native biological environment. Therefore, to provide convincing analysis often needs to perform TERS measurements *in vivo*. Such sort of requirement is a great hindrance limiting the wide exploration of TERS in the biological field. (i) From the scanning probe microscopy point of view, the precise approaching of the TERS tip requires a stable feedback from the sample surface. Feedback via tunneling current is very much unlikely in the biological samples investigating with TERS as

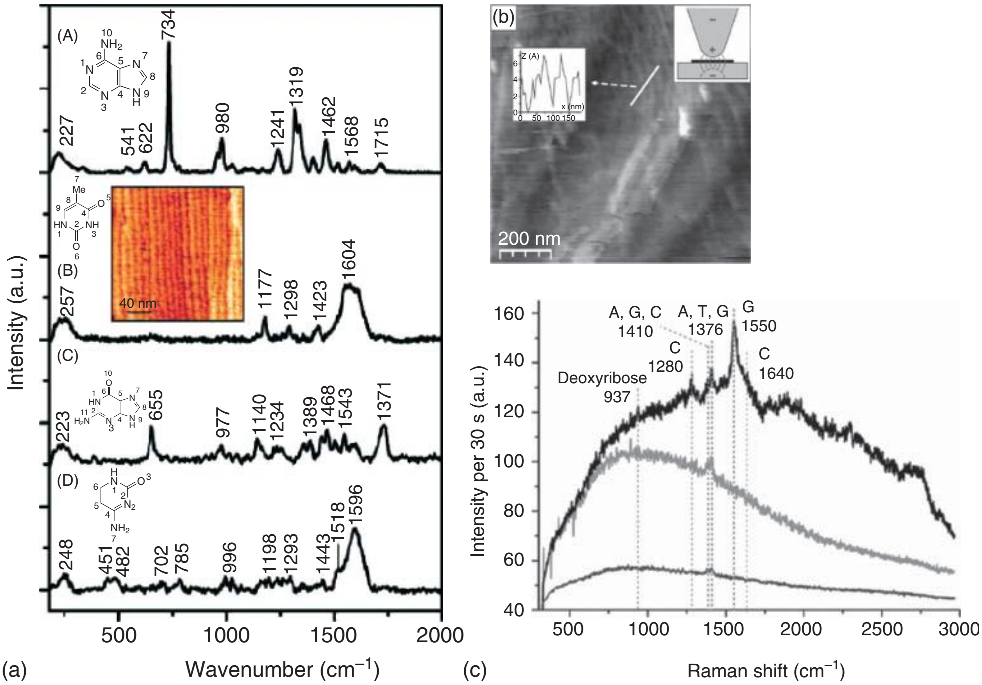

Figure 23.12 (a) TER spectra (background corrected) of DNA bases adsorbed at Au (111): (A) adenine, (B) thymine, (C) guanine, and (D) cytosine; normalized to 1 s integration time at 2 mW incident power. The inset shows an example STM image of a thymine self-assembled monolayer on Au (111) recorded after 12 h adsorption with a Au probe; tunneling current is 1 nA, bias is 150 mV, scan area as indicated. (b) TERS measurements of a (sub)monolayer of calf thymus DNA on a gold (111) crystal. (b) Shear force topographical image of the sample, including a line cut (inset graph). Sketched inset: illustration of producing a "hot spot" in the gap between a fine gold tip and the substrate. The + and − signs symbolize the dipole arising inside the tip induced via excitation with a radially polarized donut beam. The curved vertical streaks represent the electrical field lines connecting the tip and its mirror charge inside the gold crystal. (c) Three Raman spectra taken consecutively at one specific spot on the sample. From bottom to top: confocal far-field spectrum, acquisition time is 2 min but normalized to 30 s; spectrum with the tip close to the surface, acquisition time is 30 s; spectrum with the tip approached further to the surface, acquisition time is 30 s. A tentative assignment of some of the Raman bands was undertaken (A, adenosine; T, thymine; G, guanine; and C, cytosine). (632.8 nm He–Ne laser, laser power is 250 μW. a result of the conductivity of the biological sample and the complicated influence of the applied bias voltage on the native function of the biological sample. To use force as the feedback has been proved to be rather successful as seeing from the popular application of AFM in biology. However, due to the fact that relative rigid sample surface is required to give a stable force feedback, only a limited number of nonmotile biological systems can be investigated. In addition, tremendous problems occur if we targets at molecules that are encapsulated in a closed compartment, such as a cell wall. The probing of such targets seems only possible if a sliced sample is used. (ii) From the spectroscopic point of view, the complex constitutions of the real biological samples produce large fluorescence background and complicated Raman fingerprints making the precise determination of one certain species extremely demanding. In addition, within the nanometer-sized TERS probing volume, the diffusion of biological compartment or molecules cannot be neglected, which could be one of the main reasons for producing great spectral fluctuation. The far-field interference in this case can also be overwhelming. (iii) From the biological point of view, biological systems are characterized by their complex structures and their vast amount of kinetic processes necessary for proper biological function. The TERS technique based on continuous wave excitation lacks time resolution; hence, could not provide a real picture of the kinetic biological processes. (iv) When using tip-enhanced fluorescence to investigate the biological samples, the possible photobleaching from the laser irradiation and the strongly confined near-field at the tip apex should be carefully taken into account. An effective alternative is tip-enhanced two-photon excitation fluorescence, which suffers much less from photobleaching, and does not require the removal of the far-field background signal. Si tips have been used recently for this purpose, despite having a lower enhancement, they cause less quenching and allow more excitation power.

Despite the earlier-mentioned difficulties, some research groups have successfully carried out TERS investigations of biological samples *in vitro*, such as DNA deposited on gold [87], tobacco mosaic virus on glass [88], lipid domain in supported lipid layer [89], histidine on silver substrate [90], and so on. These samples have the advantage of being nonmotile and being easy to deposit on a substrate.

Bailo *et al.* [29] have demonstrated experiments on a single-strand RNA homopolymer of cytosine (poly(C)) immobilized on mica and demonstrate the potential of single-base identification, for example, sequencing, when the tip is scanned along the strand. For their TERS measurement, RNA strands were attached to a mica surface via phosphate groups, by adding Mg^{2+} cations to the sample. Figure 23.13 shows the TERS measurements from seven locations along the RNA strand. The TER spectra were assigned to the fingerprint of cytosine with significant fluctuations in band intensities and slight shift of the band positions. The spectral intensity changes were likely related to the minuscule variation of the tip–sample distance. The shift of the band positions was suggested to be due to the molecular orientation differences in a fixed RNA strand with respect to the scanning tip. In addition, the polarization condition and the electromagnetic field distribution could also induce the spectral fluctuations. The authors proposed that this principle can be applied to the sequencing of peptides and proteins in a general manner [33, 91]. To further improve the TERS sensitivity when using a transmission setup, thin gold plates that are transparent for the visible light was recommended as the substrate for biomolecule immobilization [92].

One of the first successful TERS measurements of whole cells was conducted on the Gram-positive bacterium *Staphylococcus epidermidis* (*S. epidermidis*) [93].

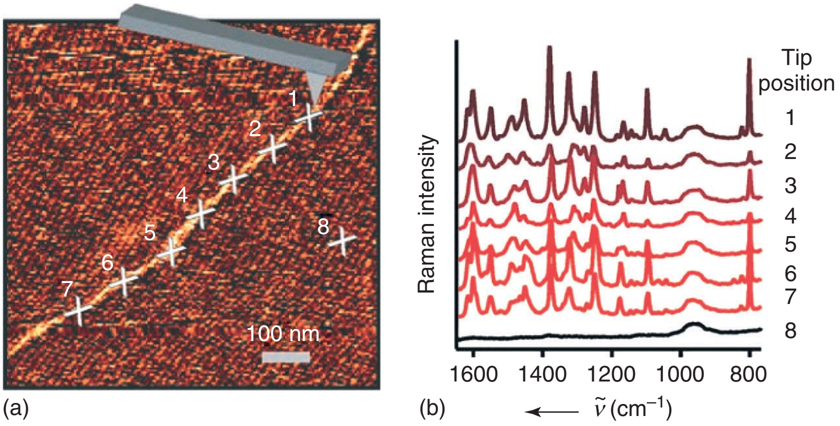

Figure 23.13 TERS experiment along an RNA strand. (a) Topography image showing seven adjacent spots corresponding to the positions of the TERS experiments and one additional spot for the reference measurement (position 8). (b) The Raman spectra of the positions in (a). (Copyright (2008) by the Royal Society of Chemistry. Reprinted from [29].)

This type of cell represents a wise choice for proof-of-concept, as it is nonmotile, reasonably stiff, phototolerant, and does not require an aqueous environment. Neugebauer *et al.* showed TER spectra for five individual cells, within each spectrum being averaged from 15 1 s acquisitions as a result of the significant tip enhancement achieved from an ultrasharp silver-coated AFM tip. The enhancement factor was calculated to be around 10^4–10^5. The majority of TERS peaks on the bacteria surface could be tentatively assigned to peptides, lipids, and carbohydrates abundant on the cell surface of bacteria.

The latest application of TERS in the samples besides cell surfaces [94], viruses, and isolated molecules were presented by Wood *et al.* [95] They have detected hemozoin crystals at <20 nm spatial resolution in the digestive vacuole of a sectioned malaria parasite-infected cell. The TER spectra show characteristic bands of hemozoin that can be correlated to a precise position on the crystal by comparison with the corresponding AFM image. They foresee that the combination of AFM/TERS paving a new way to independent drug screening modality for detection of drugs binding to the hemozoin surface within the digestive vacuole of the malaria trophozoite.

23.4
Conclusions

In the earlier sections, we have systematically explained the principle, the concept of design, the instrumentation, and the applications of SNGM. Benefiting from the near-field confinement in the gap of the tip antenna and the sample surface, SNGM achieves tight confinement of the optical field and high spectroscopic sensitivity from a nanometer-sized illuminated area. In addition, the sharp tip and the sample/substrate form an integrated unit in near-field optical microscopy. Therefore, the tip material, the tip–sample distance, and the substrate material are all key factors that need to be seriously taken into account in order to achieve an optimal performance. From the instrumentation point of view, designs such as side illumination and top illumination help to break the limitation concerning the transparency of the sample/substrate, which enables the application of high-resolution near-field optical microscopy in a variety of fields ranging from fundamental research to industrially oriented topics. Furthermore, the combination of optical microscopy and scanning probe microscopy in SNGM provides both optical and topography information correlated at the nanometer scale, which defines its extraordinary position compared with conventional optical microscopy. In summary, high-resolution SNGM is finding its way to a broad acceptance and application in the development of nanophotonics and nanotechnology.

Trends in Bioanalytical Spectroscopy

Willem M. Albers

24.1
Introduction

In the new millennium, many new breakthrough technologies in the field of bioanalysis have emerged, spurred, among others, by the efforts in microsystems and biosensor development in the United States, Japan, and Europe from the 1990s onward. For instance, two microarray platforms for bioanalysis with optical detection have recently been commercialized [1, 2], and various lab-on-a-chip systems for bioanalysis have also appeared on the market, although they still have to show their ultimate potential [3]. The general trend is to combine bioanalytical devices increasingly with nanotechnology, because of the nanomolecular scale of the analytes themselves [4]. In the near future, miniature bioanalytical systems for self-monitoring will likely become portable and, for instance, easy to linkup with mobile phones or other mobile devices. At the other end, in the area of laboratory medicine, highly automated facilities have been developed that reduce hand labor. A recent example of this kind is the DNA analysis facility for forensic analysis that was installed in Pretoria by Tecan AG, as an initiative of the European Union, to reduce the crime rates in South Africa [5]. The major bioanalysis application fields are forensic analysis, food analysis, environmental analysis, and clinical diagnostics, while the field of *biodefence* has also received increased attention. Although the main focus of this chapter is on clinical diagnostics, some of the trends and prospects of the others will also be indicated.

In the realm of biosensor technology, there has been a steady pace of development and commercialization since 1990. In the European Union especially, there have been many European Commission-funded programs that modify and integrate biosensors, and various novel prototype devices have been constructed. The results of most of these programs can be found in the journals *Biosensors and Bioelectronics* [6] and *Sensors and Actuators B* [7]. Besides new approaches, the more conventional techniques of evanescent wave-based methods, particularly surface plasmon resonance (SPR), have steadily matured. The theory and applications of SPR have been covered in a handbook and various reviews [8–12], and more than 20 commercial vendors have emerged during the last 10 years.

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

Particularly in the context of *omic* methods of bioanalysis, optical methods, and biosensor array systems hold new, exciting possibilities, although in many cases the new concepts still need to ripen, and the techniques further polished, such that they can become useful for the common user, or in the application laboratories. Although in the majority of cases, novel bioanalytical methods are still based on conventional sample handling, separation, and detection techniques, certain basic skills and know-how will always be required. The increase of technological possibilities, however, has given rise to a new bottleneck in this respect: novel technologies call for novel skills, and the training of skilled personnel does not always proceed in pace with the rates of development of new equipment [13]. For instance, the ‘‘Flexchip’’ SPR protein array system for functional proteomics research, originally developed by HTS Biosystems, and later marketed by Biacore, may have the power of simultaneous real-time measurement of up to 400 molecular interactions, but the attachment of a large collection of receptors on the surface is still a far from trivial matter. At present, the Flexchip system is no longer available, because of lack of demand. Thus, in many cases, it may prove useful to downscale the instrumentation such that it is more compatible with the size of the problem. Another persistent problem, particularly with designing assays for protein analytes, is that many novel detection methodologies reported in the technical literature have not been assessed in realistic matrices, such as serum or urine [14]. Therefore, this chapter will also briefly discuss some of the demands that are required of diagnostic tests.

24.2
Recent Progress in Holistic Methods of Bioanalysis

The mapping and functional analysis of all substances present in the human body, ranging from inorganic compounds and small organic compounds to large biopolymers (carbohydrates, proteins, and nucleic acids) has always been of primary concern in medicine, both for diagnosis and therapy, but at present is a driving force behind *theranostics* and *personalized medicine*. The main idea of comprehensive *omic* technologies – such as *genomics* and *proteomics* – is to come closer to a holistic understanding of biological processes, starting from the gene sequence, and through this improve our concept of medicine in practice, in which we identify more and more the underlying *causes* of disease instead of merely fighting *symptoms*. This paragraph pertains to give only a brief outline of the methodologies that have lately appeared. The *-ome* suffix likely has its origin in the word *Biome*, coined in 1916 to refer to an ecological community of organisms in a confined environment. *Biomes* were defined as: *the world's major communities, classified according to the predominant vegetation and characterized by adaptations of organisms to that particular environment* [15]. Biomes have changed and moved continuously during the history of life on our planet, and it is evident that human activities have drastically altered it in the last century.

In many cases, the prefix *functional* can be added to the basic *omic* term to imply the mapping of function of the components, such as *functional genomics* to map the function of genes [16, 17], and *functional proteomics*, to map the functions of proteins [18, 19]. With respect to the knowledge of the functions of genes, the situation has long been in an infant stage, as the functions of the majority of the human genes are not yet fully understood after sequencing of the human genome. Initially, the scientific community has irreverently referred to >95% of the genome as *Junk* DNA, but this picture is now changing [20]. Especially, the ENCODE consortium, founded in 2003, has set the goals to identify all functional elements in the human genome sequence, and the first pilot results, covering 1% of the human genome, were recently published in *Nature* in 2007 [21]. The most relevant *omic* technologies are summarized in Table 24.1, with references to the important internet sites for compiled databases or important projects. The annotated proteomic databases have been setup in 1990s, and they have been continuously expanded, while new ones have been added. All these databases will likely have a large impact on diagnostic and therapeutic product development and biomarker and drug discovery in the near future.

Drug discovery is mainly concerned with screening of small organic compounds against a range of receptors relevant in disease control, but screening of peptides, either produced by organisms or by combinatorial chemistry methods, has also become an important area of focus. Completely new approaches for screening very large numbers of biochemicals have been devised [22]. In *Pharmacogenomics*, the main purpose is to map the influence of genetic variation on drug response in patients by correlating gene expression or single-nucleotide polymorphisms with a drug's efficacy or toxicity. This would pave the way for a rational means to optimize drug therapy and arrive at some form of *personalized medicine*, in which drugs and drug combinations are optimized for each individual's unique genetic constitution [23].

The field of *genomics* is at present the most extensive. Valuable results have sprouted from the human genome project and these have spurred the development of novel, advanced tools for replication, sequencing, and analysis of nucleic acids. As a logical consequence of the advances in genomics, the *proteomics* field appeared in tow [24–27]. Both genomics and proteomics rely heavily on gel electrophoresis (GE), capillary electrophoresis (CE), and capillary array electrophoresis (CAE) [28, 29].

From a spectroscopic point of view, the most interesting methods for detection of nucleic acids still lie in fluorescence detection in the visible and near-infrared (vis–NIR) region (400–1100 nm) [30]. The most important techniques are laser-induced fluorescence (LIF) and fluorescence *in situ* hybridization (FISH), while upconverting phosphor particles (UPTs) have also been used as highly effective labels for laser detection with very low background [31]. FISH comprises many variants for probing DNA sequences for diagnostic purposes [32] and is particularly suited for lab-on-a-chip devices [33], while LIF is still much used in sequencing technologies. The UPTs, however, have been used in very sensitive nucleic acid assays in a lab-on-chip format, technology that has been recently commercialized and clearly points in the direction of future POC devices (point-of-care) for bioanalysis.

Table 24.1 Established omic methodologies and their main databases on the internet.

Name	Scope	On-line databases	Other sites (projects)
Genome	The sum total of an organism's genes at the DNA level (genotype)	NCBI/Entrez (OMIM and others) *http://www.ncbi.nlm.nih.gov/sites/gquery* Ensembl: *http://www.ensembl.org/*	Functional genomics initiative ENCODE: *www.genome.gov/10005107* and *http://genome.ucsc.edu/ENCODE/*
Proteome	Characterization of all proteins of an organism	UniProt: *http://www.uniprot.org/* (PDB) *http://www.pdb.org/*	*http://www.eupa.org/*
Transcriptome	The mRNA complement of an entire organism, tissue type, or cell	Genevestigator: *https://www.genevestigator.ethz.ch*	—
Metabolome	The collection of all metabolites in a biological organism, which are the end products of its gene expression	*http://www.hmdb.ca/* *http://www.husermet.org/70.php* *http://www.bmrb.wisc.edu/metabolomics/* *http://mmcd.nmrfam.wisc.edu/*	*http://www.metabolomics.ca/* *http://www.husermet.org/*
Lipidome	Large-scale study of non-water-soluble metabolites	*http://www.lipidmaps.org/* *http://lipidbank.jp/*	*http://www.lipidomics.net/*
Glycome	Entire collection of carbohydrates of an organism	Not yet established (2008)	Various small projects
Epigenome	A whole-genome approach to map environmental or developmental epigenetic effects on gene function	*www.epigenome.org*	*http://epigenome.eu/en/4,11,0* *http://www.epitron.eu* *http://www.gen-au.at*

The mapping of functions of genes relies heavily on *expression mapping* by DNA microarray technology [34]. This technology is based on fluorescent labels and utilizes a large number of DNA probes immobilized on glass slides by a photolithographic, combinatorial technique. For instance, the field of *transcriptomics* – which attempts to map the total messenger RNA expressed in a cell or tissue at a given point of time – makes extensive use of the gene chip technology.

Apart from fluorescence detection, mass spectroscopic methods have gained momentum in various genomics and proteomics methodologies [35–37], particularly, in *lipidomics* [38, 39]. The mass spectroscopic methods invariably make use of novel time-of-flight (TOF) or quadruple time-of-flight (Q-TOF) systems coupled to high-performance liquid chromatography/mass spectrometry (LC/MS), usually through electrospray ionization techniques (ESI) or via spotting on plates and subsequent matrix assisted laser desorption ionization time-of-flight (MALDI-TOF) analysis. In addition, chromatography coupled to tandem mass spectroscopy is more and more applied to the determination of whole panels of small metabolites, for example, in the field of lipidomics [40] and in endocrinology [41]. In addition to mass spectroscopy, NMR spectroscopy has become important, for example, in the field of *metabolomics* [42, 43].

Much effort has been put recently in *functional proteomics*, which attempts to map specific functions of proteins. This field is evolving fast, and various novel tools have been introduced for the study of protein–protein interactions, quantification, and comparisons of protein expression [44]. Array biosensor systems, particularly, are considered attractive in this field, although their use is still not common owing to the problem of routinely constructing large protein arrays [45].

Maybe the most significant activity in the last five years has been the search for new biomarkers by hyphenated methods, in which mass spectroscopy is coupled to other separation/detection techniques, such as microfluidic devices, solid-phase extraction, chromatography, or electrophoresis [46]. In this area, surface-enhanced laser desorption ionization (SELDI)-TOF has emerged as a popular, high-throughput tool, in which the proteins are fractionated by adsorption onto surfaces with different functionalities [47–49]. The method, however, suffers from the disadvantages that certain proteins can be missed [50], and that, for routine clinical practice, the reproducibility still needs to be improved [51]. Although analytical methods, particularly when coupled to database search capabilities, have the potential of speeding up the process of biomarker discovery, it should be realized that this is only the first step in a longer chain that includes prioritization, sample preparation, validation, marker development, and final product development. Sample preparation seems to be already a critical stumbling block in this process [52].

In the realm of bioanalytical sciences, antibody technology has kept its firm position as a tool for molecular recognition. Moreover, the *hybridoma* technique has still kept its prominent place. It is based on a sequence of (i) immunization and expression of antibodies in mice, (ii) selection of cell lines from the spleen that produce the appropriate antibody, and (iii) their fusion to cancerous myeloma cells to give a good yield of highly specific, high-affinity antibodies in cell culture. With this technique, antibodies can be produced with sufficiently high affinity and selectivity to tackle the most difficult problems of protein analysis. The recently introduced *immunoproteomics* field, which is concerned with the characterization of all proteins with ligand recognition capabilities, may yield interesting new possibilities in this area [53]. However, standard immunization approaches sometimes fail to give monoclonal antibodies with the desired specificity. Recently, *subtractive immunization* has been used for the production of monoclonal antibodies, which are otherwise unobtainable, by targeting specific epitopes within the proteome. This has given rise to the field of *epitomics* [54]. The adaptive immune system has acquired a large store of recognition DNA sequences, which are generated from peptides of microbial pathogens. This process takes place via the major histocompatibility complex (MHC). The MHC is a large collection of proteins that keep up a cycle of antigen recognition, processing, and representation to effector cells of the adaptive immune system (B and T cells). Changes in the profile of the signaling peptides give rise to an alert to the effector cells. The changes may be related to infection, but also to malignant transformations or anomalous cellular processes. This gives a cascade of microbiological reactions that ultimately results in the elimination of the affected cells, and generates an immunological memory.

For comprehensive characterization of bioactive peptides, the field of *peptidomics* has been recently introduced [55, 56]. Peptidomics aims to construct databases of all peptides that exist in a tissue or body and the changes in their expression. Already highly sensitive techniques for the separation and sequence determination of peptides with very low abundance have been devised, enabling the screening of peptides that could earlier not be easily identified [57]. For instance, a peptidomic approach has recently been applied to the identification of specific peptides with a role in cardiac failure [58].

The field of *metabolomics* is directed to characterization of all low-molecular-weight metabolites in an organism. Recently, a Canadian consortium of scientists compiled a preliminary draft of the human metabolome, in which some 2500 metabolites, 1200 drugs, and 3500 food components were listed that could be identified in the human body [59]. *Lipidomics*, a related field, is also rapidly expanding, and is concerned with multiple techniques to characterize hundreds of chemically distinct lipids in cells and determine the molecular mechanisms through which they facilitate cellular function. Recent developments in ESI-MS have enabled the precise identification and quantification of alterations in a cell's lipidome after cellular perturbations [60]. Within the collection of low-molecular-weight compounds with biological function, ions also play a key role, and the term *ionome* was recently introduced to include all the mineral nutrient and trace elements found in an organism [61]. A subset of the ionome, the *metallome*, has also been proposed to designate all the metal ions in an organism [62, 63].

Phosphorylation – by protein kinases – takes place in all fundamental cellular processes, and is a major signaling mechanism in eukaryotic cells. Nearly every property of a protein is regulated by phosphorylation. Thus, characterization of all protein kinases is an important task, and for this purpose the *kinome* has been introduced, which is the *kinase complement of the human genome* [64]. At present, the methodology only provides a starting point. For understanding the scale of the problem, it should be realized that the kinome consists of ''only'' 518 kinases, but each kinase phosphorylates a distinct collection of substrates in a regulated manner. Approximately one-third of all intracellular proteins are phosphorylated and this may give rise to as many as 20 000 states of phosphorylation.

The field of *epigenomics* had already been proposed in 1999 [65] and, at present, *epigenetics* is a particularly hot topic [66, 67], having its origin in the gene regulation theories of Waddington, who proposed the terms *epigenotype* and *epigenomic* *landscape* in 1939 to describe developmental processes of gene expression that were above, or in addition to, the classical genotype [68]. The primary subfield of epigenomics now is *methylomics*, a term coined in 2001 by Feinberg, concerned with the characterization of methylation patterns on the CpG sites of the genome [69]. The bioanalytical methods used to detect genome-wide methylations are very similar to those for normal DNA analysis, and make extensive use of bisulfite modification of methylated DNA [70].

To conclude the conspicuous list of *omes*, the *bibliome* should not be missed out: the bibliome pertains to data mining of the scientific literature, and novel ways of classifying and sorting scientific results. Indeed, new computing tools are needed to effectively scan the growing amount of scientific literature for useful information [71]. In fact, with the growth of the genomic/proteomic databases, such as (Online Mendelian Inheritance in Man), and various new developments in bioinformatics, this is already slowly materializing for the life science sector, and may serve as a good example for other, more technical sciences. At least the *Chemical Abstracts Service* has already come closer to the ideal of the bibliome by providing a new, intelligent search facility: *SciFinder* [72].

24.3
The Road to Personalized Medicine

Clinical research is at present strongly focused on the use of new devices and analysis platforms for future personalized medicine and theranostic approaches to medical treatment. Key roles in this development have initially been those of biosensor research and new nanotechnological innovations, such as microfluidics. These were combined into new lab-on-chip devices, which started to flourish strongly in 1990s [73]. At present, there are many successful commercial lab-on-chip type analyzers on the market. The first ones were the *Affymetrix GeneChip®* systems [74], based on photolithographically produced high-density DNA arrays. At present, Invitrogen has commercialized various high-density protein arrays (*ProtoArray®*) [75]. Furthermore, microfluidic electrophoresis-based devices have been introduced by Agilent, the *Agilent 2100 Bioanalyzer*, which is used for DNA, RNA, protein, and cell analysis on a single platform [76].

The first key enabling technology toward personalized medicine comprised that of biosensors. According to the definition, biosensors are devices that utilize a biomolecule for the determination of an analyte by intimate coupling of the biomolecule to a suitable detection device. Although biosensors can be based on electrochemical, piezoelectric or calorimetric principles, many biosensor types are based on optical phenomena and can therefore be placed in a spectroscopic context [77–81], such as fiber-optic biosensors based on novel molecular probes [82, 83]. Unfortunately, conventional *molecular probes* or *indicators* are repeatedly designated as sensors, even when they are applied *in vivo* as biosensors. In addition, the more recent term *colorimetric sensor arrays* has been used for indicator arrays, which are also not real sensors, but merely indicator strips, albeit more versatile ones. This misuse of terminology has given rise to a small dilemma when classifying the literature properly for reviewing. According to the IUPAC definition, a biosensor is a device that uses specific biochemical reactions mediated by isolated enzymes, immunosystems, tissues, organelles, or whole cells to detect chemical compounds usually by electrical, thermal, or optical signals [84]. A more recent definition states that ''*a chemical sensor is a device that transforms chemical information, ranging from the concentration of a specific sample component to total composition analysis, into an analytically useful signal. Chemical sensors usually contain two basic components connected in series: a chemical (molecular) recognition system (receptor) and a physicochemical transducer. Biosensors are chemical sensors in which the recognition system utilizes a biochemical mechanism*'' [85]. Some additional requirements, however, were also introduced in the latter IUPAC definition: (i) a biosensor should use a compound of biological origin as the sensing element, (ii) biosensors should be ''*self-contained, all parts being packaged together in the same unit, usually small, the biological recognition element being in direct spatial contact with the transducing element*,'' and (iii) biosensors should be clearly distinguished from an analytical system, which uses additional separation steps and sample processing, such as reagent addition. Thus, ideally a biosensor should work, for instance, as a pH meter, providing a real-time readout of the concentration of an analyte in its natural environment and follow the changes in concentrations reversibly without the need for flow cells or other devices for liquid handling. This ideal has been realized to date only for very few catalytic sensors (e.g., based on enzymatic action). For affinity biosensors, however, the term *single-use biosensor* or *dosimeter* would be more appropriate. Some have allowed a slightly broader definition of a biosensor as a device that provides a quick readout of the concentration of an analyte without the need for adding reagents [86]. This would mean, however, that affinity-based assays in which a regeneration step is included to enable multiple use of the sensor, as is the case with some immunoassay systems, may not be called *biosensors*. However, it is difficult to find equipment in the clinical laboratory that does not do any sample handling, because of the great amount of samples that need to be processed. Furthermore, the samples all need to be ''sensed'' under standardized conditions, meaning that at least a measurement medium (matrix) will need to be added, as is the case for all clinical samples, which are collected in standardized vacuum tubes with appropriate collection media. In the light of a vast number of new publications in the area of biosensors, more appropriate definitions might still be formulated.

Biosensors can be generally divided into catalytic and affinity biosensors, the former making use of enzymes and the latter of antibodies and various types of receptors. Immunoassay fits particularly well in the realm of spectroscopy, because the majority of immunoassay techniques are based on colorimetric enzyme-linked immunosorbent assay (ELISA), fluorescent [fluoroimmunoassay (FIA), fluorescence resonance energy transfer (FRET)], or electrochemiluminescent labeling techniques, sometimes enhanced by evanescent wave phenomena at surfaces. However, novel, sensitive, nonoptical detection methodologies are also gaining ground, such as methods based on as magnetic labels, and these are already forming a strong competition [87].

The first (real) biosensor system was commercialized in the early 1970s by Yellow Springs Instrument Co. (YSI) and was used for the determination of glucose in blood, urine, and bioprocesses. In 1980s, relatively little commercial activity was observed, but new sensor types were developed at a rapid pace in many research laboratories. There were many successful demonstrations of biosensors based on electrochemical, optical, microcalorimetric, and piezoelectric transducers, and an amperometric biosensor based on ferrocene mediators for glucose determination was soon commercialized [88].

In the 1990s, a number of new sensor technologies moved successfully from the research laboratory into the market place, and the amount of commercial biosensor systems for bioanalytical applications has been constantly growing thereafter. At present, biosensor technology is a mature research field that is yielding many new commercial applications in the form of rapid test devices and larger laboratory instruments. Today, biosensing instruments have application potential in diagnostics, functional proteomics, environmental monitoring, drug discovery, process industry, and food analysis [89].

Advances in optical biosensors have contributed significantly to the speed of bioanalysis by supplying real-time monitoring of biological binding reactions, without the need for labeling of biomolecules (real-time bio-interaction analysis or BIA). Optical sensor platforms have traditionally been used in a number of proteomics subfields, such as antibody screening and epitope mapping, or in drug discovery [90, 91]. For instance, the new Octet® sensor, which has been recently introduced on the market, is able to follow protein reactions through the use of eight parallel disposable sensors applicable directly in microtiter plates [92]. SPR, however, has still kept its leading position. With SPR, very small refractive index changes close to a metal surface can be detected, and this technique has flourished over the last 20 years [93–96]. The use of the SPR technology in clinical diagnostics, however, is not yet firmly established, mainly because of the fact that direct detection of low-molecular-weight compounds or detection below nanomolar concentrations has serious limitations [97]. However, the use of amplified SPR techniques have recently shown great potential, in which the SPR signal has been enhanced with nanoparticles (latex or gold labels) [98, 99].

Although optical biosensor research efforts have contributed much to the development of the large analysis platforms for DNA and protein analysis that will find their place in the realization of theranostics and personalized medicine in the near future, still there are serious technological, educational, economical, and legislative hurdles to be overcome before personalized medicine can be adopted in the wide sense as it has come to be understood in the last 10 years [100–103]. However advanced the technology may become, the more conventional clinical diagnostic practices should not be or lost out of sight and some pertinent issues related to this subject are further summarized in the following.

24.4
Clinical Diagnostics

24.4.1
Introduction

Clinical diagnostics is generally concerned with the determination of biochemical substances for a variety of purposes. This can be

1) *screening*–the early detection of disease in a segment of the population;
2) *clinical diagnosis*–confirmation or rejection of a disease;
3) *monitoring*–in which the history of a disease or response to treatment is followed in time; and
4) *prognosis*–which assesses the outcome of a disease or treatment.

Clearly, all these types of diagnostic measures place their own specific demands on the test. Screening tests generally need to be cheap and fast. For instance, the screening test for phenylketonurea (PKU) in newborn babies is – in most test kits – still based on a *fluorometric* test designed in 1962, utilizing the formation of a fluorescent product of phenylalanine by reaction with copper and Ninhydrin [104]. The modern version of this test is a mere adaptation to microtiter plate format [105]. Screening tests generally need to have a large sensitivity, such that positives are not missed. Follow-up testing is generally used to verify the positive cases, and diagnose the illness further. In case of PKU, the follow-up testing generally means a genetic test to determine the severity of the disease [106]. For clinical diagnosis, however, the testing needs to be more precise. The occurrence of false positive or false negative results has to be minimized as much as possible (Section 24.4.2). Monitoring of a disease state requires the possibility to do either continuous measurements (biosensors are ideally suited for this) or to easily provide for repeated measurements (such as with blood glucose monitoring for diabetics).

In diagnostics, yet another division can be made into three types, depending on the *closeness* of the test to the patient:

1) Over-the-counter (OTC) tests, which are sold to the common user, such as pregnancy and glucose test devices, and which need to be economically priced. The result should also be simple (generally a *yes* or *no*), and produce no ambiguity to the end user.
2) POC devices, which are used near the patient in health centers, doctor's offices, and also in hospitals, for instance near the emergency unit. These instruments should present a more reliable quantitative result and can be more expensive.
3) *Centralized* (*hospital*) *testing* by dedicated instruments that are routinely used to test a large amount of substances with great reliability. The price of these instruments is generally very high, but the price per sample can be low, owing to high throughput. The main issue is reliable measurement and validation at various levels.

For the larger part, diagnostic tests are based on immunological reactions, in which antibodies are used for the selective binding of the analyte (immunoassay).

The two most common formats of immunoassay are briefly explained in Figure 24.1. In the field of research and development of POC devices by small, pioneering firms, the goal is generally to design instruments that are capable of reliable quantitative testing, but are at the same time affordable to the smaller health centers or at home. For devices based on immunological reactions, this forces the multistep procedure to be simplified, for example, by fluid handling in a microfluidic device. The main driving force behind POC diagnostics is the increasing interest of the public for self-monitoring and the demand for quantitative results. The term *worried well* has often been coined, to describe an increasing segment of the population that is *well off*, but *worried* about their health condition, and this is seen as a new opportunity for small instrument producers. Even then, interpretation and validation of the test result by physicians is needed in most cases, and this may be an inhibiting factor for many types of home testing devices. The major challenge, at present, is to extend the applicability of POC devices to molecular diagnostics, that is, DNA detection or DNA sensing.

To conclude, with regard to methods for collecting samples, it is fortunate that nowadays samples are taken in a standardized manner, which is particularly the case for blood sampling (venipuncture or *phlebotomy*), where the use of vacuum tubes has greatly reduced the risk of infection and increased reproducibility of the determinations. When the test includes a part that will be come in contact with the patient sample, however, that part always needs to be disposable. Sometimes, it is important that tests are adapted to a specific format (e.g., microtiter plate) to facilitate better logistics and throughput.

24.4.2
Evaluation of Diagnostic Tests

The acceptance of a clinical test or method is, just like drug acceptance, a multistage process in which various sources of variance and error are rigorously evaluated, because a wrong test result may give an incorrect diagnosis, and thus a wrong decision, which may endanger human life. Although evaluation of new bioassays is generally performed in laboratories of the pharmaceutical and diagnostic industry, many new developments are offered by universities and contract research organizations, and these institutions should be aware of some of the common pitfalls in bioassay development.

Clinical diagnosis comprises various forms of testing, and each type imposes its own set of requirements to the analytical methodology. The usual chain in the diagnosis of disease starts on the technical level, with evaluation of the measured quantity and the analytical result, in which error checking, quality control, analytical evaluation, and evaluation of interferences are the main activities [107]. On the technical level, there are many possible sources of error and deviation, which are inherent to the test itself, but which also have an origin in the disease statistics. One important factor, frequently overlooked in the research phase, is the occurrence of interfering species that may invalidate the test [108]. Therefore, methods that use more specific detection schemes will always be preferred. For instance, in

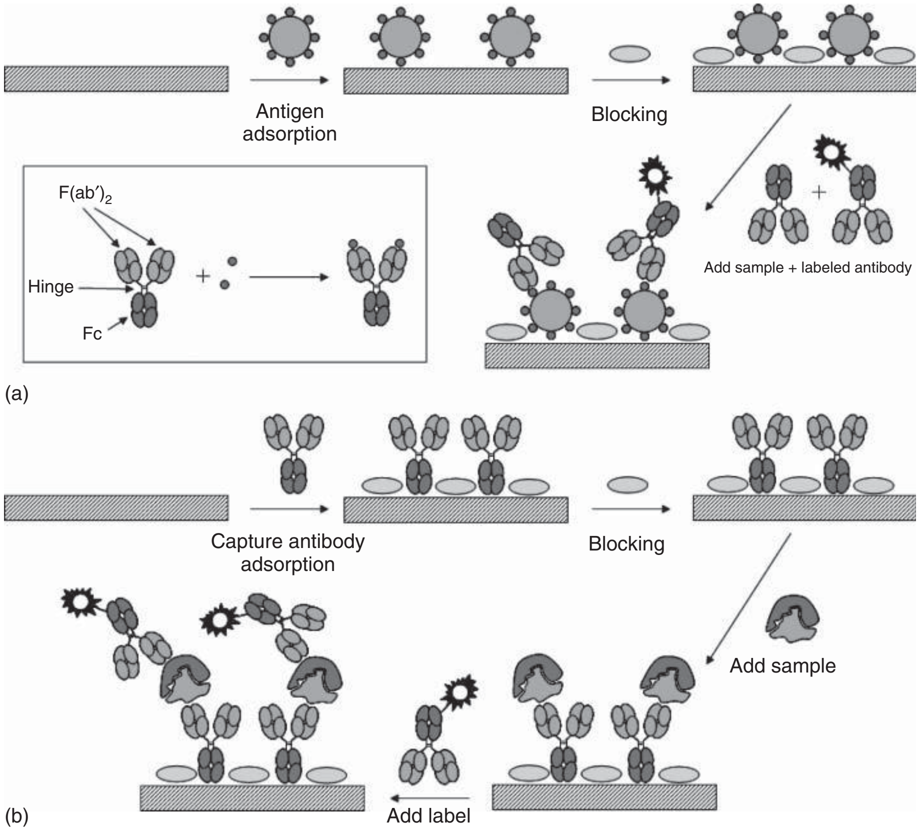

Figure 24.1 Two common formats used in clinical immunoassays. The inset shows the structure of an IgG molecule, consisting of one Fc domain and two Fab domains, linked together by a hinge. The Fab domains are ‘‘antibody binding’’ and one IgG is able to bind two antigen molecules. (a) Competitive assays are based on the competition of a labeled species with another species in solution for a limited amount of binding sites on the surface. Competitive assays can be designed in a variety of ways. In this example, a competitive assay is depicted for determining the antibody concentration in a sample, using a surface-immobilized antigen conjugate. First, an antigen conjugate is immobilized onto a suitable surface. After washing the surface, remaining space on the surface is filled up with suitable ‘‘blocking’’ protein that effectively blocks the surface from further nonspecific adsorption reactions. After washing, a sample is added that contains an unknown amount of unlabeled antibody against the antigen and a known amount of labeled antibody. The bound amount of labeled antibody will thus have a reciprocal dependence on the antibody concentration; if there is more antibody in solution, a lower proportion of labeled antibody will bind. (b) Noncompetitive (sandwich) assay making use of two antibodies that recognize different sites of the antigen (‘‘epitopes’’). One antibody is immobilized on the surface and the other one is labeled. After the sample is added, the antigen molecules will be bound to the surface; the labeled antibody is added after a washing step. The amount of label is measured after washing the excess of label from the surface. Labels can be enzymes, fluorophores, gold particles, or latex particles.

immunological tests, a sandwich assay is (in principle) more specific than a direct binding or competitive assay, because the analyte is detected by two antibodies instead of one. However, interfering species may also exist in sandwich assays and give rise to a false positive result [109].

Diagnosis of a disease is not solely dependent on the type and characteristics of the analytical method but it also depends on the *disease statistics* and the *purpose* of the test. Obviously, the analytical method should have selectivity, sensitivity, lower limit of detection, dynamic range, and accuracy sufficient for quantitation of the analyte or biomarker to establish a reliable diagnosis. Sometimes, these demands are not particularly stringent, sometimes they are. The validity of a test is defined as the *agreement of the test result with what the test was intended to determine*, such as presence of a bacterium, virus, or an abnormal value of a metabolite, protein, or drug. In addition, a valid diagnosis needs a correct assessment on the *biological level* (for the patient) and needs to be interpreted correctly in the frame of the known disease statistics (*nosological level*). Already in the former, the diagnosis of disease is far from straightforward, because the gender, age, disease history, and background of the patient will all have a bearing on the final diagnosis. A valid clinical result may even indicate more than one possible disease. Generally, a longitudinal evaluation (related to the history of the individual patient) and a transversal evaluation (related to the general disease statistics of healthy subjects compared to subjects with a disease) is performed for any new prospective diagnostic test. The largest uncertainties in laboratory findings arise from the classification of disease at the nosological level, where, in the end, new insights in disease patterns may give cause to search for new, more reliable analytes and markers [110].

When a diagnosis is based on the determination of abnormal values of a biochemical compound (analyte or marker), there will usually be some overlap of the distribution of concentrations in healthy subjects and the distribution of concentrations found in subjects with the disease (Figure 24.2a). There is nearly always a *gray area* where both distributions overlap, and it is in this area that false positive and false negative results are found. Although it may seem that this statistical factor is independent of the analytical characteristics of a test, the fact remains that some tests produce higher amounts of false negatives or false positives in comparison with other tests. Generally, hospitals will set the diagnostic cutoff concentration (Figure 24.2a) to a value, where the specificity and the sensitivity[1] of the test are both maximized to acceptable levels, but this will never completely remove the chance of encountering a false positive or false negative result. Instead, the location of the cutoff value of the test will depend on the prognostic purpose of the test: when the sensitivity of the test is more important than the selectivity (e.g., in screening where positives may not be missed), the diagnostic cutoff will be put at a lower value in the overlap area, but it will reduce the selectivity of the test.

---

[1] Note: Here the terms *ensitivity* and *specificity* have a different meaning compared to the normal analytical context: specificity indicates the incidence of negative results in persons that are free of the disease, and sensitivity indicates the incidence of a positive result in patients that have the disease.

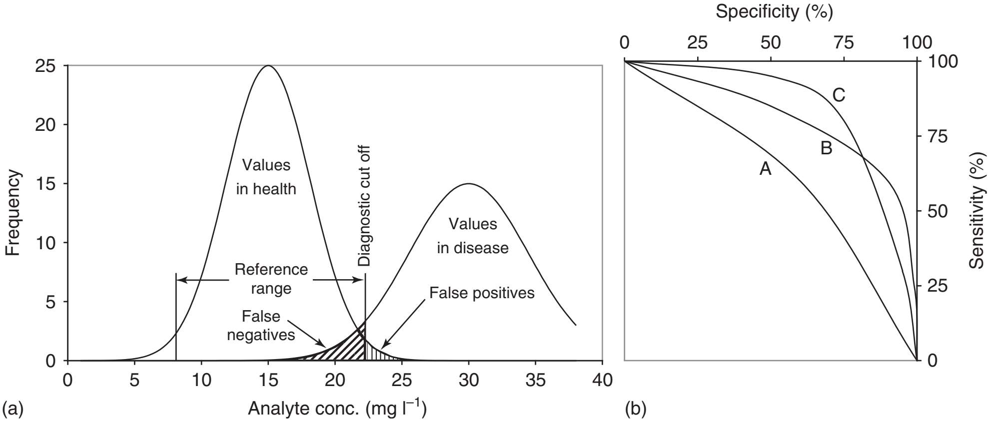

Figure 24.2 (a) Schematic representation of the overlap of concentration distributions of healthy subjects and subjects with disease. The efficiency of the test, corresponding to the overlap of the curves, is (TP + TN)/(TP + TN + FN + FP), where TP is the amount of true positives, TN is the amount of true negatives, FN the amount of false negatives, and FP the number of false positives. The specificity of the test is defined as TN/(TN + FP) and the sensitivity of the test as TP/(TP + FN). The diagnostic cutoff of the test was chosen slightly to the right, such that the specificity of the test is relatively high, but the sensitivity is relatively low. The predictive value for a positive result (PV+) is TP/(TP + FP) and the predictive value for a negative result (PV−) is TN/(TN + FN). (b) ROC curves for three hypothetical tests A, B, and C. In case of test A, the performance is relatively poor: both specificity and sensitivity are low. In test B, it has predominantly better performance, and a particularly good specificity, while test C has the highest sensitivity. Test C could be preferred as a screening tool over A and B.

Diagnostic tests are generally compared by the use of ROC curves (*receiver operating characteristic curves*), in which the specificity is plotted against sensitivity by varying the diagnostic cutoff, as illustrated in Figure 24.2b. Any new test should have at least a similar ROC curve as the preferred test, before it can be accepted.

Although nosological evaluations are usually not available to the researcher, knowledge of them is always needed. The best designers of clinical tests are the ones that actually work with patients on the hospital ward, because they know the demands in great detail and have experience in accessing how patient variables and factors of disease classification and statistics are to be taken into account. Therefore, it is favorable to include a major hospital laboratory or a clinical chemist in the research projects, if not to participate actively, at least to sit in the project meetings. Despite the fact that some of the higher aspects of clinical evaluation are out of reach of research organizations, it is favorable to include the following assessments in the development work:

1) work with real clinical samples at an early stage;
2) test for some common, known interferences;
3) make a correlation test with an established assay.

Once these three principles are followed, we may actually get to the point that clinicians start to have some interest in a new detection method.

24.4.3
Analytes of Clinical Interest

24.4.3.1 Inorganic Ions and Blood Gasses

To give a short overview of the substances of analytical interest that can be found in the human body, we begin with the first class of substances, which comprise inorganic ions and dissolved gasses. The majority of inorganic ions of biological importance are routinely determined with ion-selective electrodes, the operation of which is based on the permselective exchange of ions into a hydrophobic membrane phase [111, 112]. To achieve optical transduction, the ion–receptor complex formation will be intrinsically coupled to a physicochemical process of a light-absorbing or fluorescent dye compound. Such sensing matrices are used frequently in conjunction with fiber optics for the construction of miniature optical sensors, or *opt*(*r*)*odes* [113]. Another way to interrogate the binding of ions to ionophores at the boundary of two phases is to use second harmonics generation (SHG) [114].

A first means to achieve optical transduction is to include a lipophilic acidochromic dye (chromoionophore) into the membrane phase together with the receptor. The complexation of the metal ion by the ligand will expel a proton, which changes the absorbance spectrum. When a change in fluorescence properties is accomplished, we generally refer to *fluoroionophores*. The advantage of the approach is that no synthetic modification of the receptor or dye is needed, but the disadvantage is that these sensors have pH dependence, and buffering at an appropriate pH is necessary. Originally, lipophilic Nile blue (phenoxazine) derivatives were much used, but acridine, fluoresceine, and various other synthesized chromoionophores have also been described with signal-transducing properties [115–118]. Many of these ion receptors are commercially available from Fluka AG [119]. These sensors also have *practical* significance in clinical assays, as illustrated by Hisamoto *et al.* [117] and Wang *et al.* [116], who have described the measurement of common ions directly in serum.

In an alternative approach, the complexation of the metal ion may influence the partition of the lipophilic dye in the membrane phase, which can affect the fluorescence yield of the dye. This principle has been demonstrated with potentially sensitive dyes by Wolfbeis and Mohr [120, 121]. This approach is also applicable to the sensing of neutral species, such as 2-phenethylamine [122]. Although the majority of chromo- and fluoroionophores are cast in hydrophobic, (polyvinyl chloride type) membranes, sol–gel matrices have also become very popular [123]. Another interesting technique for making sensing layers is the electrostatic layer-by-layer technique (LBL), which has been recently used in fiber-optic pH sensors [124]. A well-established approach that enables intracellular sensing of various analytes with fluoroionophoresis is the technique called *PEBBLE*, which was acronymized from either *photonic explorer for bioanalysis with biologically localized embedding* or *probes encapsulated by biologically localized embedding*. This technique was initially used for pH and calcium sensing [125] and for potassium sensing [126], but now it is also used for the imaging of Mg^{2+} [127], Cu^{2+} [128], Zn^{2+} [129], glucose [130], and dissolved oxygen [131].

In a third approach, the dye is made an integral part of the receptor, such that absorbance and/or fluorescence parameters are directly modified by the complexation reaction. This is a more developed form of indicator chemistry – *semiochemistry* [132]. Receptor molecules modified with photosensitive groups may display very large changes in their photophysical properties on the binding of analytes, and can enable very sensitive detection. For instance, Chapoteau *et al.* [133] have already reported in 1992 a colorimetric method for the determination of lithium in blood serum, not requiring any sample pretreatment or solvent extraction steps. The chromogenic ionophore exhibited exceptionally high selectivity for lithium over sodium (>4000 : 1). In the same year, Shinkai *et al.* 134 and Diamond *et al.* [135] reported on different azophenol-modified calixarenes for quantitation of lithium. Akkaya *et al.* have reported dyes modified with phenylboronic acid groups for the detection of zinc ions [136] and calcium ions [137]. Zinc detection and imaging in neurons has also been recently reported using a new receptor [138]. Finally, the modulation of luminescent lifetime of luminescent particles in a polymeric material has been used for the simultaneous detection of carbon dioxide and oxygen in plant tissues [139]. With phosphate ion detection, optrodes are still rare, but recently some interesting ionophores for phosphate detection with ion-selective electrodes have been reported [140, 141], and therefore optical transduction may also be feasible. Besides sensors for the clinically relevant analytes, as listed in Table 24.2, sensor materials have been devised for many other ions to be applied in environmental or food analysis, such as nitrate [142, 143], bisulfite [144], mercury, and silver [145].

24.4.3.2 **Low-Molecular-Weight Analytes**

The most relevant low-molecular-weight metabolites and hormones are listed in Tables 24.3 and 24.4. Many metabolites can be determined with enzymatic biosensors, as all metabolites are in principle substrates for enzymes. Thus, electrochemical and optical biosensors have been widely reported [78, 197]. For some smaller-sized analytes, synthetic receptors have been devised, such as receptors for choline and carnitine [198], and creatinine [199]. In the latter, extensive hydrogen-bonding interactions were designed between the analyte and receptor. Signal-transducing synthetic receptors based on azophenol [133, 200], spirobenzopyran [201], antracene [202], or coumarine [203] dyes have also been synthesized. Calixarenes, with covalently linked chromogenic or fluorogenic groups, are especially the most intensively investigated [204]. Modified calixarenes have been produced for sensing of anions [205] and small organic molecules, such as dopamine [206] and 2-phenethylamine [122], and they have been used even for chiral recognition [207]. Moreover, calixarenes have been produced in which fluorescence can be switched on upon binding of the analyte, a principle that can afford far more sensitive sensors than the ones that are based on fluorescence quenching [208]. Recently, a variety of novel squarilium dyes with signal-transducing properties, for example, for carbohydrate detection, have been reported in the literature [209].

Magnesium, Mg^{2+}	0.7–1.0 mM	Hyper- and hypomagnesemia	[127, 192, 193]
Selenium, Se^{2+}	Traces	Myopathy and thyroid function	[194]
Zinc, Zn^{2+}	12–20 µM	Dermatitis and wound healing	[129, 136, 195, 196]

[a] In adults, serum, or plasma.

Home glucose monitoring and *in vivo* monitoring of glucose for diabetic care keeps receiving much attention in research and commercial R&D, owing to the large incidence of diabetes and its strong increase worldwide. Glucose detection still comprises the largest single-analyte market in diagnostics. Although most home glucometers are electrochemical sensors, some tests for detection of glucose in urine still use an older colorimetric method. The most important references for optical glucose detection have been included in Table 24.3. The very first optrode for glucose was reported by Schultz in 1982, and was based on the concanavalin A receptor [271]. This sensor has recently been further improved, and a glucose working range between 0.2 and 30 mM was attained [228]. More recently, the sensor dyes were switched so that the sensor operates in the near-infrared, making it less prone to background fluorescence from serum samples [272]. These sensors are capable of sensitive, long-term glucose monitoring, but have a strong interference from fructose. A much more sensitive and selective receptor for glucose from *Escherichia coli* has also been used [273].

Table 24.3 Some common metabolites.

Substance	Normal values	Relevance	References
Urea	3.3–6.7 mM	Renal function	[133, 153, 210–213]

Adenosine triphosphate (ATP)	—	Energy storage	[257, 258]

For noninvasive monitoring, some direct photoacoustic spectroscopic approaches in the near- and mid-infrared are still under evaluation [259–262]. The new field of terahertz spectroscopy also offers new prospects to probe glucose directly in living tissues (see Chapter 27) [263]. Various intracellular approaches to the ''sensing'' of a range of metabolites, including the PEBBLE technique, have been reviewed by Yotter *et al.* [264], and these methods are compatible with lab-on-a-chip devices.

For the human hormones thyroxine, triiodothyronine, and the steroids (Table 24.4), immunological recognition is commonly used. In fact, the very first radioimmunoassays were applied to T3 and T4 determinations, and they are still in force [268]. Direct optical sensors for the human hormones of low molecular weight are relatively rare, mainly due to the extremely high sensitivity needed. Only one study has described a direct assay for thyroxine by fluorescence quenching of thyroxine-binding globulin [274]. The measurement, however, needed 2 h to reach the maximum signal, and the lower detection limit was still a 100-fold compared to the clinically relevant concentration of free thyroxine in serum. Schrader *et al.* [275] have recently described the fluorescence activation of receptors for catecholamines embedded in cross-linked vesicles consisting of phospholipids and diacetylenes. Measurements could be performed directly in urine at micromolar concentrations.

Molecularly imprinted polymers (MIPs) have yielded interesting possibilities for recognition and detection of low-molecular-weight analytes, such as the steroids, phenethylamines, and catecholamines, and a variety of drug compounds [276–278]. The principle of molecular imprinting is basically simple: a well-optimized mixture of monomers with various functional groups is polymerized in the presence of the analyte, the latter functioning as a *template*. Hereafter, the analyte/template is eluted from the polymer matrix, which leaves cavities in the polymer to which the analyte/template or an analog can be rebound [279–281]. This polymer can then be used in an analytical system or sensor. Artificial enzymes can also be produced by molecular imprinting, in which a transition state analog of a chemical reaction is used as the template molecule [282]. Some reports have already appeared on the combination of fluorescence with imprinted polymers [283]. If the functional monomers are fluorescent and are designed to have specific chemical interactions with the analyte, it is possible to monitor the binding via changes in fluorescence of the polymer directly [284, 285]. For reasons of background and sensitivity, the activation of fluorescence by the binding of analyte to an imprinted polymer would be the most preferred situation, as previously mentioned for the catecholamine sensor [275]. Turkewitsch *et al.* [284] described a first prototype of this novel sensing scheme for template-selective recognition sites in imprinted polymers with cyclic AMP (cAMP). The polymer included a fluorescent dye, a dimethylaminostyryl-pyridinium derivative, as an integral part of the recognition cavity, thus serving as both the receptor and transducing element for the fluorescence detection of cAMP in aqueous media. The imprinted polymer displayed a quenching of fluorescence in the presence of cAMP in aqueous solution, whereas almost no effect was observed in the presence of cGMP. The affinity constant of the polymer for cAMP was about $10^5\ M^{-1}$.

Recently, the possibility to make imprinted molecular thin films has also been investigated with amperometric, capacitive, and SPR-based detection schemes [286–288]. Self-assembled monolayers (SAMs) of organic thiols and disulfides can be formed on gold surfaces in a highly defined way, and when a template molecule is included that does not interact so strongly with gold, it may become coadsorbed with the organic thiol onto the surface. The template molecule can be eluted with a suitable washing solution, and *footprints* may be formed that have the size and shape of the template molecule, allowing rebinding of the template (or an analog), as illustrated in Figure 24.3. The approach may be designated by the *imprinted self-assembled monolayer* (*i-SAM*) technique. The footprint can be formed with hydrophobic, hydrophilic, or bifunctional SAM-forming compounds. After screening several bifunctional lipoate derivatives, the highly effective imprinting of the model drug *morphine* to *i-SAM* layers of a tris(hydroxymethyl)aminomethane-derivative of lipoic acid was observed in an SPR study [288]. When the (re)binding was compared to the binding to an antibody against morphine, very similar binding characteristics were observed (Figure 24.4) [289]. This illustrates that synthetic receptors may have the same application potential as natural receptors in analytical methods.

24.4.3.3 **Protein Analytes**

Proteins are most abundant in the human body, and – although far from complete– Table 24.5 lists some of the most relevant protein analytes from the point of clinical diagnosis. Since many of these proteins are analyzed with immunoassays, no further references are included to specific optical/spectroscopic methods for their

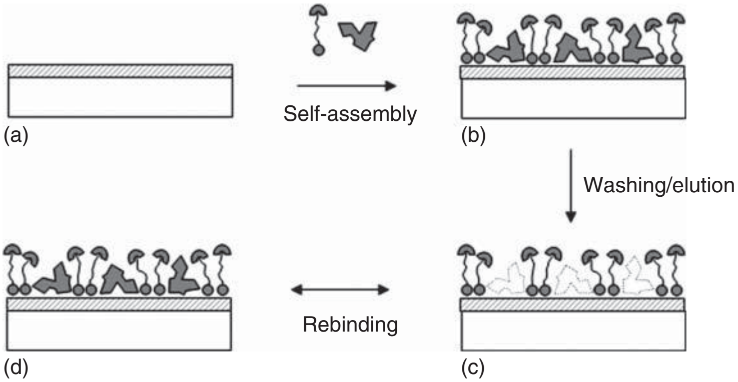

Figure 24.3 Principle of i-SAM formation. To a cleaned gold surface (a) a mixture of bifunctional ligands is added mixed with template (dark grey). The template forms weak complexes with the ligands and settle via one moiety of the ligands onto the gold surface (b). After washing, the self-assembled ligands are left in an arrangement favorable for rebinding the template (binding site shown in dotted lines) or similar compounds (c,d).

detection, but some references are included to functional and structural data of these proteins in the OMIM and PDB databases. Proteins are less suited for the conventional imprinted polymer approaches, because of the susceptibility of tertiary and quaternary structure elements to denaturation in nonaqueous environment and because of the high concentration of monomers, but some recent progress has also been made toward imprinting of proteins [290, 291].

A number of plasma proteins are very abundant and amenable to direct detection. Albumin and immunoglobulins have been determined with various optical sensor systems, of which only a few are mentioned [292–294]. As part of the biological markers, tumor markers are at present in the center of interest, and also the object of large efforts in diagnostics R&D [295]. The most important of these are the ones that are routinely tested in central hospital laboratories and are listed in Table 24.5.

A typical example of a cancer marker is prostate-specific antigen (PSA) an indicator of prostate cancer in men. PSA is a glycoprotein with a molecular weight between 30 and 34 kDa, and is secreted by the prostate gland. PSA is found at high concentrations in semen, and thus it is an important analyte in forensic analysis too. It is an enzyme belonging to the kallikrein family of serine endopeptidases (serine protease EC 3.4.21.77), and sometimes referred to as *kallikrein-related peptidase 3* (KLK3). In clinical assays, PSA concentrations need to be assessed in the concentration range of 0.05–20 ng ml^{-1}, and thus an affinity constant of around 10^{10} M^{-1} or higher would be required of the antibody or receptor in a specific test [296]. PSA detection with biosensors has recently been the subject of intense investigation, predominantly with mass-sensitive sensors and SPR. The direct detection of PSA has been studied by the group of David Myszka, making

Table 24.5 Some human protein analytes.

Protein (MW (kDa))	Normal values in adults	Function/relevance	OMIM and PDB entries
Plasma proteins			
Albumin	35–50 $\mathrm{g\,l^{-1}}$	Oncotic pressure and drug/metabolite transport	103 600/1e78, 1bm0, 1uor, 1ao6
Immunoglobulins (IgM, IgG, IgA, OgD, and IgE)	Total approximately 20 $\mathrm{g\,l^{-1}}$	Immune response and allergy	(IgG) 147 100[a]/1hzh, 1mco (IgM) 147 020[a]/2rcj
Fibrinogen (340)	1.5–4.0 $\mathrm{g\,l^{-1}}$	Blood clotting	134820[a]/1fzc
Hemoglobin (68)	Males: 130–180 $\mathrm{g\,l^{-1}}$ Females: 120–160 $\mathrm{g\,l^{-1}}$	Oxygen transport	141 800 (α1), 141 850 (α2), 141900 (β)/1gzx
Transferrin (76.5)	2.04–3.60 $\mathrm{g\,l^{-1}}$	Iron carrier	190 000/1a8e, 1a8f, 1b3e, 1bp5, 1btj[a]
Ferritin (450 without iron)	Males: 30–300 $\mathrm{\mu g\,l^{-1}}$ Females: 15–200 $\mathrm{\mu g\,l^{-1}}$	Iron carrier	134 790/1lb3
C-reactive protein, CRP (250)	$<$5 $\mathrm{mg\,l^{-1}}$	General inflammation marker and chronic cardiac diseases	123 260/1b09, 1gnh, 1lj7
Protein hormones			
Follicle stimulating hormone, FSH (30)	Adult males: 2–10 $\mathrm{U\,l^{-1}}$ females: follicular phase: 2–8 $\mathrm{U\,l^{-1}}$ post-menopausal: $>$ 15 $\mathrm{U\,l^{-1}}$	Regulates the development, growth, pubertal maturation, and reproductive processes	136 530/1fl7, 1xwd
Growth hormone, GH (22.1)	Following glucose load: $<$2 $\mathrm{mU\,l^{-1}}$ Following stress: $>$20 $\mathrm{mU\,l^{-1}}$	Stimulates growth and cell reproduction	139 240, 139 250/1a22, 1huw, 1hgu[a]
Insulin (5.8)	Fasting: 3–15 $\mathrm{mU\,l^{-1}}$ Hypoglycemia: $<$3 $\mathrm{mU\,l^{-1}}$	Metabolic regulator (e.g., for glucose uptake)	176 730/
Parathyroid hormone, PTH (±10)	10–65 $\mathrm{ng\,l^{-1}}$	Calcium regulation	168 450/1bwx, 1et1, 1fvy, 1hph, 1hpy
Prolactin (±24)	50–400 $\mathrm{mU\,l^{-1}}$	Milk production in the breast	176 760/1n9d
Thyroid stimulating hormone, TSH (±30)	0.3–4.0 $\mathrm{mU\,l^{-1}}$	Stimulates the thyroid gland to secrete thyroxine (T4) and triiodothyronine (T3)	118 850 (α), 118 840 (β)/

Table 24.5 (*Continued*).

Protein (MW (kDa))	**Normal values in adults**	**Function/relevance**	**OMIM and PDB entries**
Human chorionic gonadotropin, hCG (±46)	Highly variable ($0–100\,000\ \mathrm{IU\,l^{-1}}$)	Indicator of pregnancy, also tumor marker	118 860/1hcn, 1hrp, 1qfw
Luteinizing hormone, LH (±26)	Adult males: $2–10\ \mathrm{U\,l^{-1}}$ Females: follicular phase: $2–10\ \mathrm{U\,l^{-1}}$ post-menopausal: $> 20\ \mathrm{U\,l^{-1}}$	In females, a rise of LH triggers and indicates ovulation. In male, LH stimulates Leydig cell production of testosterone	152 780/
Cardiac markers			
Myoglobin (16.7)	$< \pm 100\ \mathrm{\mu g\,l^{-1}}$	Oxygen carrier in muscle	160 000/1m6c, 1m6m, 1mdn, 1mnh, and 1mni^{+}
Creatine kinase, CK-MB	25 and $200\ \mathrm{U\,L^{-1}}$	Energy supply in muscle	123 310/1i0e
Cardiac Tropinin I, cTnI	$< \pm 0.1\ \mathrm{\mu g\,l^{-1}}$	Binds to actin in thin heart myofilaments	191 044/1mxl, 1a2x, 1vdi
Cardiac Tropinin T, cTnT	$< \pm 0.1\ \mathrm{\mu g\,l^{-1}}$	Binds to tropomyosin, in heart myofilaments	191 045/
Tumor markers			
α-Fetoprotein (AFP)	$<10\ \mathrm{\mu g\,l^{-1}}$	Hepatocellular carcinoma and endodermal sinus tumors	104 150/
Calcitonin (3.5)	$<10\ \mathrm{ng\,l^{-1}}$	Calcium regulator, and indicator of medullary thyroid carcinoma	114 130/2glh
Carcinoembryonic antigen, CEA		Colorectal, gastric, pancreatic, lung and breast carcinoma, and medullary thyroid carcinoma	12 different types of proteins in humans, for example: CEACAM1: 109 770/2gk2
Prostate specific antigen, PSA (±33)	$<4\ \mathrm{\mu g\,l^{-1}}$	Prostate cancer in men, possibly various forms of cancer in women	176 820/1z8l, 2zch, and 2zcl

[a] Indicates multiple entries.

use of a large group of participants, to investigate the differences that may arise in the determination of the affinity constant using a selected monoclonal antibody to PSA [297]. The native antibody used in this study had a reported affinity constant of about 0.75 nM^{-1}. The anti-PSA was immobilized onto a carboxydextran surface ("CM5," from Biacore) via the amino groups of the antibody, and the binding of PSA was studied by kinetic binding experiments in a buffer supplemented with 0.2 $\mathrm{mg\,ml}^{-1}$ bovine serum albumin. Three different antibody loadings in three different flow channels were employed (500, 1000, and 2000 RU), while one channel was left blank. This channel functioned as a reference to compensate for long-term drift. The variability in antibody loading yielded the possibility to relate the maximum PSA response to the antibody loading. In this way, an immobilization efficiency of 44% was inferred for the antibody/CM5 combination. At the highest antibody loading, the maximum response was from 160 to 350 RU ($\approx$pg mm^{-2}), and a distribution constant (K_D) was found of 1.1 nM (i.e., $K_A = 0.91\,\mathrm{nM}^{-1}$) with a coefficient of variation of 18%. These results prove that the SPR method is able to give a direct assay of PSA, although it should be noted that for reliable diagnostic tests, on real samples, the method has not yet been employed. Moreover, in the survey, the reported affinity is a decade lower and the variation in affinity is much higher than required in a diagnostic assay.

PSA has also been the object of various other studies pertaining to direct detection. For instance, single-chain dromedary antibodies against PSA have been immobilized in a highly ordered way through the use of fusion proteins of the antibody with an S-layer protein, and regular immobilization yielded up to 78% immobilization efficiency [298]. The amount of antibody bound to gold was 5770 RU, and under saturating conditions 1074 RU of PSA was bound. Binding isotherms and detection limits for PSA, however, were not reported, although the affinity constant of the antibody was separately assayed as 11 nM^{-1}.

In a recent study by Besselink *et al.* [98], various detection techniques for PSA were compared, all based on SPR detection, and the results have also been underpinned with theoretical calculations. Employing a new type of hydrogel-modified gold surface (commercially available from Ssense, Hengelo, the Netherlands) a very high antibody loading could be attained (20 500 RU) and it showed a saturation response of 3280 RU for PSA (at 34 $\mu\mathrm{g\,ml}^{-1}$). At the lower concentration of 300 $\mathrm{ng\,ml}^{-1}$ PSA, however, the response was only 98 RU, which still lies far above the clinically interesting concentration range. Highest sensitivity could be obtained, however, for particle amplification on planar surfaces, enabling detection down to 0.6 and 2.4 $\mathrm{ng\,ml}^{-1}$ respectively for gold and latex particles. Finally, Choi *et al.*, [299] using recombinant protein G to orient the (monoclonal) capture antibody and a polyclonal antibody gold label, claimed to have achieved a detection limit of 0.3 pM for PSA (0.01 $\mathrm{ng\,ml}^{-1}$). Indeed, in most cases in the literature, the detection of PSA without further amplification was conducted at concentrations far above the clinically interesting range, and only amplification with secondary antibody, gold, or latex particles gave the possibility to detect PSA at the required low concentrations.

Besides SPR phenomena on flat gold surfaces, localized surface plasmon resonance (LSPR) phenomena in dilute solutions of gold colloids have been successfully used for direct and highly sensitive detection of various clinical analytes such as theophiline, digoxine, troponin I, and hCG [300, 301]. The binding of an antigen to gold colloids coated with monoclonal antibodies gives a measurable shift of the absorbance spectrum. The effect is largest for gold colloids of 50 nm, because they still have a pronounced absorbance peak, with optimal sensitivity to local perturbation of the LSPR. With this size of nanoparticles, ratiometric absorbance measurements at 530 and 620 nm afford real-time analysis of association and dissociation constants. The issues discussed earlier thus, clearly, illustrate the possibilities (but also limitations) for plasmonic techniques in bioanalysis.

24.5
Conclusion

An important issue remaining, which is also of some bearing to optical sensing, is the immobilization of receptors and biological compounds on the surface of sensor devices. Immobilization techniques have been developed for proteins, DNA, aptamers, and cells for a variety of purposes. As outlined in the review by Borisov and Wolfbeis [80], immobilization materials are emerging increasingly as active ingredients of optical sensing devices. The general issues related interfacial aspects of biomolecule immobilization have been recently reviewed [302, 303], and many practical protocols have been published [304]. In SPR biosensors, the general issues of surface chemistry have been reviewed by Gedig [305].

Site-directed immobilization, that is, the attachment of biomolecules to a surface in an oriented manner to maximize the amount of available binding sites or activity, is particularly important with antibodies, owing to the fact that the antigens with which they need to interact are generally rather bulky. Proteins A, G, and L, have been used to orient whole antibodies on gold surfaces via the Fc part, with which they specifically interact (see Figure 24.1 for a schematic structure of an antibody) [299]. Unfortunately, these scaffold proteins do not always interact strongly enough with the antibody for stable attachment during the measurement, and therefore, immobilization of biotinylated antibodies onto surfaces via various avidins [306] or covalent attachment [307] may be preferred . One of the first site-directed methods for antibody immobilization was by activation of the carbohydrate moiety in the Fc part of antibodies and their attachment to amino surfaces [308]. IgG molecules can also be split into $F(ab')_2$-fragments with pepsin digestion, and bound directly to hydrophilic gold [309] or to SAMs via the terminal thiol groups [310]. Various polymeric matrices have also been used for immobilization. The efficacy of carboxy dextran matrices, as introduced by Pharmacia Biosensor in 1990, has been one of the factors that contributed to the success of the Biacore® SPR biosensing system. At present, there have emerged a few alternative providers of chips coated with similar matrices: Xantec Bioanalytics GmbH, in Germany, and Ssense, in the Netherlands. In the design of new polymers with low protein binding, various biocompatible functional groups can be considered, such as the ones screened by Ostuni *et al.* [311].

Clearly, there are very many important developments in bioanalytical methods, and it was only possible to give a small cross section of the literature in this introductory chapter. As everything nowadays converges to miniaturization, some preference has been given to biosensor and solid-state devices in this chapter, and to a few issues related to bionalysis that are not discussed in the chapters that follow in this section.

As a concluding outlook it can be stated that (i) synthetic receptors are clearly gaining territory next to the receptors given by nature, (ii) detection schemes become more and more integrated with immobilization, as evidenced by new discoveries in imprinted polymers and self-assembled molecular layers, and (iii) the operation of many new prototype devices in the field of clinical chemistry still needs to be evaluated in more realistic sample matrices.

Quality Assessment of Spectroscopic Methods in Clinical Laboratories

Heike Schneider, Georg Kurz, and Peter B. Luppa

25.1

Introduction

Clinical chemistry is concerned with the clinical diagnosis and prognosis of disease and with patient therapy monitoring through the analyses of body fluids for specific (patho)physiological constituents. Diagnostic inputs by clinical chemistry analyses are important for more than 60% of all diseases treated in hospitals and in outpatient clinics. Specimens of blood, serum, plasma, urine, cerebrospinal fluids, other body fluids, and feces provide the samples for the various measurements in order to diagnose illness or to monitor the disease progress.

The modern clinical laboratory is characterized by the mostly automated utilization of a wide variety of techniques and equipment. These analyzers require constant maintenance and performance surveillance, as well as internal quality control and external ring trials. In Figure 25.1, some examples of commonly used analyzers with photometric units are shown.

25.2

Spectroscopic Methods in Clinical Chemistry

25.2.1

Overview

More than 90% of the analyses in clinical laboratories are based on photometric methods. Analyses done by spectroscopic methods vary from high concentrated analytes such as electrolytes, substrates, metabolites, or enzymes to the low concentrated micronutrients. In addition, spectroscopic methods are used for drug monitoring in different concentration ranges. The methods include an assortment of detection methods such as UV–Vis (ultraviolet and visible), fluorescence spectroscopy, and infrared spectroscopy in the field of molecular assays as well as flame atom emission spectrometry (F-AES) and atom absorption spectrometry (AAS) in the field of atom quantitation. Each method requires a superior specificity

for the analyte and should be coupled with efficient sample preparation and/or separation technologies.

When choosing an appropriate analytical method in the clinical laboratory – as in other fields – a compromise must be found for the pivotal issues requirements, feasibility, practicability, and affordability. Adjacent to analytical aspects, the fundamentals of the already established quality assessment schemes in clinical chemistry have to be applied during method development.

25.2.2
Basic Requirements for Quality Assessment in Clinical Chemistry

Four main fields contributing to quality assessment in clinical chemistry in general have to be focused on:

- method validation;
- standardization;
- instrument performance surveillance;
- statistical quality control (internal, external).

The latter two, that is, the application of statistical quality control and the instrument surveillance performance are the central topics of this chapter. The first two aspects are typically part of the assay certification and covered by assay manufacturers. These issues are not the main subject of this chapter, but as there is a close relation to the instrument performance and statistical quality control, some important facets are discussed here.

Basic requirements for the utilized methods are adequate sensitivity and specificity for the analyte as well as the required precision and the linearity of the calibration. For the application in clinical chemistry analysis, particular attention should be paid to possible interference and the robustness of the method. In addition, calibrator and control material have to be internationally standardized.

Sensitivity and linearity are well characterized by the lower limit of quantification (LLOQ), the upper limit of quantification (ULOQ) as well as the r^2 value. These characteristics are determined during method validation, but might change during application. Thus, instrument performance surveillance as well as statistical quality assessment are strongly advised (Figure 25.2).

25.3
Quality Assessment by Basic Technical Prerequisites

25.3.1
Instrument Performance Surveillance and Preclusion of Sample-Dependent Variations in Different Spectroscopic Methods

A series of instrument factors and requirements dictate the sensitivity, stability, selectivity, robustness, and accuracy of the measurement. But the principle of

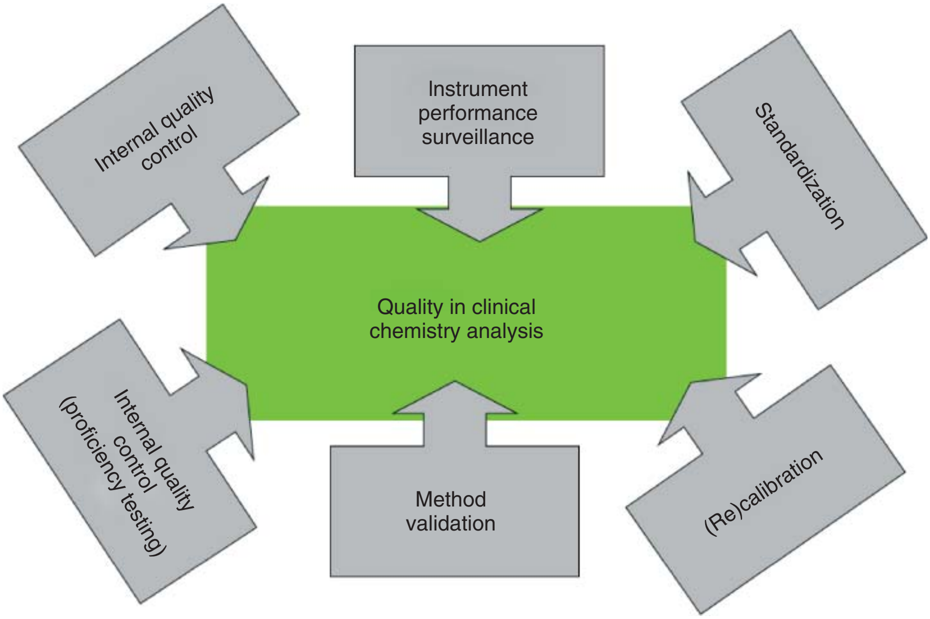

Figure 25.2 Capital fields contribute to quality assessment in clinical chemistry in general: instrument performance surveillance, method validation, standardization and statistical quality control, (re)calibration, and proficiency testing.

operation and the nature of the detected optical signal also contribute to the analytical performance.

Most of the above-mentioned basic requirements have to be considered before or checked during method validation. There are a series of factors that shift during the use of the instrument. For example, changes in the intensities of the light source affect the sensitivity of *AAS*, *flame atom emission spectroscopy* (*F-AES*), *Fourier transform infrared* (*FTIR*) spectroscopy, *fluorescence* or *UV–Vis measurements* and therefore the LLOQ. As most methods are performed using external standard calibration curves, the linearity and the ULOQ might also be affected by instrument changes. Some factors are monitored by modern instruments before the start of routine measurements as so-called *instrument self-check*. Otherwise, the instrument has to be checked by the user. Instrument self-checks and/or user-induced checks (to be defined for each instrument and each test configuration) should be passed according to a defined timetable and invariably after every service intervention.

An automated processing mode should warrant the requirements for analyzing the samples. The requirements to analyze samples refer to sample-dependent variations, given by the *matrix effects* of biological materials used in clinical chemistry. Some of the matrix effects are well known, such as hemolysis-caused effects. Some others, however, are patient specific and hard to define. Certain effects can be compensated for, for example, by using internal standards (ISs), but others lead to determination errors. These samples have to be excluded from the analysis.

Subsequently, it is stated which instrument and sample specific provisions are made for the different spectroscopic methods in clinical chemistry.

25.3.2
FTIR

Urinary tract concrements are investigated by the use of middle infrared (MIR) or classical infrared (MIR; wave number: 4000 to 400 cm^{-1}; wave length: 2.5–25 μm). The qualitative analysis of urinary stones (mostly urates, calcium oxalates, and phosphates) and, infrequently, gallstones is, at present, the only routine application of FTIR in the clinical laboratory [1].

There are two methods to prepare solid materials as urinary stones for FTIR. First, it is possible to dilute the well-pestled stone in dry potassium bromide (KBr) to prepare a KBr pellet. Second, attenuated total reflectance (ATR) can be used to analyze the pestled urinary stone directly. Sample preparation for ATR is quite simple, as the material is directly placed onto the diamond face of the measuring chamber. The preparation of KBr pellets is time consuming and needs well-trained technicians, as nonuniformly prepared KBr pellets lead to poorly reproducible analytical results. However, to date, KBr pellets are still used more frequently than ATR to analyze urinary stones. This refers to the interpretation of the data.

Both, ATR and KBr pellet spectra are analyzed by the comparison to databases entries in a qualitative mode. Almost all commercially available databases are established for KBr pellets. A switch between the ATR and KBr technique may lead to shifts in band intensities and result in worse spectra comparability. Presently, databases using ATR for measuring are in preparation. On completion of this databases, ATR can be used for routine analysis of urinary stones, to make sample preparation much simpler.

FTIR is used for qualification of urinary stones without calibration in terms of concentration, as there is no clinical need to quantify the composition better than ±10%. Nevertheless, there are some quality issues that should be considered using the FTIR system. The exact and reproducible position and band intensities should be guaranteed. Interferences should be avoided or at least identified.

During initialization, modern FTIR systems automatically check source, laser, scan, and calibration. A user-initialized system validation should be performed at least once a month. For this purpose a polystyrene sample is integrated into the system. In the automatically performed validation process, the position of the bands, band intensities, as well as the noise of the system are tested. A background correction is carried out per working day by the user.

Water leads to interferences in the FTIR spectrum; for this reason, urinary concrements are to be dried well and exhaustively dried KBr should be applied. In addition, each measurement is assessed automatically regarding interferences and weak or overloaded bands, resulting from disproportional sample amounts.

The qualification of urinary stones by FTIR is coupled to a database match of the spectra. To ease the match to the databases, modern FTIR systems offer correction facilities: baseline correction and absorbance expansion (ABEX) are often used. The baseline correction mathematically eliminates disruptive effects caused by scattering without distortion of the bands. ABEX processes the data to correct changes in sample concentration or thickness. By simply autoscaling the transmission, band shapes would be expressed incorrectly, leading to poor database matches.

In addition, it is possible to retrofit the databases by own entries. For this purpose, urinary stones with exactly known composition are measured. The use of own entries into the database, however, should be done carefully, as the database match provides the base of the evaluation process by the analyst. The database matches deliver a list of matches sorted by the quality of fit. The 10 best matches are given as a list and the best fitted spectrum is overlaid by the measured spectrum of the patient's urinary stone. The final classification of the urinary stone, however, depends on the professional judgment of the database match by the analyst [2].

25.3.3
AAS and F-AES

Although there are more sensitive methods than AAS, this method is still the gold standard for the determination of monovalent and divalent cations at low concentrations in human serum and urine. AAS is used for the quantification of micronutritions such as Cu^{2+} and Zn^{2+} in serum as well as Cu^{2+}, Mg^{2+}, and Fe^{3+} secretion in urine. Higher concentrated analytes such as Na^{+}, K^{+}, Ca^{2+}, or Li^{+} are determined by F-AES. AAS and F-AES are relative measurements using an external standard to get absolute molar concentrations [3].

In AAS, spectral interferences are revised or lowered at least by background correction. For this purpose, beside a hollow cathode lamp (radiant source for AAS) an additional deuterium lamp (D_2-lamp) is placed into the optical path. Alternatively, the Zeeman effect can be used to compensate for elevated background signals in AAS: if a special spectral band of an atom is viewed without exposure to a magnetic field, only a single wavelength is recorded. If a magnetic field is turned on, most elements display additionally three or even more bands. The light component polarized in the direction of the magnetic flux is absorbed by the atom, but the light component polarized perpendicular to the magnetic flux is only scarcely absorbed. On the contrary, molecules, particles, or the background do not show this effect.

Besides these actively performed corrections, it should be stated that interferences are minimized by using a powerful detector, which is able to completely separate all relevant spectral lines. For this reason, the incident light intensity (I_o according to the Lambert–Beer law) has to be controlled by the instrument after each start of the lamp.

F-AES systems compensate for matrix effects by using the reference line method [4]. For the reference line method, an F-AES-sensitive element is added in exactly the same concentration to each sample. In most cases Li^+ is added, as the human body contains only minute amounts of Li^+ without essential biological function. Only samples from patients under antidepressant therapy with Li^- salts (resulting in concentrations between 0.5 and 1.5 $mmol\,l^{-1}$ Li^+, higher concentrations being toxic) have to be measured without the correction by the reference line method. In contrast, Li-heparinate plasma samples can be used to measure Na^+, K^+, and Ca^{2+} applying the reference line correction. A prerequisite for this approach is, however, the knowledge of the exact Li^+ content of the Li-heparinate tube batch and test series with the Li^+ program of the flame photometer. The Li^+ concentration contributed by the Li-heparinate (mostly $<0.5\,mmol\,l^{-1}$) has to be integrated into the correction factor (see subsequent text).

In practice, all samples are diluted with a 5 $mmol\,l^{-1}$ Li^+ solution. With any variation in nebulization, the air and gas pressure has nearly the same effect on the measured electrolytes (e.g., Na^+, K^+, and Ca^{2+}) as referenced to lithium. During the calibration with the external standard, the Li^+ concentration is determined and set to 1. Each change in Li^+ in patient or control samples is converted into a correction factor being used to correct the concentration of the measured electrolyte.

25.3.4
HPLC-Coupled Methods

High-performance liquid chromatography (HPLC)-coupled methods are used in clinical chemistry in cases where for a certain analyte no satisfying selectivity can be achieved by simpler methods. There are HPLC methods available with fluorescence, UV–Vis, and partly diode array detection mode [5]. The alternative electrochemical and mass spectrometric detection systems are not related to spectroscopic methods. As expected, those quality control principles, which are applied for enzyme-coupled UV–Vis spectroscopic methods, are equally used with HPLC-coupled methods. There is, however, one important advantage of HPLC-coupled methods: the principle of using an IS can be implemented easily. As specified before, the best opportunity to exclude effects caused by individual sample characteristics or by the preparation of the sample is the use of ISs. Preferred ISs are as similar to the analyte as possible without changing the analyte-specific signal. For HPLC with UV–Vis fluorescence or electrochemical detection mode, ISs with a structure similar to the analyte are used. However, for this detection method, a separation by the retention time is essential. The best choice by far is the use of deuterated ISs, as they have the highest level of analogy with the analyte. A chromatographic separation of deuterated substances from nondeuterated, however, is not possible. Thus, the use of deuterated standards is only feasible for a mass spectrometric detector. Besides, the general quality assessment HPLC-coupled methods using an IS have to be additionally checked for the signal of the IS. The signal intensity should not vary for more than 20% if the same sample matrix is used, for example, serum or urine. Larger differences from sample preparation should be avoided, even if manual sample preparation, for example, by solid-phase extraction (SPE) is used. If larger differences are observed, they might be the result of an interference factor. In this case, the sample should be analyzed again. If the rerun gives no better result, another patient sample should be requested [6].

Besides the important advantage of using an IS, HPLC methods hold the special risk of sample mix-up; as always, a sample preparation in a secondary sample tube is necessary. And the sample preparation is carried out ‘‘offline’’ in most HPLC applications. That is why the user has to take special care, even if microplates are used for autosampling. There is one straightforward control that can be performed, in particular for drug monitoring applications: solely changing the sequence position of the control material. As controls have to have special composition, on the brink controls might assist the position control in offline measurements.

25.3.5
Automated Systems with UV–Vis Detection

25.3.5.1 Serum Index Measurement

Clinical laboratory tests can be affected by endogenous constituents in the sample matrix. Some of these potentially interfering factors can be recognized in the preanalytical phase by a colored appearance of the sample. Interferences due to lipemia (turbidity), hemolysis, and hyperbilirubinemia are difficult to predict because of their strong method-dependent interference.

A quantification of these interfering substances is possible by applying the serum index (SI) measurement, which can be performed on automated clinical chemistry analyzers. They are capable of semiquantitative measurement and reporting of the lipemia index (L), hemolysis index (H), and icteric index (I) [7].

Lipemia is observed as a visible turbidity in serum and plasma samples. The turbidity leads to an increased scattering of the irradiated light. The most frequent cause of lipemia is elevated triglyceride and/or chylomicron (remnants) concentration plasma and serum. This may be caused by diet, a disturbance of lipoprotein metabolism, or intravenous infusion of lipids.

Hemolysis is defined as the release of intracellular components of erythrocytes and other blood cells into the blood plasma. It can appear *in vivo* (e.g., due to a transfusion reaction or during malaria parasite infection) as well as *in vitro* during the preanalytical phase (sampling, sample transport, or storage). After the separation of blood cells, hemolysis is observed in serum or plasma samples by the red color of hemoglobin.

Hyperbilirubinemia (icterus) is defined as an elevated level of different conjugated and unconjugated bilirubin species in serum and plasma. Increased levels can be caused by diseases or conditions that, through hemolytic processes, produce bilirubin. Rapid bilirubin liberation overstrains the clearance capability of the liver. Liver immaturity and several other diseases in which the bilirubin conjugation mechanism is impaired cause similar elevations of circulating unconjugated bilirubin. Bile duct obstructions or damages to hepatocellular structures also increase the levels of both conjugated and unconjugated bilirubin in plasma.

The SI measurement is based on calculations of absorbance measurements of diluted samples at different bichromatic wavelength pairs to provide a semiquantitative representation of levels of lipemia, hemolysis, and hyperbilirubinemia present in serum and plasma samples [8].

The primary wavelength is at or near the peak absorbance of the chromogenic product and the second wavelength at which only a negligible absorbance of the desired chromogenic substance occurs.

Any absorbance (A_2) that occurs, due to interference from other substances in the sample, is measured at the secondary wavelength. This amount is then subtracted from the total absorbance (A_1) occurring at the primary wavelength to yield the net absorbance (A^C) (Figure 25.3).

The analyzer pipettes an aliquot of the diluted patient specimen to measure the absorbances for lipemia at 660/700 nm (primary/secondary wavelength), for hemolysis at 570/600 nm, and for hyperbilirubinemia at 480/505 nm (Figure 25.4). From these absorbance values the instrument calculates SI values using appropriate correcting factors that correct overlapping interference spectra. A measured SI result (L, H, or I) exceeding the specified value indicates that the corresponding test is affected by endogenous interferences beyond an acceptable deviation (Figure 25.4).

25.3.5.2 **Liquid Level and Clot Detection**

The sample and reagent probes are equipped with a *liquid-level detection system* checking the availability of sufficient sample and reagent volumes in the respective containers. In addition, the liquid-level detection serves to control the correct immersion depth of the probes in the samples and reagents for proper pipetting. If the sample or reagent level falls below a predetermined height, an alarm

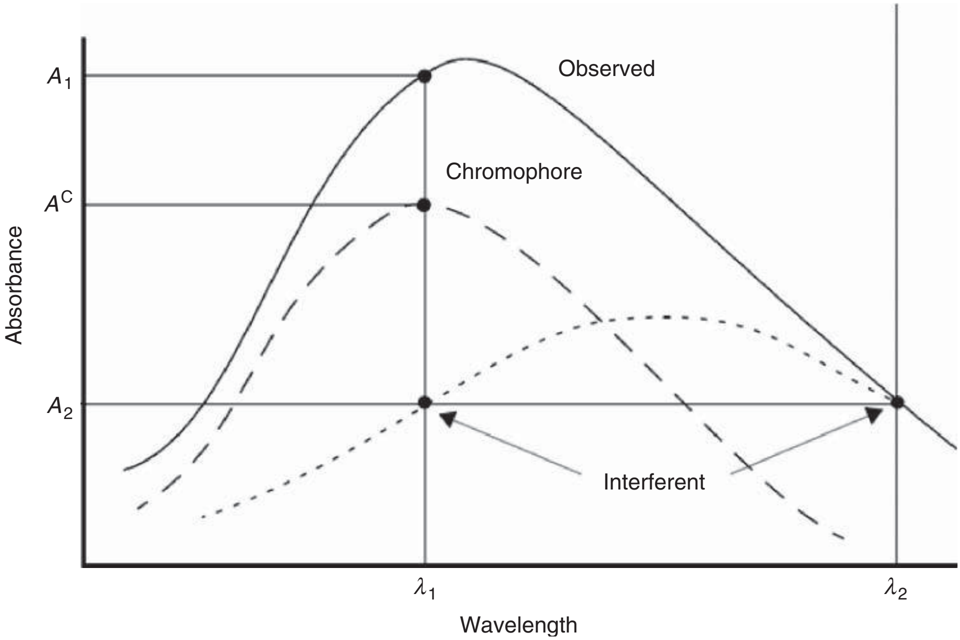

Figure 25.3 Photometric test using two wavelength readings to calculate results (bichromatic measurement).

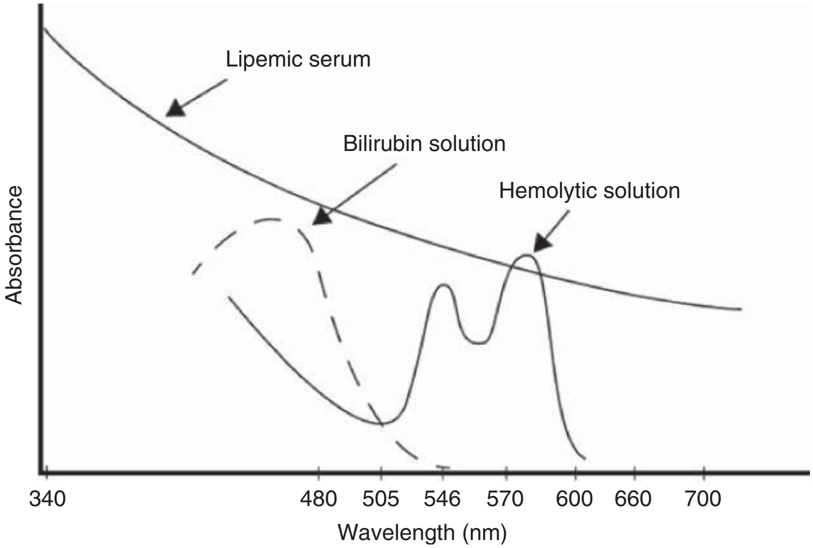

Figure 25.4 Absorbance against wavelength of the different interferences factors: lipids, hemoglobin, and bilirubin.

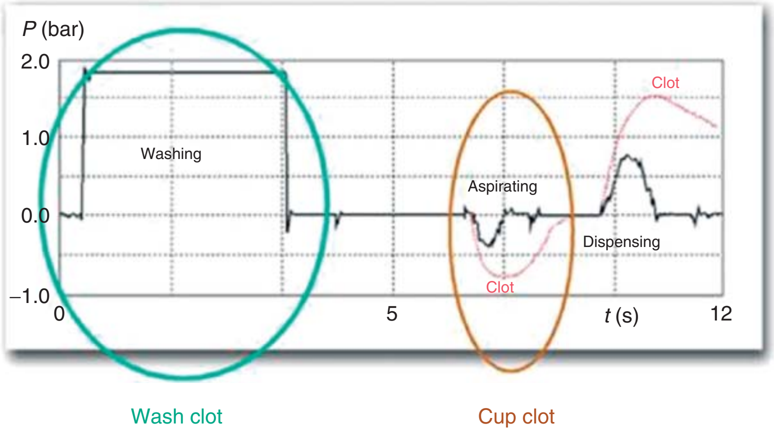

Figure 25.5 Clot detection: the sample probe is equipped with a pressure sensor that detects pressure changes during aspiration.

message is displayed. The liquid-level detection is accomplished by a highly sensitive capacitance measurement. The probe carries a high-frequency, low-voltage electrical charge. Changes in frequency and electrical amplitude characteristics are evaluated to detect the contact of the probe with the liquid. The liquid-level detection is a component of the pipetting integrity check of a clinical chemistry analyzer and increases the result security.

The *clot detection* is a further component of the pipetting integrity check. The sample probe is equipped with a pressure sensor that detects clots during the sample aspiration. Evaluating the clogging of the probe avoids false sample volume pipetting. The aspiration of a clot causes the measured pressure profile to exceed predefined threshold values, subsequently triggering an alarm message (Figure 25.5).

25.3.5.3 **Instrument Checks**

Multiple instrument checks are used to detect abnormalities during the measurement and result calculation and thereby significantly increase the result integrity. Results of calibrations or measurement results of patient or control samples are flagged accordingly. Some of the most important instrument checks are listed here.

- *Absorbance limit check*. The absorbance limit check induces a flag, if the absorbance value used for the calculation exceeds the photometer linearity limit. A potential cause might be that the sample concentration is too high or the sample is lipemic. The measurement has to be repeated after adequate dilution.
- *Antigen excess check*. Another possibility of ruling out high sample concentrations in assays that use antigen–antibody reactions is the antigen excess check. If the sample contains excess antigen concentrations, a valid result cannot be calculated. This is caused by an effect shown in the “Heidelberger curve” for turbidimetry. If the antigen exceeds the antibody concentration by a certain ratio, the signal decreases (Figure 25.6, [9]).

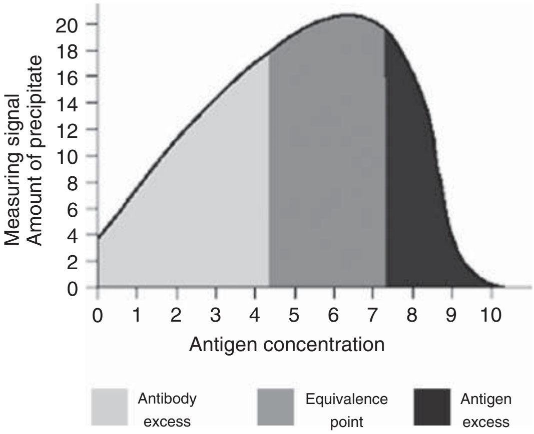

Figure 25.6 Heidelberger curve.

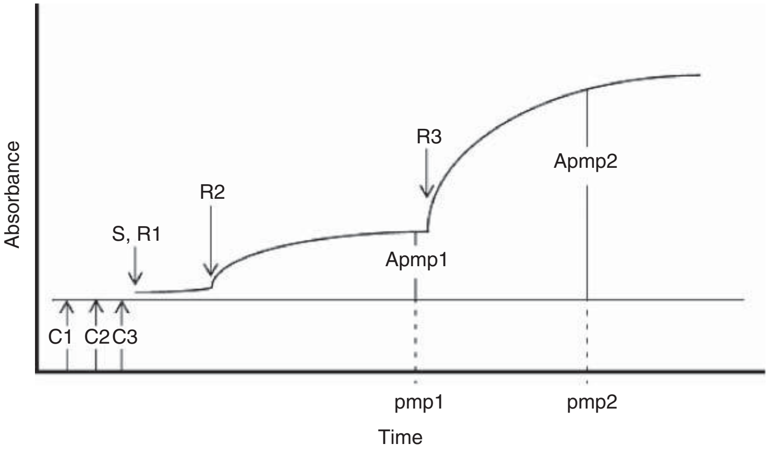

C1, C1, C3	Reaction cell s water blank values
S	Pipetting of sample
R1, R2	Pipetting of R1 and R2
R3	Pipetting of antigen excess reagent

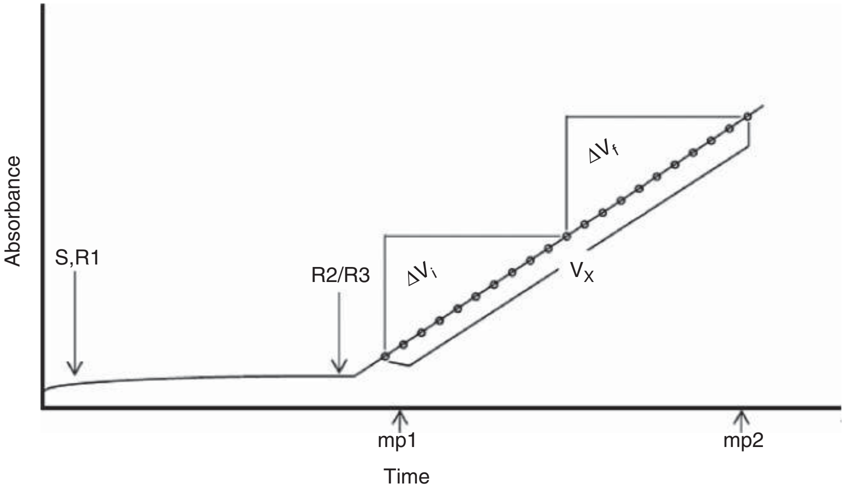
Apmp1, Apmp2	Absorbance at pmp1 and pmp2

Figure 25.7 Antigen excess check.

Antigen excess checks applying the antigen readdition method compare the absorbance before and after the addition of an antigen excess reagent, as indicated in Figure 25.7. If the signal height at Apmp2 underruns a limit value, the measurement should be repeated after adequate dilution.

- *Linearity check*. If the first and the second half of the reaction curve have different slopes exceeding a specified limit value, a flag appears (Figure 25.8).



S	Pipetting of sample
R1, R2, R3	Pipetting of R1, R2, or R3
mp1	First photometric measuring point
mp2	Last photometric measuring point
Vx	Rate of change in absorbance calculated for all measuring points between mp1 and mp2 by least square analysis
Vi	Rate of change in absorbance calculated for the first half of the reaction curve
Vf	Rate of change in absorbance calculated for the half of the reaction curve

Figure 25.8 Linearity check.

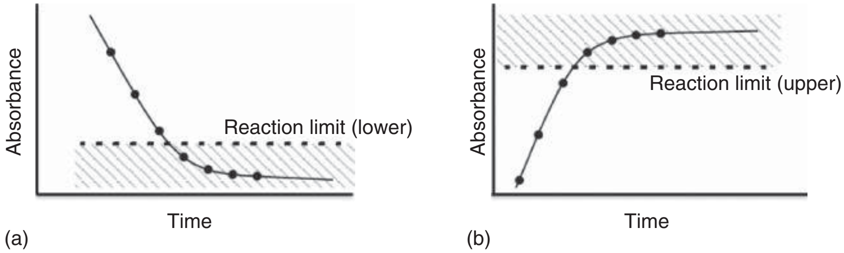


Figure 25.9 Reaction limits for (a) ascending and (b) descending rate assays.

The nonlinearity flag may have different causes (e.g., sample is lipemic). It is recommended that the measurement be repeated after adequate dilution.

- *Substrate deletion check*. If the substrate is depleted, the enzymatic reaction runs out of the linear area. The rate of change in the main wavelength absorbance exceeds the predefined limit value (reaction limit). This flag is caused, for example, by an extremely high sample concentration (Figure 25.9). The measurement should be repeated after adequate dilution.

In general, it must be stated that fully automated analyzers can be programmed in such a way that the above-mentioned ''flags'' trigger automatic reruns using predefined sample dilutions.

25.3.6
Sample Measurements and Calibrations with Photometric Analyzers

25.3.6.1 Routine Photometric Measurements

Photometric measurements on a clinical chemistry analyzer should be performed at the respective optimum wavelengths. Specific measure points – part of the so-called application parameters – for each individual test have to be selected.

There are two fundamental types of photometric tests: *endpoint* and *rate tests*.

If measurements are performed after the reactions are completed, the intensity of the colored product or the turbidity serves as indicators of the sample component's concentration. These are called *endpoint tests*.

If measurements are taken as the reaction proceeds, the rate of the reaction is directly proportional to the sample component's concentration or activity being analyzed. These are called *rate reactions*. Modifications of these two techniques are also possible, as well as a combination of the two.

The reaction time of samples on most clinical chemistry analyzers is approximately 10 min or less.

Absorbance readings are performed each time the reaction cell rotates past the photometer. When the reaction cell passes through the light path, absorbance at 12 wavelengths for each individual test is measured. When the light beam enters the photometer, it strikes a diffraction grating that separates the light into its constituent wavelengths and reflects them onto a fixed array of 12 photodiodes (340–800 nm). Each photodiode is permanently positioned to detect light at a certain wavelength (Figure 25.10).

There are some rare methods in clinical chemistry that are still manually performed and either measured by (spectro)photometers or by microtiter plate readers. Most of the quality checks for these types of instruments are done as described, with the following additional aspects:

Some ring trial organizations (see subsequent text) offer control material for quality control measurements of stand-alone spectrophotometers. These samples consist of aqueous solutions of dyes. The dyes have specific extinctions at the following wavelengths: 260, 280, 334, 340, 365/366, 405, 546, and 560 nm.

The quality control samples are used as ring trials and serve as sensitive photometer checks. They help to localize (mostly monochromator) defects of the photometer earlier than they would cause erroneous analytical results.

Microtiter plate readers are often used with multichannel detection depending on the plate format that is used. In this case, a control should check each channel even if not for every measurement, but in a fixed time frame.

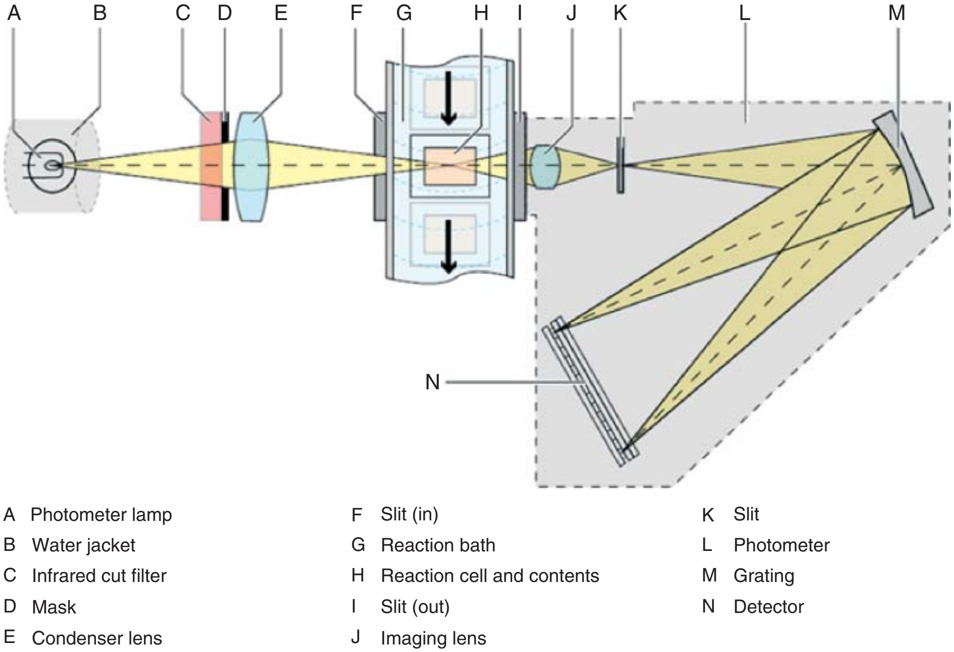

Figure 25.10 Assembly schema of a modern photometer (photometric absorbance reading). (With copyright permission of Roche Diagnostics.)

25.3.6.2 External Standard Calibration

Almost all clinical chemistry methods use external standards for quantification. Right from the method validation stage, it has to be worked out which standards have to be used and which calibration frequency is needed. As a routine, aqueous external standards are used. If quenching effects, however, occur, the use of matrix-loaded standards is required. Within this context, the assay supplier always specifies which calibrator has to be applied and which material (serum, plasma, urine, or special material) is valid for analysis. The calibration frequency also depends on the manufacturer's guidelines.

In general, in immunoassay methods a calibration is carried out for each test, whatever the detection method used. Enzyme immunoassays might be detected by different UV–Vis active or other dyes, but the signal height always depends on the immunoreactions carried out before the detection step. Exceptions to this calibration mode are made in fully automated systems: in these systems, the reaction sequence and all used reaction solutions are mostly standardized. For this reason, it is possible to reduce the calibration frequency significantly even for multistep enzyme-coupled reactions. If the calibration stability is high, the manufacturer might reduce calibration duty for the user. Thus, a one- or two-point recalibration is needed only when using a new lot of reagent, as the fully calibrated curve is provided within the product code. No further calibration of fully automated systems is required as long the criteria of all internal quality control measurements are fulfilled and the same reagent lot is used.

In HPLC-coupled methods and for AAS, a calibration is made within each batch to balance measurement deviations. In F-AES, the calibration is carried out even more often. Some systems, in particular F-AES systems for emergency laboratories, recalibrate at least every 15 min with a zero calibrator and one medium concentrated calibrator.

25.4
Quality Assessment – Regulatory Issues

The contemporary concepts of quality assessment of clinical chemical analyses (e.g., the Westgard rules [10–13]; see also *www.westgard.com*) have led to improvements in reliability of the analytical results, and also to marked improvements in equipment, methodology, reagents, calibration materials, and control specimens. But the statistical bases have also been improved in the past two decades [14]. Moreover, clinical chemistry measurements should be comparable and independent of the analytical system. Thus, establishing metrological traceability of results improves patient care and disease monitoring [15–17].

The goal of producing reliable analytical results for the benefit of the patient has enabled various assessment schemes in a series of different countries in the United States [12, 13], in Europe [11], and other parts of the world, but the underlying principle of the dual internal and external quality control is found in all of these concepts. These assessment schemes are dedicated to a variety of parameters. The various analytical chemistry techniques do not influence these rules. Also, intense efforts toward harmonization of quality systems and accreditation issues were spent [18–20]. Norms of the International Organization for Standardization (ISO) regarding the requirements for quality and competence in medical laboratories were devised [21].

Thus, this chapter aims to give an example of these quality assurance schemes, which are due for all of the applied spectroscopic methods.

German law mandates a set of quality regulations, known as the ''RiliBÄK'' (Richtlinie der Bundesärztekammer) [22], which govern medical devices in laboratory medicine. These regulations are further tied to the European IVD (*in vitro* diagnostic) directive and the ISO standards, for example, 15189 [21]. They are updated periodically to reflect changes in clinical need of regulated analytes, as well as improvements in technological capability of the clinical chemistry devices. The most recent update was proposed in 2008 with full implementation by April 2010.

RiliBÄK is the term for ''Guideline of the German Federal Medical Association (Bundesärztekammer, BÄK) for quantitative analytical measurements in the medical laboratory.'' The system described in this guideline is aimed at safeguarding the quality of analysis carried out in medical laboratories [23]. In other words, the quality assurance of medical laboratory examinations as part of the medical care should improve patient safety.

The guideline aims to ensure, in particular

- minimization of influence factors and *in vitro* effects during the preanalytical phase;
- proper performance of medical laboratory examinations including identify cation and minimization of factors interfering with the tests;
- correct assignment and documentation of results, including the generation of a report.

The RiliBÄK also defines the structure of medical laboratories: organizations in which medical laboratory analyses are performed must be legally identifiable. The responsibility, duties, and competence of the staff performing medical laboratory analysis must be clearly defined and documented. Medical laboratories must be headed by professionally qualified persons. The responsibility of the management encompasses all technical, organizational, administrative, educational, and advisory functions. Medical laboratory tests must only be performed by professionally qualified persons who fulfill the legal requirements. The number of personnel must be sufficient with regard to the amount of work. Regular participation in continued training and education programs must be ensured for all staff members. Participation in training and continued education programs must be documented. It must be stipulated and documented who is responsible for the training of new employees or training for new devices and new test methods and how such training is to be performed. The performance of mandatory training and educational sessions must be documented.

There are also strictly defined rules concerning:

- accommodation and environmental conditions;
- equipment;
- medical laboratory examinations concerning the pre- and postanalytical period; and
- medical laboratory test procedures for all analytical methods applied.

Very similar to the CLIA (Clinical Laboratory Improvement Amendments) in the United States [24], the RiliBÄK rule is meant to provide minimum requirements for the quality of quantitative clinical chemistry test results. The described quality requirements are in close relationship with the well-known ISO 15189:2007 standards. The RiliBÄK mandates quality requirements/allowable analytical errors/uncertainty recommendations for 67 analytes in serum and whole blood, as well as 10 analytes in urine, and seven in cerebrospinal fluid. The guideline also gives a decided statistical method for determining specifications for any unlisted (‘‘non list B1’’) analytes, as well as the permission for laboratories to apply the specifications of listed analytes to similar unlisted analytes.

The RiliBÄK guideline covers both *internal* quality assessment as well as *external* quality assessment. The internal assessment guideline is designed to assess a laboratory's quality using only a target value (TV) supplied by the manufacturer and the laboratory's routine QC data. These assessments are done on a daily basis as well as retrospective over a period of time (the so-called control cycle, CC). A laboratory must perform external quality tests, or peer comparison testing for any analytes that they test. For those analytes not listed in the RiliBÄK, laboratories are strongly encouraged to do also external quality testing. If the laboratory fails two successive external quality assessment events for the same analyte being listed in Table B1, a report must be filed with the government. Germany's equivalent (Bundesinstituts für Arzneimittel und Medizinprodukte, BfArM) (*www.bfarm.de*) of the Food and Drug Administration (FDA) in the matter of medical products is to receive the notice and investigate the deficiencies. Further failures of the laboratory are prosecuted by exclusion from the reimbursement system.

25.4.1
Internal Quality Assessment

All quantitative tests performed by medical laboratories are subject to internal quality assurance procedures. If several instruments are used to analyze a measurand, internal quality assurance procedures need to be performed on each of these instruments. The RiliBÄK from 2008 introduced a new quality metric for internal assessments, *root-mean-square deviation*, abbreviated as $\%RMSD$ and expressed as a percentage relative to a TV [25]. Previous versions used disconnected quality goals for bias and imprecision. These were replaced by the %RMSD as indicator of a total analytical error type of metric, being in accordance with the ISO concept of uncertainty. The %RMSD is computed from data acquired during a CC, which is a time period containing at least 15 observations, generally about 1 month of data, but not more than 3 months.

$$\%\mathrm{RMSD} = \frac{\sqrt{k^2(\mathrm{SD}_{\mathrm{CC}}^2) + \mathrm{Bias}^2}}{\mathrm{TV}}$$

where

$\mathrm{SD}_{\mathrm{CC}}$ = standard deviation,

Bias = difference of observed mean from TV,

k = statistical coverage factor to account for uncertainty (1 for metric, 3 to calculate specification), and

TV = target value for the control sample (from manufacturer).

The RiliBÄK provides a set of explicit goals for the uncertainty limits of the listed analytes. The tables also provide a concentration range for the tests – if your test value is within the specified range, then you can use the specification given in column 3 of Table B1, of the RiliBÄK (see *www.bundesaerztekammmer.de*; Richtlinien). Note that multiple ranges are provided in several cases (e.g., total bilirubin, digoxin, ethanol) where performance goals at low-analyte concentrations are different than that for the rest of the range. The statistical evaluation using a

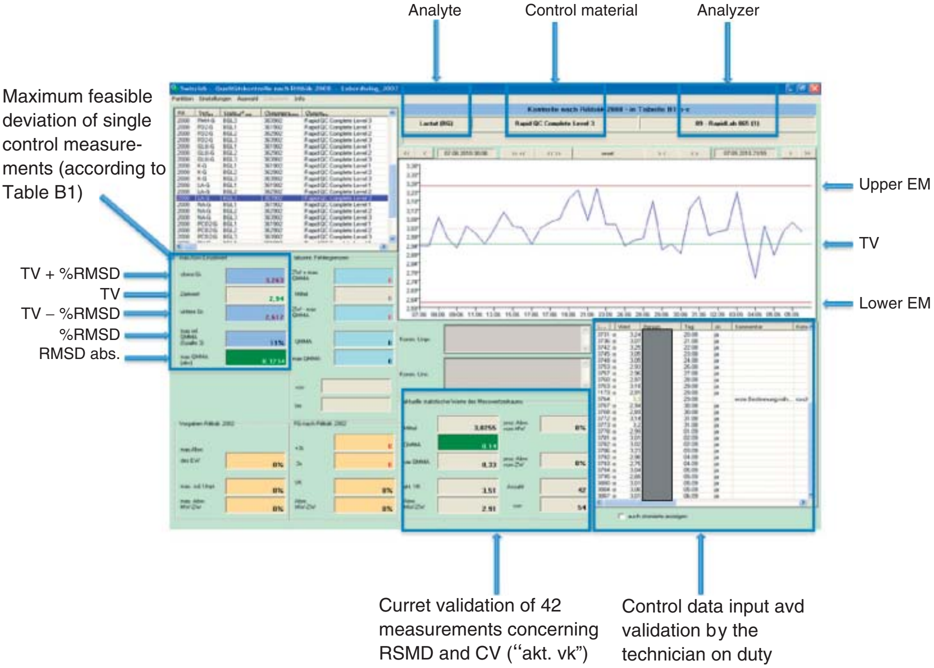

Figure 25.11 Internal quality control LIS screen for lactate in serum, according to the RiliBAK rules. (With copyright permission of Roche Diagnostics.)

commercial laboratory information system (LIS) is depicted in Figure 25.11 for one of the list B1 analytes.

For parameters not found on the B1 list, or for concentration ranges not found on the list, the establishment of internal laboratory limits of permissible error for the individual control sample measurement has to be installed as follows: a control sample result per day is chosen for each used control sample covering a period of at least 15 days and at most one CC. The selection is based on the same pattern, that is, each time the first, the xth, or the last value is used. Selecting values based on the statistic principles of random is also admissible. Subsequently, the limits of permissible error are calculated on the basis of TV $\pm\,\Delta_{\max}$. The calculation of $\Delta_{\max}$ is based on the following formula:

$$\Delta_{\max} = \sqrt{(k^2 \mathrm{SD}_{\mathrm{ep}}^2) + \mathrm{Bias}_{\mathrm{ep}}^2}$$

where

k = 3, coverage factor to calculate the internal laboratory limits of permissible error,

$\mathrm{SD}_{\mathrm{ep}}$ = experimental standard deviation of the control sample measurements used for the calculation during the specified period (ep), and

Bias_{ep} = difference of observed mean from TV used for the calculation during the specified period (ep).

To make it more simple, the correction of the variance SD_{ep}^2 with $(n-1)/n$ is dispensed with. In order to calculate the relative internal laboratory limits of permissible errors, Δ_{max} must be divided by the TV. This calculated %RMSD result becomes the *laboratory observed specification* and is done separately for each level of control used in the laboratory.

Once the %RMSD goal is reached by applying the RiliBÄK tables or the calculated laboratory observed specification, one can start the internal assessment. There are two periods of time when this internal assessment should be performed. First, there should be a daily assessment of control results versus the *error margin* (TV ± %RMSD). The laboratory's daily control values should not exceed the respective error margin. Second, there should be a retrospective check for CC. For each level of control, calculate the mean, SD, bias, and %RMSD from the daily control results over the entire CC. The calculated values should not exceed the respective %RMSD goals.

If an individual daily control result exceeds its error margin, the method is out of control and results are not released until an analytical or procedural cause is identified and corrected. Often, it is advisable to run additional QC or validation for resuming the method. If the monthly retrospective result fails the goal, it is also called *out-of-control* method. One must perform the same corrective actions as with the individual control result failure, but one must do more to revalidate the method. The consequences of failing consecutive retrospective assessments are more severe, requiring significantly more effort and documentation to revalidate the method, as well as potentially needing to notify the BfArM. The laboratory has to inform this federal authority as soon as it fails two times (2 months) in a row.

There are some additional rules in the context of internal QC: as to the period used to establish the internal laboratory limits of permissible errors, the ranges given by the manufacturer of the control samples apply. The internal laboratory limits of permissible error need to be within these ranges. Internal laboratory limits of permissible error do not need to be established for control samples with a lifetime of a lot below 12 weeks. Concerning these, the ranges indicated by the manufacturer of the control samples apply.

25.4.2
External Quality Assessment

The external assessment goals in the RiliBÄK are intended so that the analytes and specifications in the tables will be regularly reviewed and updated. Medical laboratories must take part in ring trials, at least every 6 months for the mandated analytes, as a certificate of passing from the RiliBÄK is only good for 6 months. Depending on the analyte, however, testing may be offered more frequently, up to eight times a year. Ring trial organizations in Germany are the Referenzinstitut für Bioanalytik (RfB) of the Deutsche Vereinte Gesellschaft für Klinische Chemie und Laboratoriumsmedizin (DGKL) (*www.dgkl-rfb.de*) and the Gesellschaft zur

Förderung der Qualitätssicherung in medizinischen Laboratorien e.V. (INSTAND) (*www.instandev.de*).

A special feature of the RiliBÄK is that the goals also indicate the grading system. Nearly half the mandated analytes are supposed to be graded against a reference method [designated in the table as ''Referenzmethodenwert'' reference method value (RMV)], the others only against the peer group median (designated in the table as ''Zielwert'' TV). Part of this reflects the sustained effort of the German DGKL to establish reference methods for the external quality assessment.

25.4.3
Quality Management Manual

The RiliBÄK demands for a quality management manual (QMM). This is depicted in part A of the guideline and is valid for all following parts B1, B2, and so on. The QMM has to describe the quality management system and the documentation used in the medical laboratory. The quality manual must include or make reference to all procedures. Laboratory personnel must be instructed on the use and practical application of the quality manual and all referenced documents. The quality manual must be kept up to date at all times.

The QMM also implies chapters for document control, resolution of complaints, examinations by referral laboratories, and procedures for nonconformities.

UV–Vis and NIR Fluorescence Spectroscopy

Gabor Patonay, Garfield Beckford, and Pekka Hänninen

26.1
Introduction

The development of fluorescent dyes for optical spectroscopy has attracted considerable new interests in quantitative and qualitative bioanalytical science. Although common separation techniques such as gel electrophoresis (GE), capillary electrophoresis (CE), and high-performance liquid chromatography (HPLC), as well as gene probe and immunoassays, relied on detection in the visible region of the spectrum, scientists are now taking full advantage of mid-red and infrared regions because of the comparative optical advantages. The application of these fluorescent molecules continues to demonstrate a plethora of photophysical properties, making them unique for bioanalyses [2–6]. Table 26.1 provides an overview of the use of fluorescent probes in bioanalytical applications.

Traditional fluorescent probes, for example, rhodamines and fluoresceins, absorb and emit in the ultraviolet or visible (300–700 nm) region of the spectrum. With the development of new excitation sources, and in particular light-emitting diodes (LEDs) and diode lasers, optical spectroscopy in the short range near-infrared (NIR) (700–900 nm) and NIR (900–2000 nm) regions have proven more advantageous and profitable. Optical light sources and detectors in this spectral window become continuously cheaper through large-scale use in the telecommunication industry and opto-digital recording. Among the benefits of using the NIR region is the inherent reduced Rayleigh and Raman light scattering, which is the reciprocal of the wavelength to the fourth power dependence and diminished autofluorescence of biological tissues, thereby making biomedical applications in particular very attractive [46]. In addition, the NIR region is favorable in fiber-optic sensing because of the reduced light intensity loss associated with quartz fibers at higher wavelengths. A comparative list of these benefits is illustrated in Table 26.2.

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

Table 26.1 Overview of fluorescent probes [1, 2].

Application area	Subfield or teaching technology	Typical dyes or assay system used	Description	References
Ion indicator dyes	pH	Near-neutral pH: ruthenium-1,2-dicarbonylhydrazide, fluorescein diacetate, carboxyfluorescein, and its ester, 5-sulfofluorescein diacetate, BCEFC	Physiological detection of pH is presently performed with various new fluorescent dyes. BCEFC and its membrane-permanent ester have become the most widely used fluorescent indicators for estimating intracellular pH. Studies are related to the role of intracellular pH in diverse physiological and pathological processes, cell proliferation, apoptosis, muscle contraction, malignancy, multidrug resistance, ion transport, and homeostasis, endocytosis, and Alzheimer's disease	[7]
	Na^+ and K^+	Crown ethers conjugated to the benzofuranyl fluorophore (SBFI and PBFI), sodium green, CoroNa Red, and squaraines	Detection of physiological concentrations of Na^+ and K^+ in the presence of other monovalent cations. Applications are estimation of Na^+ gradients in isolated mitochondria measurement of intracellular Na^+ levels or Na^+ efflux in cells from a variety of tissues. Blood (platelets, monocytes, and lymphocytes), brain (astrocytes, neurons, and presynaptic terminals), muscle (prefused heart, cardiomyocytes, and smooth muscle), secretory epithelium cells correlation of changes in intracellular Na^+ with Ca^{2+} concentration, intracellular pH, and membrane potential has been used in combination with other fluorescent techniques	[8]
	Ca^{2+}, Mg^{2+}, and Al^{3+}	Calcein, fura-2, BTC, various derivatives of calcium green, fluo-3 AM and fluo-4 AM, and some of their dextran conjugates	Measurement of intracellular and extracellular, Ca^{2+} concentrations (fluorescence microscopy, flow cytometry, and fluorescence spectroscopy). Conjugates with dextrans are used to confine the indicator to the cytosol. Major applications to the study of calcium regulations and transport	[9]
		EGTA, APTRA, and BAPTA aequorin (bioluminescence indicator for Ca^{2+})	—	
		Calcein, mag-fura-2, Magnesium Green™, and others	Mg^{2+} detection is important for studies of enzymatic reactions, DNA synthesis, hormonal secretion, and muscular contraction. For example, mag-fura-2 was first used to detect Mg^{2+} fluctuation in embryonic chicken heart cells	

Zinc and other metal ions	Newport Green™ DCF and PDX, FuraZin, FluoZin, and TSQ indicators (Zn^{2+})	Zn^{2+} is an important divalent cation in biological systems, influencing DNA synthesis, microtubule polymerization, gene expression, apoptosis, immune system function, and the activity of enzymes such as carbonic anhydrase and matrix metalloproteinases (MMPs)	[10]
	Calcein, Phen Green™ FL, and SK (Fe^{2+}, Cu^{2+}, Cu^{+}, Hg^{2+}, Pb^{2+}, Cd^{2+}, and Ni^{2+})	Zn^{2+} is functionally active in synaptic transmission and is a contributory factor in neurological disorders including epilepsy and Alzheimer's disease	
	2,3-Diaminonaphthalene (selenium)		
F^{-}, Cl^{-}, Br^{-}, I^{-}	Calcein, 6-methoxyquinolium derivatives (SPQ), MQAE, MEQ, cell-permanent DiH-MEQ, and lucigenin	Measurement of intracellular Cl^{-} has renewed relevance to research on cystic fibrosis, and can be performed with a variety of probes. Conventional applications of Cl^{-} detection are membrane chloride transport (e.g., sodium-dependent transport, renal brush border, $GABA_A$ receptor) intracellular chlorine activity in the quenching of Al^{3+}-calcein complex, fluorescence has been used as the basis of the method for fluoride determination with a detection limit of $0.2\,mg\,ml^{-1}$ detection of Cl^{-}, Br^{-}, and I^{-} are also much performed via chemiluminescence	[11]
CN^{-}	*O*-Phthaldialdehyde and naphthalene-2,3-dicarboxaldehyde	Determination of cyanide in blood, urine, and other samples via reaction of fluorophore in presence of primary amine	[12]
Sulfide	5,5′-Dithiobis-(2-nitrobenzoic acid) (DTNB OE Ellman's reagent) and monobromobimane	Sulfide has been determined for histochemical studies, probing of dynamic changes of red cell membrane thiol groups, subcellular location of cathepsin D, and studies related to glucose-6-phosphate dehydrogenase, glutathione, and glutathione transferase, 6-mercaptopurine	[13]
Phosphate and pyrophosphate	DCIP, NBT, and Amplex red/resorufin	Detection of free phosphate in solution through the formation of the fluorescent products (e.g., resorufin via maltose phosphorylase, glucose oxidase, and HRP resorufin)	[14]

(*continued overleaf*)

Table 26.1 (*continued*)

Application area	Subfield or teaching technology	Typical dyes or assay system used	Description	References
	Nitric oxides	4-Amino-5-methylamino-2′,7′-difluorofluorescein (DAF), 2,3-diamino-naphthalene, and *N*-methyl-4-hydra-zino-7-nitrobenzofurazan	Role of nitric oxide in signal transduction has been recently realized, yielding new fluorimetric assays for NO^{2-} and NO	[15]
Gases	Oxygen, peroxide, and so on	Fluorophores that generate or detect reactive oxygen species, such as singlet oxygen, superperioxide, hydroxyl radical, peroxides. These include merocyanine 540, rose bengal diacetate, and xanthene dyes for the detection of peroxide via HRP	Various applications in bioscience: oxidation/peroxidation of lipids, fatty acids, and cholesterols, NADH, NADPH, dopamines, ascorbic acid, histidine, tryptophan, tyrosine, cysteine, glutathione, proteins, and nucleic acids. Relevance to research of Alzheimer's disease	[16]
General biomolecule detection	Functional group labeling and detection with single-dye molecules	Nearly, all known fluorescent dye conjugates of drugs, haptens, proteins, immunoglobulins, and nucleic acid: coumarins, fluorescein cyanines, rhodamines, specialized dyes: BODIPY and Alexa Fluor® and various extended cyanine dyes	Main application in diagnostic, laboratory assays, immunoassay, histochemistry, immunohistochemistry, flow cytometry, and cellular diagnostics	[1–6]
	Labeling and detection with fluorescent proteins and other fluorescent biomolecules	Phycobiliproteins, green fluorescent proteins	Diagnostic assay use, histochemical staining, imaging of live organisms and their functions	[17]

	Functional group labeling and detection with fluorescent latex particles	Fluorescent dye-loaded micro- and nanoparticles	Diagnostic assay use (particularly in immunochromatography tests) and flow cytometry	[18]
	Enzyme-labeled fluorescence (ELF)	Various phosphate-labeled fluorescent dye, ELF 97	Uses phosphatase-based signal amplification. Applicable to immunohistochemical and cytological staining, mRNA *in situ* hybridization, detection of endogenous phosphatase activity, and blot analyses	[19]
	Tyramide signal amplification (TSA) Technology	Various tyramide-labeled dyes	Utilizes the catalytic activities of horse-radish peroxidase (HRP) to generate high-density labeling of target (also *in situ*). Involves coupling of tyramide-fluorescent dye conjugate to protein tyrosine side chains via peroxidase-mediated formation of an *O*,*O*′-dityrosine adduct. Applied to immunohistochemical staining and *in situ* hybridization	[20]
Protein and nucleic acid detection	Protein quantification in solution in gels, in CE and 2DE, and on blots	SYTO, SYBR, fluorescamine and ophthaldialdehyde, novel dyes: BODIPY, NanoOrange$^{®}$, CBQCA, and SYPRO$^{®}$ protein gel stains	In addition to the conventional dyes for protein staining (Coomassie blue, colloidal gold), many novel fluorescent stains have been developed that allow highly sensitive protein quantification in solution and in gels, particularly the SYPRO protein gel stains	[21]
	Peptide analysis, sequencing, and synthesis	All fluorescent dye labels with reactive groups for amine, dansyl chloride, and dabsyl chloride	N-terminal amino acid analysis, peptide sequencing, peptide synthesis, labeling peptides in solution, and solid-phase synthesis of labeled peptides	[22]
		Fluorescent isothiocyanates		
	Detection of cytoskeletal proteins (actin, tubulin)	Fluorescent, Alexa Fluor, BODIPY, and other conjugates of actin, tubulin, and phallotoxins	Study of *in vivo* cytoskeleton dynamics. Labels of phalloidin and phallacidin are used for selective labeling of F-actin. Tubulin conjugates are used for observation of cell cycle-dependent microtubule dynamics, mitotic spindle morphogenesis, and visualization of tubulin transport in neurons	[23]
	—	SYBR$^{®}$ dyes for sensitive detection in cells and blots	The three classes of ‘‘classic’’ nucleic acid stains are	[24]

Table 26.1 (*continued*)

Application area	Subfield or teaching technology	Typical dyes or assay system used	Description	References
		Chemically reactive SYBR dyes for bioconjugates	Intercalating dyes (ethidium bromide and propidium iodide)	
			Minor-groove binders, (DAPI and the Hoechst dyes)	
			Miscellaneous nucleic acid stains with special properties (acridine orange, 7-AAD, and hydroxystilbamidine)	
	Hybridization detection including FISH (fluorescence *in situ* hybridization)	Chromatide nucleotides	Fluorophore- and hapten-labeled nucleotides for enzymatic incorporation into DNA of RNA probes for FISH (fluorescence *in situ* hybridization), for DNA arrays and microarrays and for other hybridization techniques	[25]
	—	SYBR Green	Real-time quantitative nucleic acid gel stain used in PCR	[26]
	—	Universal Linkage System™ (ULS)	Platinum-based chemistry for producing bright, fluorophore-labeled hybridization probes	[27]
	—	Enzyme-labeled fluorescence (ELF)	Phosphatase-based signal amplification assay also applicable to nucleic acid labeling	[28]
	—	Tyramide signal amplification (TSA™) technology	HRP-based assay with tyramide-fluorescent dye conjugate also applicable to nucleic acid labeling	[29]
Membrane and lipid research	General lipid and cell membrane labeling	Fluorescence-labeled lipids and fatty acids are generally used to investigate lipid traffic, for example, fluorescence recovery after photobleaching (FRAP) and other techniques examine lipid–lipid and lipid–protein interactions via FRET measurements	—	[30]

		characterize lipid domains by fluorescence correlation spectroscopy (FCS) characterize lipid domains by near-field scanning optical microscopy detect phospholipase activity investigate the cellular uptake of lipids investigate lipid metabolism and signaling study membrane fusion (pyrene eximer formation) and structural dynamics		
	Membrane potential-sensitive probes	Various styryl dyes (ANEP, RH) and Indo-, thia and oxa-carbocyanines, merocyanines, bisoxonols, and rhodamines	Dynamic optical detection and imaging or membrane potential changes	[31]
Detection of enzymatic actions	Glycosidases, glucuronidases, and so on	A large variety of β-galactosidase, β-glucuronidase, amylase, neuraminidase, sialidase, chitinase, and cellulose substrate	Endogenous glycosidase activity is frequently used to characterize strains of microorganisms and to selectively label organelles of mammalian cells. Defects in glucosidase activity are characteristic of several diseases. β-ᴅ-glucuronide activity is used primarily for contamination detection of *Escherichia coli*. β-amylase level in various fluids of the human body are of clinical importance. Plant and microbial β-amylase are important industrial enzymes. Cellulase enzymes are relevant in food, fuel, animal feed, and clothing applications	[32]
	Proteases and peptidases	7-Aminocouramins, rhodamine 110, fluorescein casein	Peptidase and proteases play essential roles in protein activation, cell regulation, and signaling, in the generation of amino acids for protein synthesis or utilization in other metabolic pathways	[33]

(continued overleaf)

Table 26.1 (*continued*)

Application area	Subfield or teaching technology	Typical dyes or assay system used	Description	References
	Metabolism of phosphates and polyphosphates, ATP phosphatases	Phosphatase substrates (classic chromogenic substrates: BCIP and NBT. Novel fluorescent substrates: fluorescein diphosphate, methylumbelliferyl phosphates, ELF 97e.o.) of bioluminescent determination of ATP	Detection of phospholipases phosphordiesterases, alkaline phosphates, ATPases, GTPases, DNA, and RNA polymerases	[34]
	Oxidoreductases	Fluorogenic reagent for H_2O_2 in conjunction with peroxidases (HRP) and catalase. (Amplex Red/resorufin, and so on). Electrochemical and chemiluminescence approaches are also much used	Systems are used in a wide variety of bioassays by linking various oxidases to HRP via hydrogen peroxide	[35]
			Determination of glucose, cholesterol, choline glutamate, xantine, and uric acid	
	Miscellaneous enzymes	Various probes for microsomal dealkylase, lipase, acetylcholinesterase, acetyltransferase, and carbonic anhydrase	—	[35e, 36]
Carbohydrate analysis	Lectins	Fluorescent concanavalin A, wheat germ agglutinin (WGA) fluorescein conjugates, lectins from *Griffonia simplicifolia, Phaseolus vulgaris, Arachis hypogaea, Helix pomatia, Glycine max*, cholera toxin subunits A and B	Lectins and other carbohydrate-binding proteins that bind to specific configurations of sugar molecules can serve to identify cell types or cellular components, making them versatile primary detection reagents in histochemical applications and flow cytometry	[37]

			Fluorescent derivatives of carbohydrate-binding proteins have been used to detect cell surface and intracellular glycoconjugates by microscopy and flow cytometry, to localize glycoproteins in gels and on protein blots, to precipitate glycoproteins in solution, and to cause agglutination of specific cell types	
Cellular biochemistry	Probes for mitochondria	Rhodamines and rosamines, carbocyanines, styryl dyes, lipophilic acridine orange, lucigenin, Mito-Tracker®, and MitoFluor™ Probes	Mitochondrion-selective reagents for assessment of mitochondrial activity, localization, and abundance, monitoring effects of pharmacological agents, such as anesthetics that alter mitochondrial function. Important role in apoptosis	[38]
	Probes for the endoplasmic reticulum (ER) and Golgi apparatus	The flattened membranous sacs of the ER and the Golgi apparatus can be stained with a variety of lipophilic probes and then distinguished on the basis of their morphology	The ER, and Golgi apparatus are responsible for the proper sorting of lipids and proteins in cells. Cell-permanent probes for these organelles are lipids or chemicals that affect protein movement. Enzymes in the ER are involved in synthesis of cholesterol and the membranes in the detoxification of hydrophobic drugs through the cytochrome P-450 system. Several enzymes in the Golgi glycosylate lipids and proteins, resulting in some fluorescent lectins being useful markers for this organelle	[39]
		Probes for the Golgi apparatus are fluorescently labeled ceramides and sphingolipids, which tend to associate preferentially with the trans-Golgi

Table 26.1 (*continued*)

Application area	Subfield or teaching technology	Typical dyes or assay system used	Description	References
	Calcium regulation	Cyclic adenosine 5′-diphosphate ribose (aADP-ribose), 3-deaza-cADP-ribose, Ryanodine derivatives, BODIPY FL thapsigargin, and so on Fluorescent-labeled calmodulin	Studies of calcium release. Calmodulin mediates many of the regulatory functions of calcium ions. Fluorescently labeled calmodulin is used to study the *in vitro* behavior of the protein (e.g., in the mammalian mitotic spindle). *In vitro*, fluorescently labeled calmodulin has been used for following the binding of protein kinase substrates by calmodulin studying the interaction of myogenic basic helix-loop-helix transcription factors with calmodulin investigating the molecular mechanisms for calmodulin trapping by calcium/calmodulin-dependent protein kinase I characterizing inhibitors of calmodulin activation of MLCKA-catalyzed phosphorylation of the smooth-muscle regulatory chain	[40]
	Blood coagulation	Fluorescent heparin conjugation	Study of heparin binding to thrombin, low-density lipoproteins, lipoproteins, lipase, circulatory serine proteases, proteinase inhibitors, heparin-binding growth factors, blood vessel-associated proteins (fibronectin and laminin), and binding to cells and tissues. Study of anticoagulant activity and the modulation of the structure, function, and metabolism of many proteins and enzymes	[41]
	Protein kinases, protein phosphatases, and nucleotide-binding proteins	Bisindolylmaleimides, fluorescent polymyxin B analogs, hypericin, hypocrellins, blue-fluorescent *N*-methylanthraniloyl (MANT) analog of cGMP, and fluorescent forskolin	Studies on protein kinase inhibitors and activators, cyclic nucleotides, adenylate cyclase, and so on	[42]

Receptor binding	Various acetylcholine receptors (probes to α-bungarotoxin probes, fluorescent derivatives of pirenzepine), andrenergic receptors (derivatives of prazosi and CGP 12177), GABA_A receptor (muscimol conjugates), neurokinin receptors (conjugates of substance P), neuromedin C receptor, angiotensin II receptor, and opioid receptors (naloxone and naltrexone probes), and so on Ca^{2+} channels α-conotoxin probes, fluorescent dihydropyridines, and verapamil ryanodine, and so on Probes for the Na^+ channel and the Na^+/H^+ antiporter. Amiloride analogs Na^+/K^+-ATPase: ouabain probes Probes for K^+ channels and carriers: glibenclamide conjugates for ATP-dependent K^+ channel, apamin probes for small-conductance Ca^{2+}-activated K^+ channels Probes for Cl^- channels and carriers: ivermectin probes for glutamate-gated Cl^- channels, stilbene disulfonates: (anion-transport inhibitors)	Fluorescent receptor ligands can provide a sensitive means of identifying and localizing some of the most pivotal molecules in cell biology. Many types of fluorescently labeled and unlabeled ligands exist for various cellular receptors, ion channels, and ion carriers. Many of these site-selective fluorescent probes may be used on live or fixed cells, as well as in cell-free extracts. Many new dyes provide extremely sensitive detection, which enables the measurement of low-abundance receptors. Various methods for further amplifying detection of these receptors have been reported. A variety of probes for Ca^{2+}, Na^+, K^+, and Cl^- ions channels and carriers have been described. Ion flux that affects the cell membrane potential, can be indicated with potential-sensitive probes	[43]

	Phagocytosis	Dichlorodihydrofluorescein diacetate and OxyBURST® technology	Monitoring of the oxidative "burst" produced by activation of an NADPH oxidase in a chain of events starting with the binding of surface-bound immunoglobulin G (IgG) immune complexes interaction with Fc receptors	[44]
	Apoptosis	Various fluorescence-based kits, for example, those using annexin V conjugates Caspase protease activity	Apoptosis is a genetically controlled cell death. Various approaches are used in studying apoptosis, in distinguishing live cells from early and late apoptotic cells, and in forming necrotic cells. Apoptosis assay may be based on nucleic acid and stains annexin V conjugates protease activity mitochondrial stains free radicals ion indicators esterase activity ATP–ADP ratio	[45]

Table 26.2 Comparison of noise levels in the NIR and visible regions [2].

Source of noise	Visible region	NIR region
Detector	High	Low
Scatter (Rayleigh/Raman)	Greater at lower wavelengths (scattering is 1/4 dependent on λ)	Reduced
Autofluorescence	Most biomolecules exhibit fluorescence	Reduced

26.2
Chemistry of Vis–NIR Dyes

The application of new NIR sensors in the detection of key biomarkers continues to advance primarily because of an increasing scope of clinical application and the need for better microenvironmental monitoring. Interestingly, most commercially available fluorescent dyes self-aggregate in aqueous solutions resulting from π-stacking of the planar π-electron conjugation systems giving rise to both H-(hypsochromic) and J-(bathochromic) aggregation. Self-aggregation depends primarily on solvent polarity, but may also be affected by temperature, pH, dye concentration, and ionic strength [46]. Besides the aggregation properties of conventional fluorescent, they also suffer from low photostability, poor quantum efficiency, low Stoke shifts, and severe quenching of the fluorescence of cyanine dyes in biopolymer conjugates, for example, quenching of Cy5 and Cy7 dye variants on conjugation [47, 48]. Visible and NIR fluorescent dyes, which are relatively stable in the solid state, are, however, susceptible to photochemical degradation, which may result in photobleaching. Given the propensity to self-aggregate and photooxidize, the application of fluorescent dyes in solution is rather limited, thus, many new analogs are being developed with enhanced solubility and reduced photosensitivity.

26.3
UV–Vis Fluorescent Dyes

26.3.1
Rhodamines

Rhodamines are fluorescent molecules belonging to a family of 3,6-di(substituted-amino)-9-benzoate derivatives of xanthenes, and are commonly used as fluorescent probes in trace metal analysis [48], labeling of biological compounds, for example, antibodies or DNA [49], and as fluorescent tracers in histochemical studies [38]. These molecules can be derivatized with either an isothiocyanato group, for example, tetramethylrhodamine isothiocyanate or an *N*-hydroxysuccinimidyl

(NHS) ester functionality, for example, 5-carboxytetramethyl-rhodamine succinimidyl ester for covalent labeling at the amino group of proteins or amino-functionalized nucleotides. As hydrophobic compounds, rhodamines and their derivatives usually display poor water solubility, a prerequisite of effective conjugation reactions involving biologically relevant macromolecules (proteins, nucleic acids, and carbohydrates). In addition, the suitability of rhodamines as fluorescent probes may be further limited by poor solubility in aqueous solutions, which enhances aggregation and dimerization reactions [50, 51] (Figure 26.1).

To overcome the disadvantages of aggregation and unspecific absorption, a simple and efficient method is used to increase the water solubility of rhodamine and its derivatives. Recent studies have reported the successful synthesis of water-soluble sulfonated rhodamine 6G with rigidized xanthenes fragments. Besides reducing aggregate formation, sulfonation of the probes proved quite useful in inhibiting fluorescence quenching associated with conjugation, enhancing the photostability and pH sensitivity [49]. In addition, with the advantageous spectral characteristics displayed on sulfonation of the rhodamine molecules, further spectral tunability can be achieved with variation at the c-*meso* substituent [52, 53]. There are only a few discussed synthetic routes that yield novel rhodamine derivatives with ideal spectral properties suitable for biomolecular labeling. Wu and Burgess [53] demonstrated the preparation of new rhodamine analogs by modification of the 2-carboxylate group to yield fluorescein, rosamine, Tokyo green, and Pennsylvania green (Figure 26.2 and Table 26.3).

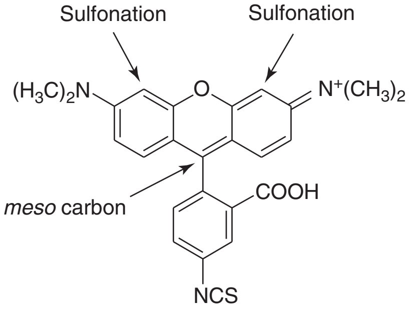

Figure 26.1 Structure of isothiocyanato-functionalized fluorescein.

O	OH	H	H	CO_2H	Fluorescein
O	OH	F	F	CH_3	Pennsylvania Green
O	OH	H	H	CO_2H	Tokyo Green

26.3.2
Coumarins

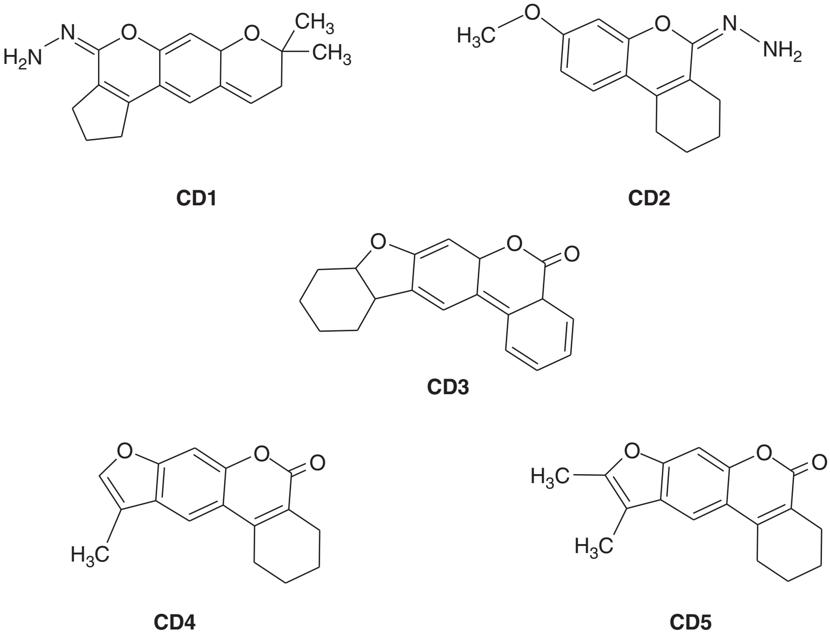
Coumarin is a group of low-molecular-weight fluorescent dyes with maximum absorbance in the 320–530 nm region of the spectrum. Similar to most fluorescent compounds previously discussed, coumarins exhibit strong fluorescent intensity in the UV–Vis range; thus, making them applicable in laser-active media, optical brighteners, and LEDs [54]. Coumarins are synthesized as heterocyclic aromatic molecules derived from cinnamic acid via the ortho-hydroxylation synthetic pathway. Derivatization of the molecular structure results in unique photophysical behavior and may further induce photosensitizer properties [55]. Unlike most fluorescent dyes, coumarins and its derivatives are produced naturally in plants as essential oils; thus, further enabling their pharmaceutical suitability. Bryantseva *et al.* [55] studied the fluorescent characteristics of coumarin photosensitizers using furocoumarins; a class of derivatized coumarins (**CD1**, **CD2**, **CD3**, **CD4**, and **CD5**) that absorb in the 320–400 nm spectral range. Intersystem crossing in the order of $\sim 10^{10}$ to $10^{11}\ s^{-1}$ was reported, which confirms the applicability of the substituted dyes as prime photosensitizers (Figure 26.3).

In addition, new sequential biosynthetic oxidation and alkylation reactions of coumarins (to form furanocoumarins) that have been reported enable the molecules to act as bifunctional photoreagents, capable of conjugating double-stranded DNA by cross-linking both strands (Scheme 26.1) [54, 56–59].

26.4
Near-Infrared Fluorescent Dyes

26.4.1
Carbocyanine Dyes

Among the large variety of commercially available fluorescent probes, carbocyanine dyes are highly recognized because of their intense absorption in the NIR region. These probes typically comprise two heterocyclic rings that are bound together



CD1 CD2 CD3 CD4 CD5

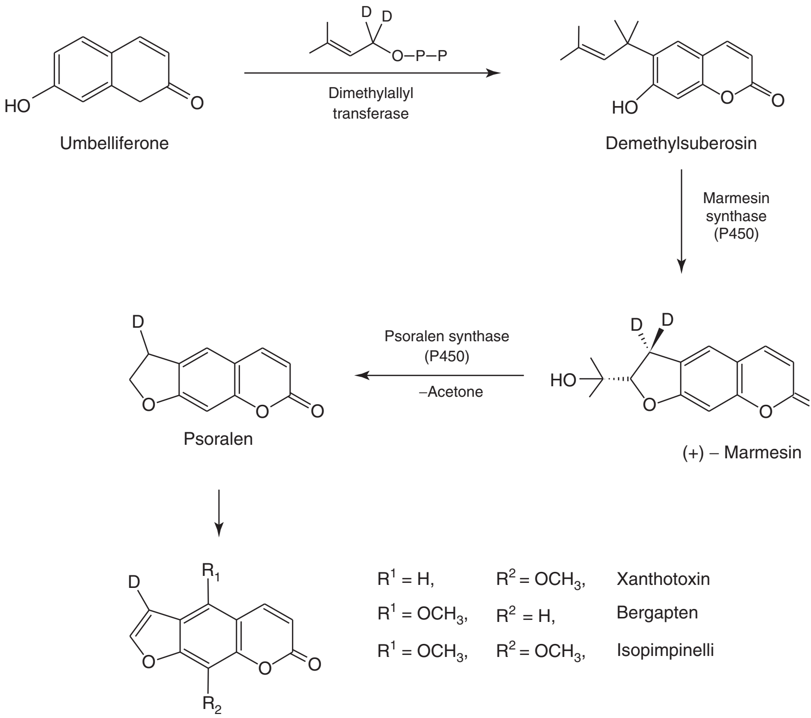
Figure 26.3 Substituted coumarin dyes characterized by Bryantseva *et al.* [55].

by a polymethine linker; each heterocyclic ring system incorporates one or more nitrogen atoms as shown in the general structure of Figure 26.4.

Variation in the length of the polymethine linker affects the absorption and emission properties on these NIR dyes and their common names denote the number of methine groups in the polyene chain [60]. In fact, it is reported that incorporation of an additional methine group can result in redshifts of up to 100 nm in the absorbance maxima [48]. Kim *et al.* [46, 61] have proposed a new synthetic pathway for the preparation of novel dimeric bis(heptamethine) carbocyanine dyes (BHmC)-***n***; ***n*** = **4**, **6**, **8**, and **10** that are relevant to the DNA labeling and *in vitro* studies of human serum albumin (HSA) with absorbance maxima in the order of 780 nm (Scheme 26.2).

Interestingly, there is a unique polymethine chain length-dependence spectral behavior observed with bis(heptamethine) dyes. Although the monomeric molecules exhibit strong fluorescence intensity in the 780 nm region, there is a common reduced photoactivity in the H-band of this class of compounds. In addition to low fluorescence that is observed, there is reduced quantum efficiency with the intermolecular H-aggregates of the monomeric analogs **4**. This highlights the unique spectral properties associated with aggregate formation in NIR fluorophores.

Carbocyanine dyes are popular in the development of digital data processing, optical communication, molecular labeling, light harvesting, and drug delivery agents. In a more recent study, Ma *et al.* [62] investigated the application of NIR cyanine dyes in the development of an organic light-emitting diode (OLED) for



Scheme 26.1 Biosynthetic pathway reported by Stanjek *et al.* [57] toward the formation of furanocoumarins: xanthotoxin, bergapten, and isopimpinellin from umbelliferone (a coumarin compound).

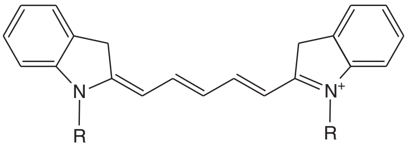


Figure 26.4 General structure of a carbocyanine dye.

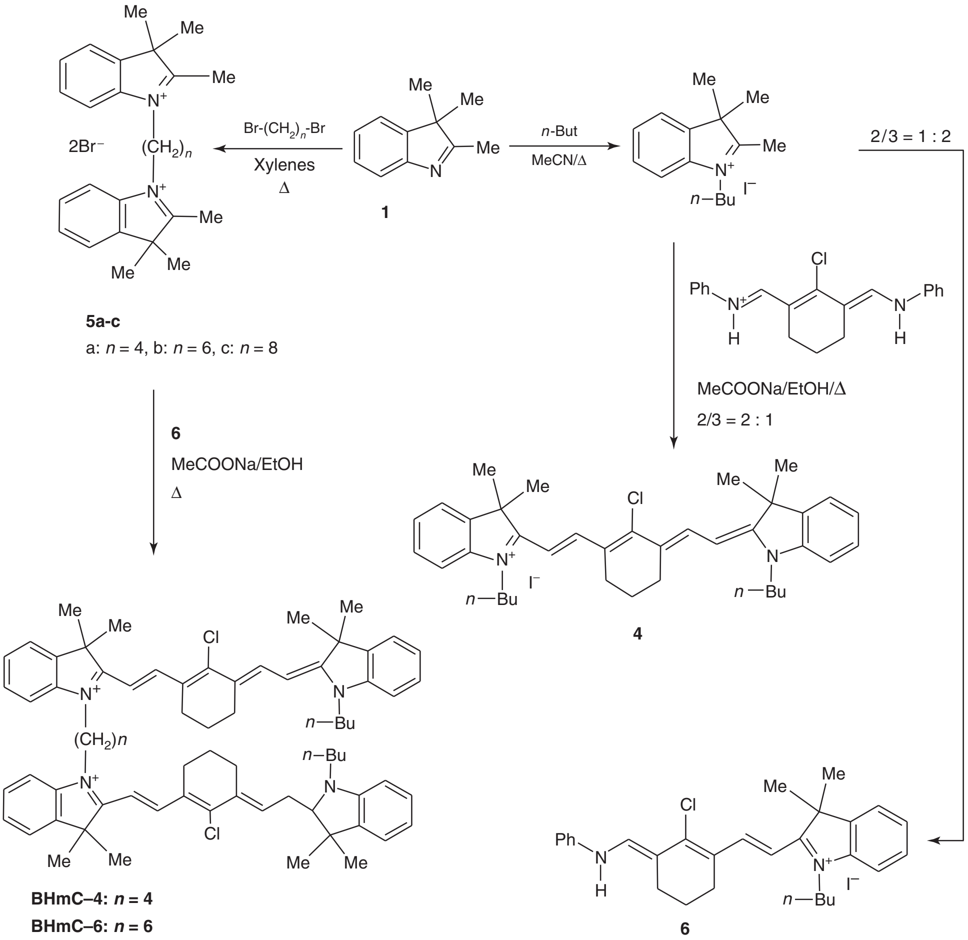
use in optical communication and information processing. The optical properties of a fluorescence conjugate of poly(*N*-vinylcarbazole) (PVK) doped with the commercial NIR cyanine dye, 2-[2-[2-Chloro-3-[2-(1,3-dihydro-1,1,3-trimethyl-2H benzo[e]-indol2ylidene)ethylidene]-1-cyclohexen-1-yl]-ethenyl]-1,1,3-trimethyl-1H-benzo[e]-indolium-4-methylbenzenesulfonate (ADS830AT) was studied by spin-casting techniques [63]. In this work, the investigator developed an OLED of improved electroluminescence (EL) efficiency and reduced overlap from ultraviolet emission.

Most of the light-emitting materials reported in literature are ionic cyanine dyes with limited practical applications because of low EL efficiency. During the studies,



Scheme 26.2 Synthetic route to symmetrical indoleum bis(heptamethine) dyes by Kim *et al.* [46, 61].

Ma [63] discovered that in addition to improved EL efficiency, a single-emission layer PVK OLED device doped with NIR dye emits pure monochromatic NIR radiation at 890 nm and displayed stable spectral properties with forward bias voltages. Further advancements around the NIR region of the spectrum led to the fabrication of other optoelectronic cyanine analogs. New acidochromic molecules were synthesized and studied. Alonso *et al.* [64] developed novel heptamethincyanine dyes that have proven useful in the fabrication of inexpensive communication components. The rapid technological growth in the telecommunication field propelled an increased demand for new and less-expensive optochemical sensors. This resulted in the proliferation of chromoionophoric-embedded plasticide polyvinyl chloride (PVC) optodes capable of detecting the optical transduction signal generated by chemical reactions. Although classic acid–base indicators with absorption maxima in the visible region of the spectrum are suitable as potential chromoionophores, their applicability as plasticide PVC optodes is limited by spectral interferences. Only few classes of molecules fluoresce in the NIR region thus, enabling reduced spectral interferences and enhanced sensitivity. Puyol *et al*. further characterized three types of chromoionophores (Figure 26.5): nortricarbocyanine dyes (**3**), norindosquarocyanine dyes (**5**), and norindocrococyanine dyes (**7**) based on acid–base equilibrium with an aim to optimize the spectral characteristics by lowering the pK_a values.

This work highlights the effects of acid–base equilibrium on the optochemical properties of newly synthesized cyanine dyes. New trends in PVC optodes are geared toward widening the scope of chromoionophore applications by miniaturization of chemical analytical platforms, with a subsequent reduction in the size and complexity of optical systems. Laser diodes emitting at 670 and 780 nm are most suited for this purpose because of the high molar absorptivities of the dyes used with them, the high intensity of the laser diodes and low overall cost [64, 65]. It was demonstrated that the improved spectral characteristic and subsequent chromoionophore suitability in optochemical sensing of cyanine dyes, depend primarily on the conjugated chromophoric system and the nature of the polymethine side chain. Nortricarbocyanine dyes commonly consist of longer polymethine chains than its norindosquarocyanine and norindocyanine counterparts, thereby displaying favorable absorption characteristics for longer wavelength in the NIR region of the spectrum. Besides, the ability to induce ring formation of the side chain further

enhances spectral stability and thus greater potential for optochemical fabrication and chemical-sensing capabilities [66]. Similar to the approach used by Puyol, Qian *et al*. characterized the spectral behavior of two groups (one symmetrical and the other asymmetrical) of novel NIR cyanine dyes (Figure 26.6) as fluorescent pH sensors by monitoring the pK_a value of the molecules. The studies indicated strong fluorescence enhancement, as well as distinct bathochromic shifts, of the absorption peaks from 525 to 570 nm as a result of the protonation of two of the symmetrical NIR fluorescence analogs. In addition, R-group substitution at the C-3 position of the indole ring resulted in distinct spectral changes to the emission maxima and the quantum efficiency of these cyanine dyes (Table 26.4).

Table 26.4 Spectral characteristics of novel cyanine dyes bearing different R groups at the C-3 position indoleum ring, developed by Xu *et al*. [67].

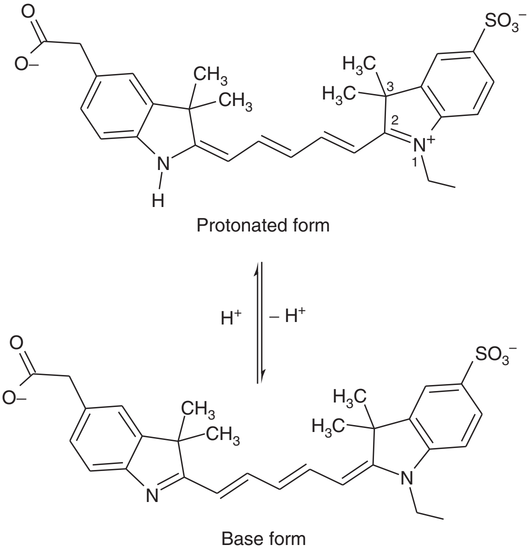
However, such favorable spectral changes could not be explained through mere proton deprotonation or resonance effect within the molecule. It was reported that pH sensitivity is attributed to changes from photoinduced electron transfer (PET) to intramolecular charge transfer (ICT) mechanisms, thus the compound can be fabricated into a pH sensor of high pK_a [66, 67]. Zhang *et al.* [67] also prepared a modified analog to a novel fluorescent molecule for improved spectral properties as a fluorescent pH indicator.

As reported by Zhang and Achilefu *et al.* [67], norcarbocyanines dyes such as indocyanine green (ICG) and cypate conjugates are easily prepared as target-specific pH indicators, through substitution on the indole ring for conjugation of the free carbonyl groups in biomolecules [63, 68] (Scheme 26.3).

26.4.2
NIR Dyes for *In Vivo* Molecular Imaging

In recent years, the development of new sensors for the detection of key biomarkers continued to advance primarily because of an increasing scope of clinical application and the need for better microenvironmental monitoring. For example, redox-active dinuclear ruthenium conjugates are functionalized with cyanine dyes for clinical monitoring of important biochemical substances such as glucose or hydrogen peroxide under physiological conditions. Xun *et al.* [68] have successfully synthesized various redox-active conjugates of ruthenium-1,2-dicarbonylhydrazide, and these complexes display intense absorbance in the NIR region of the spectrum when present in the mixed valence state as Ru^{2+} and Ru^{3+} because of the oxidative potential of hydrogen peroxide or any strong available biological oxidant. Glucose



Scheme 26.3 The NIR cyanine base-form pH-sensitive fluorescence probe [64, 66, 67].

oxidation to hydrogen peroxide provided a suitable oxidative pathway for the formation of the ruthenium-mixed valence complexes and as such creates the ideal platform for the fabrication of the glucose NIR optical sensors [69]. The combination of simplicity in design and low electrical interferences further propelled the development of redox-based NIR optical sensors.

Research has shown that synthesized monosubstituted Vis–NIR cyanine dyes are suitable for use as transducers in distributed fiber-optic ammonia sensors [70, 71]. While most commercially available Vis–NIR fluorescent molecules display diminished optical properties and are less suitable for sensing chemically and biologically important substances such as ammonia. Simon *et al.* [72] reported a cyanine dye displaying ammonia-induced absorption peak at 620–680 nm. These newly developed fluorescence probes are been designed for the near to mid-infrared (MIR) regions with diminished light-scattering interference and background autofluorescence. The application of these dyes has even been extended to incorporate the fabrication of optical fiber sensors utilized in evaluating the decomposition of heavy hydrocarbons in transformer oil. The application of NIR dyes to detect slight changes in refractive indices incorporates the partial discharge of gaseous hydrocarbons, such as methane, ethane, propane, and butane, resulting from chemical disturbances in liquid hydrocarbons, for example, transformer fluids. This technique involves evanescent field absorption (EFA) measurements with an NIR optical sensors-coupled spectrometer, for enhanced performance. Although the intensity of the C–H, N–H, or O–H bond vibration is reduced by as much as a factor of 100 in the NIR as opposed to the corresponding ground modes at higher wavelength, such as, the MIR region, the former is preferred for its advantage of enhanced spectral purity and improved signal-to-noise ratio [46]. Furthermore, hydrocarbon sensing by EFA-MIR techniques requires the use of silver halide fibers, which, because they are sensitive to chemical attacks, suffer from UV degradation and high-transmission loss, making them less attractive for optical fiber development. As a result, the NIR-fabricated devices are more applicable for both their mechanical and optical properties, hence are more suitable for practical sensing applications [73–75].

The field of NIR spectroscopy has undergone an unprecedented surge in the application of NIR fluorophores specifically in the areas of optoelectronics and optochromic technology. More researchers are taking advantage of improved sensitivity resulting from lower background autofluorescence and reduced light scattering for deep tissue *in vivo* imaging. Typical examples of NIR cyanine dyes reported in literature include ICG and the IRDye78 [76]. Chen *et al.* [77] discussed noninvasive imaging and quantification of $\alpha_v\beta_3$-positive integrin level in the blood. $\alpha_v\beta_3$ integrin is believed to be responsible for the regulation of tumor growth and metastasis as well as angiogenesis. Increased blood level of this target molecule is a key factor in the evaluation of the aggressiveness of the disease. In this work, the researchers outlined the integrin receptor specificity of the newly synthesized peptide-dye conjugate arginine-glycine-aspartic acid (RGD)-Cy5.5 as a contrast agent *in vitro*, *in vivo*, and *ex vivo* imaging. An intravenous injection of a 3 nM dose of the fluorescent probes resulted in an instantaneous whole-body imagery of an athymic nude mice specimen. However, after 4 h postinjection, the U87MG tumor could be distinctly differentiated from the background tissue. Although the uptake and decomposition of the fluorescent probe was rapid in healthy tissue, it was rather slow in affected tissue. *Ex vivo* evaluations were also performed and results revealed improved sensitivity, achieving enhanced emission intensity and tissue contrast. This fluorescence probe is ideal for intraoperative NIR imaging because of its superb tissue contrasting capabilities and overall low toxicity. ICG-polyamine (polyethylamine, PEI) (IR820-PEI) is also a prime NIR dye conjugate developed specifically for *in vivo* NIR fluorescence imaging with improved photostability and reduced aggregation formation. With a large Stoke's shift of 115 nm in aqueous solution, this NIR fluorophore displayed strong binding affinity for DNA. Coupled to the low molecular weight and relatively high-quantum efficiency of ICG, this newly synthesized conjugated NIR fluorescent dye facilitates improved deep tissue imagery for the evaluation of liver function and noninvasive angiography in ophthalmology [78]. Similar results are achieved with *in vitro* optical NIR-imaging studies using novel carbocyanine–glucosamine conjugates. In addition to improved quantum efficiency and decreased aggregation tendencies in polar environments, NIR dye–glucosamine conjugates exhibit low toxicity and moderate-to-low pH response at physiological pH range. Owing to improved solubility in aqueous solutions and increased quantum yields, conjugation results in enhanced cellular uptake and a concomitant intracellular NIR fluorescence enhancement in breast epithelial cell lines [79]. NIR fluorescence monitoring of glucosamine levels has also enabled *in vivo* assessment of lysosomal proteins and provided a viable option for the evaluation of cancer and metastasis in their early stages [80]. Similar approaches have being attempted in order to study lysosomal target cells using NIR dyes. This is achieved primarily by binding a self-quenching targeting moiety, which is subsequently internalized into the lysosomal target cells. The application of this self-quenched avidin-rhodamine X conjugate (Av-ROX) facilitates the *in vivo* targeting as well as NIR-imaging differentiation of the aberrant tumor cells and the healthy background tissue. While intracellular degradation within the lysosomes leads to dequenching and subsequent fluorescence reactivation within the target cells, virtually no effect is observed within the surrounding tissue [81]. Besides achieving high-fluorescence signal-to-noise ratios for the targeted tumor cells, this technique allows improved molecular imaging.

NIR dyes have found application for *in vivo* molecular imaging of cellular events in early aortic valve disease. NIR dyes are used to visualize endothelial cells, macrophages, proteolysis, and osteogenesis in the aortic valve of hypercholesterolemic apolipoprotein E-deficient mice. Early detection of aortic valve diseases, such as macrophage activation, osteogenesis, and protein intramolecular degradation, can be achieved by utilizing NIR molecular imaging [82] also, and it is reported that NIR molecular imaging visualization of valvular cell functions *in vivo* may identify therapeutic targets in early atherosclerosis diagnosis.

A free-radical precipitation polymerization method was used to prepare thermally responsive poly(*N*-isopropylacrylamide-co-acrylamide) (P(NIPA-co-AAm)) nanohydrogels, which can later be evaluated by *in vivo* NIR fluorescence imaging on healthy and S180 tumor-infected denuded mice specimens. Fluorescent imaging studies may be performed by evaluating the overall fluorescence intensity of an entrapped novel NIR dye NIRD-12 into P(NIPA-co-AAm) nanohydrogels on both sets of specimens, which may or may not be exposed to controlled hyperthermic treatment. The researchers have reported passive and nonspecific thermally targeted behavior. In reality, the thermal-responsive, fluorescence-tagged nanohydrogels are only accumulated at higher temperatures in both healthy- and tumor-affected tissues. Although in other research experiments, the affected cells are differentiated by the NIR fluorescence, in the current experiments these results were not fully observed. Nonetheless, the thermal response of P(NIPA-co-AAm) nanohydrogels, regardless of health status, provided a viable option as a thermal carrier of drugs, especially for tumor diagnosis. In addition to the key thermal response of the P(NIPA-co-AAm) nanohydrogels, NIR dye conjugate is indicated by a distinct bathochromic shift at the absorption maxima. This is further characterized by enhanced photostability resulting from the entrapment of the fluorescent probe within the nanohydrogel polymer [83]. The technique improves molecular imaging and enables extending the overall time available for *in vivo* monitoring of the dynamic process of dye-loaded nanohydrogel polymers.

26.4.3
Squaraines and Rotaxane Dyes

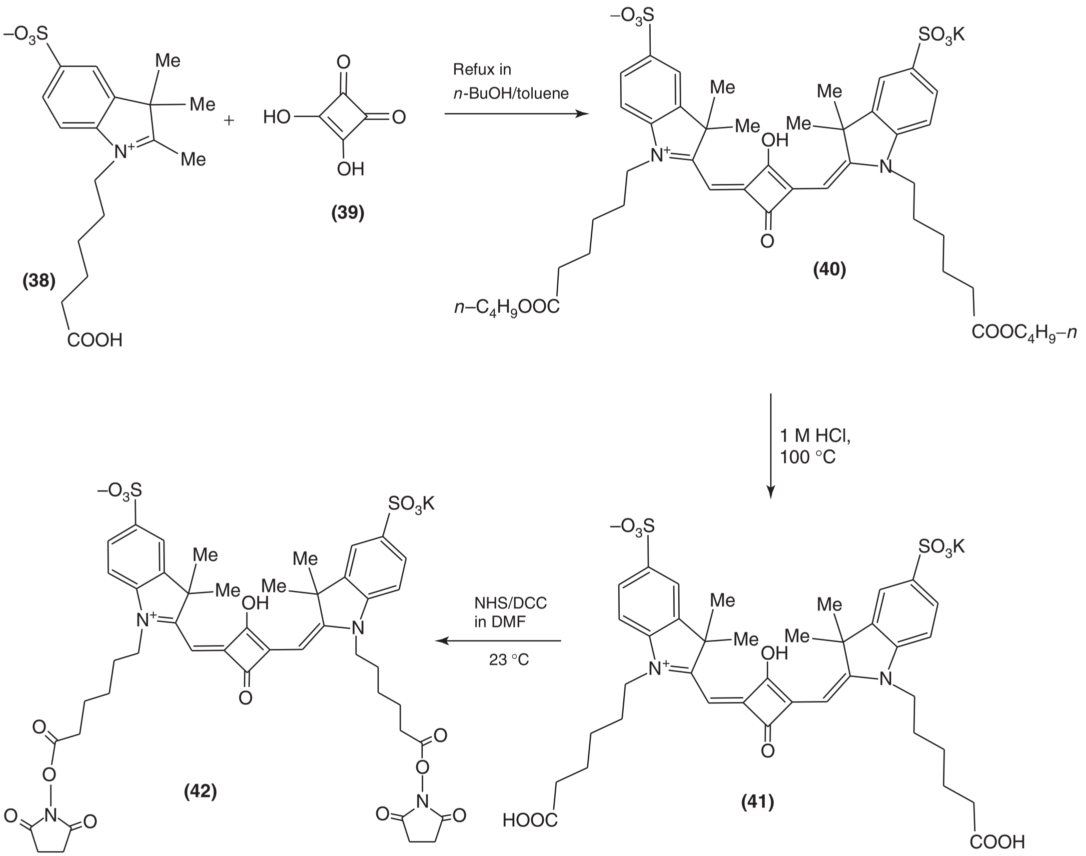
Squaraines are a class of dyes that are well known for their intense fluorescence in the NIR region of the spectrum. These NIR molecules exhibit significant triplet quantum yields and are characterized by their unique aromatic four-membered ring system derived from squaric acid [84–88]. A number of squarylium derivatives are now being developed for application as such as chemosensors [89], *in vivo* imaging [90] photovoltaics, and low cost, large-area solar cells [91]. Unlike most of the other commonly encountered fluorophores, the applicability of squaraines is limited by the high electron-deficient four-membered ring, which inherently undergoes nucleophilic attacks [86]. As a result, Xue *et al*. [88] have proposed a new synthetic pathway for the preparation of a pair of triptycene-based tetralactan macrocycles, which can protect the squaraine molecules from polar solvents by formation of a dye–macrocycle complex. Furthermore, there is currently a vast number of commercially available squaraine-derived rotaxanes that have been developed for improved protection from nucleophilic attacks and enhanced spectral characteristics such as reduced aggregate formation [92]. Most often, the rotaxanes analogs exhibited the same excellent photophysical properties as the precursor squaraines, as well as improved spectral properties as a result of the encapsulating macrocyclization [88].

A common spectral improvement to the rotaxanes is the retardation of photobleaching tendencies of the molecules. In fact, Arunkumar *et al*. [92] reported the preservation of the color of the rotaxane molecule in aqueous solution after several weeks as oppose to the squarylium precursor, which undergoes photobleacing within 48 h at similar experimental conditions. In addition, incorporation of the encapsulating macrocycle results in diminished adsorption band broadening by inhibiting interchromophoric interactions both in solution and in the solid state. The spectral versatility of squaraine dyes make them quite unique as fluorescent probes and NIR labels for biomedical applications [93]. Terpetschnig *et al.* described a novel *N*-succinimidyl ester-derivatized indolium squaraine dye, which displayed strong conjugation affinity for HSA. Conjugation of the water-soluble NIR fluorophore yielded fivefold improved quantum efficiency and enhanced fluorescence lifetime [98]. In addition to the common ''methylene base'' synthetic pathway involving squaric acid or its derivatives, a novel synthetic route for monosubstituted squaraines by reacting with malononitrile, cyano-, and nitroacetic esters, barbituric acid, and 1,3-indanedione was proposed [94]. Interestingly, these monosubstituted squaraine dyes are in a similar spectral range of the more popularly known Cy5 and Cy5.5 NIR fluorescent dyes and are even considered more stable in aqueous solutions with molar coefficients in excess of 265 000 M^{-1} cm^{-1} [95] (Scheme 26.4).

26.4.4
Phthalocyanines and Naphthalocyanins

Similar to the squaraines, phthalocyanine (Pc) and naphthalocyanin (Npc) dyes are versatile planar fluorophores exhibiting strong fluorescent intensity in the NIR of the spectrum. Pcs and Npcs have been recently attracting enormous popularity for their use in the fabrication of molecular devices, such as electrochromic displays [100], LEDs [101], gas sensors [101–103], and photodynamic therapy agents [104]. While Pcs exhibit the natural tendency to self-aggregate owing to the large aromatic π-system [105, 106] as a result of coplanar Pc ring association, the general spectral characteristics are easily ''fine-tuned'' by a central metal and peripheral substitution at the rings [102, 107]. Thus, these NIR fluorophores are usually prepared as metal-free or metal-complexed conjugates. Generally, the peripheral substituents are used to modulate the hydrophobic character of these compounds making them more or less soluble in polar solvents. Consequently, the octasubstituted Pcs usually exhibit reduced solubility in comparison to the tetrasubstituted counterparts. In addition to modifying the solubility and hydrophobic behavior, peripheral substitution to these compounds yields a diverse range of functionalities enabling greater applicability. For example, the electrochemical and spectroelectrochemical behaviors of copper–Pc complexes have been investigated in relation to the position of tetrasubstituted phenylthio groups in the alpha and beta positions [108].

Similar to the squarylium dyes, rotaxanes belong to a unique class of fluorescent compounds. Rotaxanes are supramolecular compounds comprising macrocyclic and dumbbell-shaped components [87, 109, 110]. These molecules also consist of a ring and a threadlike component incorporating two recognition sites (stations). Within the last decade, there has been tremendous progress in the development of new synthetic pathways of these interlocked molecules. In recent work, Michaels *et al.* [111] have proposed the synthesis of novel conjugated polyrotaxane compounds by an aqueous Suzuki polymerization pathway, using hydrophobic binding to promote threading of cyclodextrin units. In this study, new cyclodextrin-encapsulated



Scheme 26.4 Synthetic route to Sq635 squaraine dye **42** containing *N*-succinimidyl ester moieties. Sq635 is utilized in fluorescence resonance energy transfer (FRET) immunoassay by Terpetschnig *et al*. [2, 96–99].

fluorescent compounds were fabricated with conjugated polymer cores based on poly(*para*-phenylene), polyfluorene, and poly(diphenylene-vinylene), threaded through 0.9–1.6 cyclodextrins per repeat units. Besides improved overall quantum efficiency, these conjugated fluorescent rotaxanes molecules exhibit enhanced chemical stability, attracting widespread interest for optoelectronic applications [111]. Recently, there have been increased interests in insulated π-conjugated systems with high stability, high solubility, and improved quantum efficiency as a result of the isolation of the π–π-conjugated systems from the external environment and reduced π–π interactions among the conjugates [110].

Among the most notable characteristics of the rotaxanes is their photoswitching capability [112–115]. The photophysical properties of the bistable rotaxane molecules are attributed to molecular movements stimulated by external stimuli and are controlled by the two recognition sites as a shuttling process, which may alter the ring position [97, 113, 114, 116–132]. Most of the rotaxane-based molecular switches reported in literature involve mechanical movement of a ''ring'' component between the two ''thread'' components induced by pH [122], electrical potential [128, 132], chemical interactions [116, 123–125], and photochemical stimuli [126] (Figure 26.7).

However, new research is focused on developing alternative switching principles such as photoinduced charge–transfer interactions of a tetracationic ring with a photoactive electron donor. This subsequently reduces conformational changes to the rotaxane supramolecules and maintains overall molecular structure [117]. This principle of switching involves a rapid PET cascade that last only a few seconds, with the rotaxanes being in their tropylium state. It is believed that

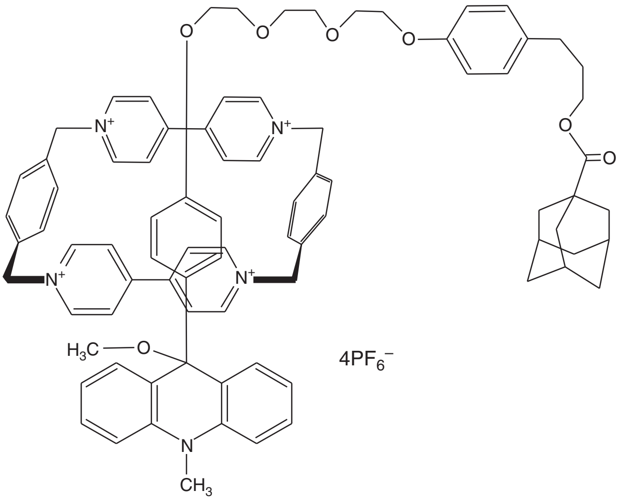


Figure 26.7 Switching mechanism reported by Abraham [97, 117]. Charge–transfer interaction between the tetracationic ring (cyclobis (paraquat-4,4′-bisphenylene) with photoelectron donors (arylcycloheptatriene) into an aryltropylium electron acceptor.

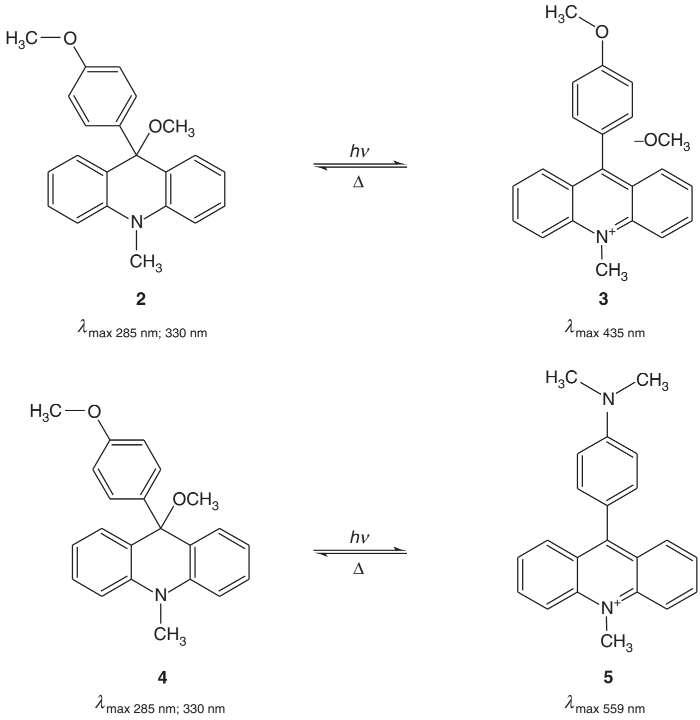

Scheme 26.5 Two types of photoswitches in rotaxanes were developed by Abraham *et al.* [97, 117].

the irradiation of the arylcycloheptatrienes molecules **2** ($\lambda_{\text{max}} = 285$ nm) and **4** ($\lambda_{\text{max}} = 285$ nm) shown in Scheme 26.5, results in a single-step photoreaction to form the respective acridinium salts; **3** ($\lambda_{\text{max}} = 435$ nm) and **5** ($\lambda_{\text{max}} = 559$ nm). Although the conventional chemical or pH-triggered shuttling processes often lead to undesired side reactions, photoswitching eliminates the formation of waste products, enabling these bistable rotaxanes to serve as archetype molecules for nanoscale photoelectronic systems [121, 133]. Nonetheless, although the use of fluorescence detection in sensors is widely explored, there are still only a few fluorescence-triggered rotaxane photoswitches [126, 133] reported in the literature.

Principles of Vibrational Spectroscopic Methods and their Application to Bioanalysis

David S. Moore, Peter Uhd Jepsen, and Karel Volka

27.1
Fourier Transform Infrared Absorption Spectroscopy

27.1.1
Introduction

The ability of infrared spectra to elucidate even minute changes in the chemical structure or composition of a sample has stimulated many studies of biological objects or their components. The opportunity to obtain relationships between the parameters derived from the spectra and the symptoms of disease, pathology, injury due to environmental pollution, and so on, has driven the research for medical, clinical, biological, environmental, and many other applications.

A great potential of infrared spectroscopy, especially when combined with Raman spectroscopy, lies in the fact that information about the structure or content/concentration of individual components can be gained with some of the following advantages:

- no treatment or separation of the sample;
- reagent-free analysis;
- all state forms (solid, liquid, and gas) measurable;
- rapid analysis;
- macro as well as micrometer size objects measurable;
- measurements possible *in situ, in vivo*, or at the point of care;
- noninvasive, that is, without direct contact between the transducer and the probed biological object.

Naturally, these applications are inherently faced with the following problems of complexity of the objects and the properties of infrared radiation:

- Low penetrability of the infrared radiation, which is of the order of tens of micrometers in the mid-infrared region. The low penetrability is determined by the strong absorption of infrared radiation by water and other components of the tissues. Water absorption also limits the applicability in the near-infrared

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

region, but there are several transmission windows for which the thickness of the measured layer can be as large as 10 mm.

- Heterogeneity of the measured medium, responsible for strong scattering of radiation. Even infrared spectra of single biological cells are strongly distorted because the size of the nuclei and other organelles are of the same dimensions as the wavelength of mid-infrared radiation (1–10 μm). Only a small fraction of the photons passes through the measured medium without change in the optical path, but for the majority of photons, the length of the optical path is poorly defined.
- Spatial (inhomogeneous arrangement of cellular elements) and temporal variability (aging) of the biomaterial.
- Complexity of the measured spectra. Absorption bands of the individual components, usually of macromolecular nature, strongly overlap. This fact in most cases excludes quantitative or even qualitative conclusions without extensive computational processing of the spectral data.

27.1.2
Instrumentation

Bioanalytical applications of infrared spectroscopy greatly profit from the advantages of the Fourier-transform (interferometric) technique over the dispersive technique. Nowadays, research has shown that infrared spectrometers nearly exclusively use the interferometric technique of measurement, but for routine applications and in single-purpose/dedicated equipments, especially in the near-infrared region, they also work with the dispersive elements or optical filters (e.g., temperature-controlled acousto-optical tunable filters).

The Jacquinot advantage of Fourier-transform infrared (FTIR) spectrometers has made routine a number of techniques, for example, ATR (attenuated total reflection), IRRAS (infrared reflection-absorption spectroscopy or transflection spectroscopy), GIR (grazing incidence reflection), and DRIFTS (diffuse reflection infrared Fourier transform spectroscopy), which were unthinkable in the era of dispersive spectrometers because of inadequate signal-to-noise ratios. It also provides an opportunity to use optical fibers for remote measurements or as an ATR element, which has special attraction for medical *in vivo* measurements in real time. Unfortunately, infrared spectroscopy is handicapped in this respect compared to Raman spectroscopy, as only a limited number of suitable (and expensive) materials exist with sufficient spectral transmission in the mid-infrared range (e.g., silver halide, chalcogenide, or fluoride fibers). In addition to the required transparency and low-optical attenuation in the required range, these materials must be nontoxic, flexible, nonhygroscopic, and stable long term. Nevertheless, promising applications of silver halide fibers in ATR and reflection modes already have been demonstrated for *in vivo* applications [1].

Infrared microscopy enjoys a prominent position in bioanalytics without regard to the diffraction limit. Infrared microspectroscopy allows the study of individual regions within a sample in different modes (transmission, reflection, transflection, or ATR) by mapping (sequential, point-by-point measurement of the spectra of neighboring regions of a sample), imaging (acquiring an image of the sample on an array detector), or hyperspectral imaging (an image recorded at multiple wavelength bands by a 2D-array detector) [2]. Recent progress in this field has been demonstrated using the new generation of focal plane array detectors with mercury cadmium telluride elements of dimensions $40 \times 40\,\mu\text{m}$ that can operate with frame rates of 3000 Hz [3]. Usage of synchrotron infrared radiation allows a number of studies requiring extremely high source brilliance [4].

The commercial availability of vibrational circular dichroism (VCD) accessories to FTIR spectrometers has significantly improved the study of chiral compounds. VCD spectroscopy measures IR absorption difference spectra using left and right circularly polarized radiation. In contrast to the widespread electronic circular dichroism spectrometers, the spectral bands in VCD spectra are more easily assigned to individual groups and hence allow a more straightforward interpretation of the spectra [5].

The main progress in the understanding of the conformational dynamics lies in the exploitation of two-dimensional infrared spectroscopy. Theoretical and experimental aspects of this nonlinear technique have been reviewed by Woutersen and Hamm [6].

An inseparable part of the instrumentation of FTIR spectroscopy for bioanalytics is the software, allowing processing of the spectral data and application of chemometric methods. There are only limited cases where a simple library search for an identification or single-band absorbance for determination can be used. Multivariate classification (pattern recognition) and multivariate regression techniques need to be applied in bioanalytics [7]. The algorithms applied in infrared (and Raman spectroscopy) include [3] Mahalanobis distance, principal component analysis (PCA) and soft independent modeling of class analogies (SIMCAs), cluster analysis, linear discriminant analysis (LDA), partial least-squares regression (PLSs), artificial neural networks (ANNs), Bayes rule, support vector machines, and ensemble methods.

27.1.3
Applications

It is very difficult to briefly map all the fields of application that stem from the origin sometime in 1950s, as noted by Henry Mantsch [8] in his historical survey. This situation is documented in a great number of recently available books or chapters related to these topics [9–22].

Bioanalytics is a typical border discipline for which the spectroscopist has full insight into the relation of spectrum and structure only in the simplest cases. To this type of analysis belong structural studies, where support from model calculations allows the assignment of the spectral bands in the way typical for analysis of small organic molecules. The increasing complexity of the mixtures typical of biomaterials excludes such detailed analysis and a comparison of the spectra with known patterns or their clusters is only possible. To proceed from this type of information to the information relevant for clinical diagnostics, medicine, biology, and so on, an expertise in many fields is needed, including chemometrics, microscopy, clinical biochemistry, pathology, and cytology.

The following text is an attempt to give some examples from this broad field and is not intended to be exhaustive.

27.1.3.1 Structural Studies

The analysis of the infrared spectra of peptides and proteins, with the aim to determine the secondary structure, conformational changes, or unfolding processes, belongs to ''classical'' tasks of infrared spectroscopy. The manifold problems of use and misuse of FTIR in the determination of protein structure has been analyzed by Jackson and Mantsch [23].

Recent progress in this field is tightly wedded to the progress in the computational modeling of vibrational spectra [24]. Studies using *ab initio* Hartree–Fock, density functional theory (DFT) as well as excitonic coupling models are used to support interpretation of normal infrared spectra, as well as VCD spectra [24]. This approach allows not only the elucidation of the effect of secondary structure on the most relevant amide modes (amides I, II, and III) but also to make conclusions on the participation of the tertiary structure in the overall band shape formation. VCD spectra of chiral moieties are more sensitive to conformational changes than conventional infrared spectra.

Biomolecules undergo complex conformational dynamics, ranging from seconds to the pico and sub-picosecond timescales. To study the very fast timescales, two-dimensional infrared spectroscopy (2D IR) is the method of choice [6]. The present state of the analysis of the amide I band has been reviewed [25]. Theoretical and experimental considerations for interpretation of amide I bands in tissue have also been published [26].

27.1.3.2 Identification of a Component in the Biological Material

A typical bioanalytical task is the identification of kidney stones or its components. There are now available commercial spectral databases of real kidney stones (212 stones found in human kidneys), spectra of the primary components found in typical kidney stones, or synthetic spectra of kidney stone samples. In this case, the identification of the main kidney stone components can be carried out by suitable library search software [27] and, in some cases (for synthetic spectra), quantitative information can also be obtained.

Similarly extensive studies exist for gallstones [28–31].

27.1.3.3 Determination of a Selected Component

The determination of components in *food or agricultural products* using near-infrared spectroscopy is now widely accepted as simple, accurate, rapid, and inexpensive and it is routinely used [9, 15, 16].

On the other hand, the determination of *clinically important analytes* in human blood, urine, saliva, and other body fluids is still seeking acceptance as an official alternative to the standard biochemical methods in spite of the great research effort.

Of considerable interest is the *in vitro* determination of *glucose in blood*, which represents a very important piece of information. There are numerous studies by NIR and mid-IR spectroscopy on model mixtures, whole bovine blood, whole human blood, human blood plasma, or human blood serum (Table 27.1) using different sampling techniques, including microdialysis for quasi-continuous monitoring. The studies often included determination of other accompanying analytes, as indicated in the table.

The advantage of reagentless analysis, the possibility of the simultaneous determination of several analytes, or the possibility to use only a minimal sample volume (1 µl and even smaller) makes these techniques very attractive. Results are very encouraging, but unfortunately they still do not fully meet the requirements for clinical adoption. The low analyte concentration and mutual interference of the components makes the calibration process very difficult, which should cover the full physiological range of all individual components. A solution seems to be to waive the advantage of using the native fluid (as liquid or dry film) and preprocess the sample before spectroscopic measurement [83].

The noninvasive *in vivo* determination of glucose is another challenge for infrared spectroscopy, which could substitute the painful and inconvenient test-strip technique used by patients with diabetes mellitus. Unfortunately, only near-infrared radiation has a chance to penetrate deep enough into the human body. There are numerous attempts to do it noninvasively by near-infrared spectroscopy [84–93] using the drift technique on human skin [94–97] (also on rat skin [98]), lips [99, 100], or finger [101]. Fiber probes have also been applied [102, 103]. It remains clear that all the problems of *in vitro* determination of glucose are multiplied for *in vivo* analysis.

To date, no commercial product exists for noninvasive measurement of blood glucose [104]. One of the obstacles to the success of NIR spectroscopy is the problem of chance correlation induced by instrument drift or interference [104]. There are several critical parameters that should be respected to obtain valid data [105]: optical path length, wavelength range, instrumental performance, model dimensionality, and the chemical basis of model selectivity. Calibration models based purely on statistical data, not incorporating chemically specific information, can be misused [104].

27.1.3.4 **Identification of Biological Objects**

In many cases, there is no need to characterize and identify individual components, but rather to characterize and identify entire objects, for example, bacteria, yeasts, tissues, or cells.

The characterization and identification of *microorganisms* by infrared spectroscopy is considered to be one of its best-developed and most frequent applications

Table 27.1 Some details on the *in vitro* determination of glucose in blood by infrared spectroscopy.[a]

[a] This table contains information available from published abstracts only and a simplified notation is used for some components.

and it is now routinely used in microbiological laboratories [106–108]. The full advantages of infrared spectroscopy predominate if used as microspectrometry, which allows identification of microcolonies of a few hundred cells. This approach allows significant speedups in the process of identification [109]. FTIR spectroscopy can also be used to monitor the response of yeast cells to stresses induced by chemical, physical, or biological agents [110].

Valuable results for chemotaxonomy of horticultural and agricultural corps can be obtained from the combination of mid-infrared spectroscopy and multivariate analysis: primary constituents (proteins, lipids, and carbohydrates) as well as secondary plant metabolites (phenolic substances, terpenoids, and alkaloids) can be identified or determined [111].

To the same type of tasks belong the characterization and identification of tissues. To distinguish healthy, precancerous, and cancerous tissues, a deep understanding of the cellular and tissue architecture is needed, as well as of the spectral changes related to tissue or cell composition, which vary because of differentiation, maturation, and different stages of the cell life cycle [112]. Understanding of the processes and distribution of individual components in the tissue provides an opportunity for the early detection of diseases and their treatment and hence there are numerous applications to the characterization of bone, brain, breast, lung, skin, or tooth tissues [3, 113]. The spectral data detect molecular changes, which precede any morphological changes, thus enabling earlier diagnosis [114]. An effort to use FTIR spectroscopy as a diagnostic tool can be illustrated by discrimination between normal and tumor brain tissue, carried out on thin cryosections during tumor resection surgery [3].

Progress in this field is strongly related to the developments in FTIR microimaging and also to the availability of the synchrotrons around the world. Synchrotron IR microspectroscopy has significantly enhanced worldwide capabilities in protein structure analysis [115] and in single biological cells, as well as cell nuclei [116]. Unfortunately, the relative sizes of the cells to the employed wavelengths give rise to a strong scattering (dominated by Mie scattering), which strongly distort the spectra [117].

27.1.3.5 Concluding Remark

There are many other fields of applications not mentioned here, for example, a noninvasive method for measuring blood flow through an organ [118] or blood oxygenation by NIR spectroscopy [118], the study of structural changes of proteins in fingernails [119] or the permeation of drugs through the outer layer of human skin [120] by mid-IR spectroscopy, and so on. The application of infrared spectroscopy in bioanalytics has a great chance for further development. Experience of the past shows two key points that should be respected to achieve precise and accurate results: (i) the cooperation of all experts in the field and (ii) the development of standardized procedures and protocols for every stage of the study.

27.2
Raman Spectroscopy in Bioanalysis

27.2.1
Introduction

Raman spectroscopy has enjoyed a tremendous increase in usage in the past decade as a result of great advances in Raman instrumentation, including lasers, spectral filtering, spectrometers, detectors, and fiber optic probes. These advances have paved the way for wider application of Raman to bioanalysis, not only because of the large amount of information contained in a Raman spectrum but also because of ease of use and its noninvasive character. For example, disease can be linked to changes in the molecular makeup of tissues. Raman spectra contain detailed information on the molecular composition and structure without the need for labels or dyes and in a nondestructive manner, enabling its use *in vivo* for early disease diagnosis or to guide clinical intervention or treatment. There have been a large number of publications and reviews on the application of Raman to bioanalysis, including reviews by Pappas *et al*. [121] and Baena and Lendl [122], to which the reader is referred for additional information. Recent books with large portions devoted to the subject have been written by Salzer and Siesler [2], and McCreery [123]. Therefore, the material presented here is constructed as a tutorial rather than an exhaustive review.

27.2.2
Raman Systems

27.2.2.1 Laser Sources

A common laser source in the latest Raman systems is the frequency-stabilized diode laser, because of its small size, reasonable power, and low-cost considerations. Wavelength stabilization is usually accomplished using distributed Bragg reflector (DBR) lasers, where the laser resonator is made with at least one DBR outside the gain medium. A DBR is a wavelength-selective mirror based on Bragg reflection with a periodic structure [124]. Some other laser sources used for Raman bioanalysis include diode-pumped solid-state lasers, such as Nd:YAG (and its harmonics), and gas lasers, such as argon ion and helium neon.

27.2.2.2 Spectral Filtering

Compact Raman systems have been made possible by the introduction of optical filters with very high extinction (>OD 6) at the excitation wavelength and very sharp spectral cutoff edges to drastically reduce the intensity of the Rayleigh scattering before entering the spectrometer. These Rayleigh filters were accomplished first using a double spectrometer (additive or subtractive) as a prefilter or using resonance atomic absorption (e.g., mercury resonance radiation for excitation and a mercury vapor cell as notch filter). Other early notch filters were interference band, edge or line filters [125], or a chevron arrangement of bandpass filters [125].

In the early 1990s, holographic notch filters using volume hologram methods became available [126]. More recently, multiple-cell, thin-film filter designs have achieved the same level of rejection as holographic notch filters at a reduced cost [127]. The stringent requirements of optical filters used in dense wavelength division multiplexing in the optical fiber telecom industry has resulted in dramatic improvements applicable to fiber Raman probes. For example, the notch filter can be replaced by a fiber Bragg grating filter [128]. While these are only presently applicable to single-mode fibers, the methodology bodes well for future advances, especially for use *in vivo* or *in vitro* where diameter and flexibility are important.

27.2.2.3 Spectrometers

At first, Fourier transform Raman instruments were utilized for bioanalysis, because the Raman excitation laser was in the near-infrared (usually 1064 nm from an Nd:YAG laser) avoiding most of the fluorescence problems in biological materials and reducing the photochemical damage [129]. FT Raman also has a Jacquinot (optical conductance) advantage and a multiplex advantage versus grating-based spectrometers [125, 129].

Nevertheless, with the advent of high-efficiency charge-coupled device (CCD) multichannel detectors, the advantage shifted back to grating-based spectrometers, because the entire Raman spectrum could be obtained simultaneously, effectively negating the multiplex advantage of FT Raman systems. In addition, further advances in CCD technology (e.g., back thinning and antireflection coating) drastically improved their NIR response allowing NIR excitation, which dramatically reduces fluorescence interference, and photochemical damage, but at the cost of Raman signal strength (the ν^4 dependence) [125, 129]. The grating-based spectrometers utilized at present include high-resolution, long focal length spectrometers down to small monolithic aberration-corrected single-optical-element spectrometers with lower (typically $\sim 4\,\text{cm}^{-1}$) resolution. These latter devices are perfectly adequate for most liquids and solids, especially for analytical (detection and identification) purposes or for dedicated Raman instruments for *in vivo* or clinical use.

27.2.3
Fiber Optic Probes

In order to best obtain Raman spectra *in vivo*, fiber optic coupling between the larger portions of the Raman system (laser, spectrometer, detector, and computer) and the probe is usually used. Transmission of the excitation laser through silica (usually) optical fibers produces confounding Raman signals that must be suppressed. This suppression has been accomplished by use of optical filters in the probe, usually a short wavelength pass or bandpass filter on the excitation fiber and a long wavelength pass filter in front of the Raman signal fibers, as shown schematically in Figure 5 of Chapter 56, as well as in Figure 27.1 and Figure 27.2. A number of probes are available [130–132], as well as a novel, small-diameter, internally filtered probe (IFP) design (Enviva, Visionex Inc.) that moves the optimal Raman signal collection volume close to the probe end [133]. The IFP allowed large improvements

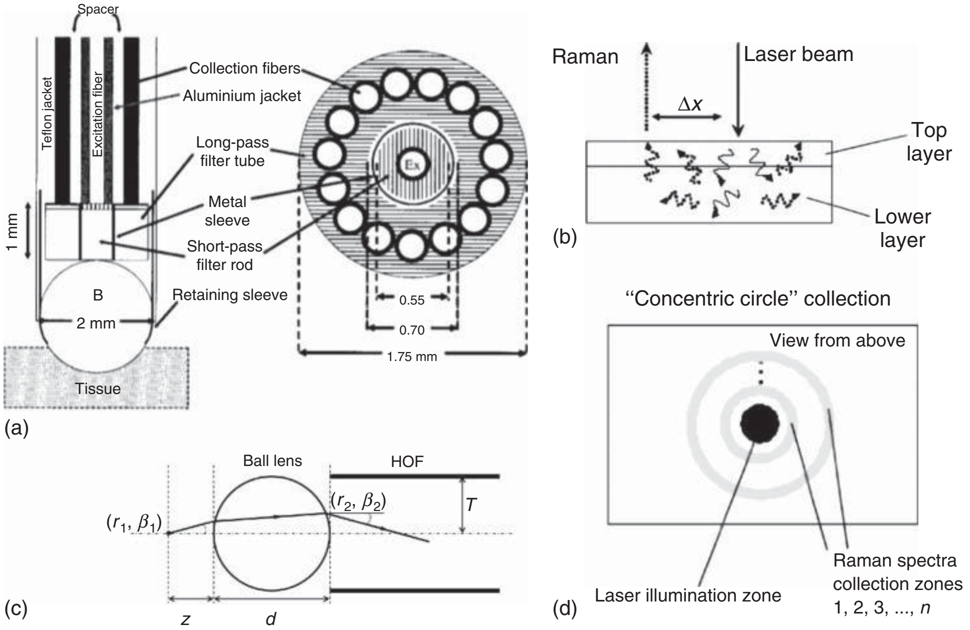

Figure 27.1 Optical fiber Raman probes for bioanalysis. Fifteen around one arrangement with in-line short-pass (excitation) and long-pass (collection) filters and a sapphire ball lens [134] (a). Hollow-core fiber/sapphire ball lens design [138] (b). SORS probe with offset collection fibers, concept (c) and concentric ring design (d) [139]. (Reprinted with permission from a) Optical Society of America, b) SPIE, c) and d) Society for Applied Spectroscopy.)

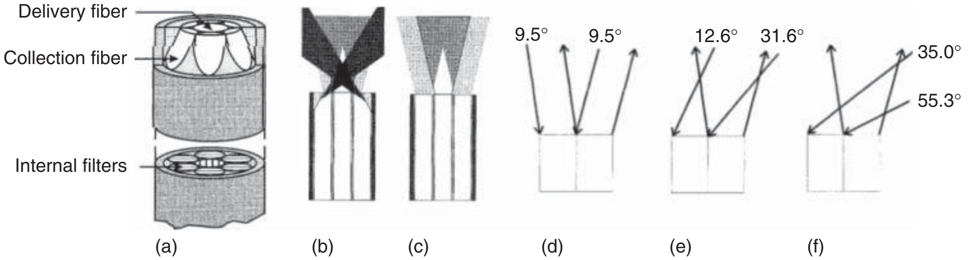

Figure 27.2 Enviva probe design. (a) Enviva probe with in-line filtering and beveled tips to increase overlap with the excitation close to the probe end (comparison of standard probe (c) to beveled probe (b), and illustrated for three different bevel angles in the (d–f) [133]. (Reprinted with permission from Society for Applied Spectroscopy.)

in Raman signal quality, as well as Raman-to-baseline signal ratios, by controlling the sampling depth in a variety of tissue types, and can be manufactured in very small diameters (<1 mm) for possible endoscopic use. Another design in clinical use involves an excitation fiber filtered using a short-pass filter rod and a circular array of collection fibers filtered using a long-pass filter tube, as well as a simple sapphire sphere as focusing element [134]. Their probe was used for *in vivo* Raman spectral pathology of human atherosclerosis [135]. Similarly, Komachi *et al.* [136, 137] have used custom filters to reduce their probe diameter to <1 mm and demonstrated its use *in vitro*. They also developed a confocal Raman endoscopy probe using a silvered, hollow-core fiber to carry both the excitation laser to the probe tip and the Raman signal back to the spectrometer. The internally silvered, hollow-core fiber does not generate spurious fiber Raman signals that must be removed at the distal end of the probe, greatly simplifying the probe design [138]. A sapphire ball lens version of their probe is small enough and sealed to allow sterilization for use in endoscopy.

Fiber optic probes are being used in other ways to obtain depth-resolved information, using a method called spatially offset Raman spectroscopy (SORS) [139–141]. The offset distance between excitation and Raman collection at the sample interface determines the average depth interrogated. The offset could be point to point, but more Raman signal is collected using concentric circle collection. The latter can be efficiently accomplished using a circular array of optical fibers surrounding the excitation fiber at some radial offset, followed by a circular to linear arrangement transition for optimal coupling into the spectrometer slit, as shown in Ref. [141]. Another embodiment of this concept uses a dielectric filter at the end of the optical fiber in direct contact with the sample [142]. The filter has high transmission for normal incidence excitation wavelength, but high reflection for non-normal incidence photons. It passes the collimated incident laser into the sample, but reflects most of the random-direction, sample-scattered excitation light back into the sample, enhancing the Raman signal level. A small hole in the center of the filter allows the Raman signal to pass back into the signal collection fiber.

27.2.4
Raman Imaging

There are several instrumental variations for performing Raman imaging of biological samples. Adar [143] has discussed these recently at the tutorial level. The global imaging scheme bathes the imaged area of the sample in laser excitation light and records the microscope image through a narrowband filter that selects the Raman spectroscopic feature of interest. The method has little depth resolution because it is nonconfocal and does not work well for complex biological samples, which usually do not have well-separated Raman features that can be isolated. Alternatively, the sample can be point illuminated and the full Raman spectrum obtained at each point, scanning the sample in x-, y-, and z-directions to obtain the full Raman image hypercube. In between, line-focus or line-scanning methods acquire full spectra along a line of points by imaging the illuminated line onto the slit of the Raman spectrograph, with y- and z-scanning to obtain the full Raman image hypercube. Because the Raman spectra of biological samples are complex, multivariate methods must usually be used to extract Raman images from the spectral hypercubes (Section 27.2.5).

The power of Raman imaging in bioanalysis has been illustrated in many publications. For example, van Manen and collaborators [144] showed that lipid bodies (LBs) rich in arachidonate as revealed by their Raman spectra associate with latex bead-containing phagosomes in neutrophilic granulocytes. The images show that different LB accumulation in phagosomal membranes is mediated by a flavohemoprotein, which is a catalytic subunit of the NADPH oxidase enzyme that plays a critical role in innate immunity. Puppels and collaborators [145] have demonstrated a large number of applications of Raman imaging to bioanalysis. For example, they have provided an overview of Raman imaging applied to mapping of tissue sections [146]. They have also demonstrated the effect of skin care products on molecular concentration-depth profiles using *in vivo* confocal Raman microspectroscopy [147].

27.2.5
Spectral Data Analysis

The key to use Raman spectroscopy in bioanalysis is not just obtaining a spectrum, but rather in much larger part how that spectrum is treated and interpreted within the enormous and exponentially increasing body of available bioanalytical Raman data. In another chapter 56 in this Handbook, the methods used to establish and search Raman spectral libraries are discussed, including both multivariate and spectral analysis tools. Some available commercial spectral libraries contain upward of 15 000 spectra of pure chemicals. To identify a pure material, the spectral search algorithms return usually unambiguous results. Mixtures present another set of difficulties. For the most part, biological materials are complex mixtures, necessitating the use of chemometric or multivariate classification tools to categorize and understand their complex nature. The huge number of investigators and clinicians using Raman tools to measure biological specimens and making their spectra available is producing a constantly growing data volume, which needs to be processed and analyzed in order to highlight the useful information, as well as to cope with noise, collinearities, and missing data.

A simple approach that has achieved much success is multivariate projection [148], wherein the table of observational data (spectra) is represented as a swarm of points, K (K is the number of variables), which is projected down to a low-dimensional plane or hyperplane. Methods used are PCA, soft independent modeling of class analogy (SIMCA), and partial least-squares discriminant analysis (PLS-DA) for classification, and principal component regression (PCR) and PLS for latent variable regression. To simplify interpretation of experiments with many variables, hierarchical PLS and PCA are recent modifications, which help divide the variables into conceptually meaningful blocks. A recent open source toolbox for MATLAB – called *Biodata* – to help accomplish this task for Raman spectral data has been developed and made available [149]. Other approaches include the sequential application of PCA and discriminant functional analysis (DFA), as well as hierarchical cluster analysis (HCA). PCA is usually used to identify those parameters that give the greatest differentiation between dimensions of multivariate data. DFA then discriminates between groups based on these retained principal components (PCs) and any a priori knowledge of which spectra were replicates. DFA is performed to maximize between-group variance and minimize within-group variance. To validate discrimination performed by DFA, projection analysis is also employed to project test data to PCA space and DFA space generated by the training set [148].

27.2.6
Pathology and Cytopathology

The number of pathology studies using Raman spectroscopy increased dramatically in the late 1990s and more recently, apparently coinciding with the availability of compact simple-to-use instrumentation (Figure 27.3) and acceptance of the efficacy of Raman data to differentiate tissue types.

The capabilities of micro-Raman imaging and spectroscopy have been used extensively to detect and differentiate cell types. Singular-value decomposition to remove noise has been among the various types of data analysis used [150]. HCA can be performed on Raman imaging data matrices to visualize regions in cells with high-Raman spectral similarities. In the cluster analysis routine, PCA scores are taken as input variables, squared Euclidean distances used as distance measure, and Ward's algorithm used to partition Raman spectra into clusters. HCA has also been used for rapid epidemiological analysis of bacterial strains [151].

Recently, spatially offset Raman spectroscopy (SORS) has been applied to measurement of bone tissue composition for studies of bone development, biomechanics, and bone health. The study compared five different fiber optic probe

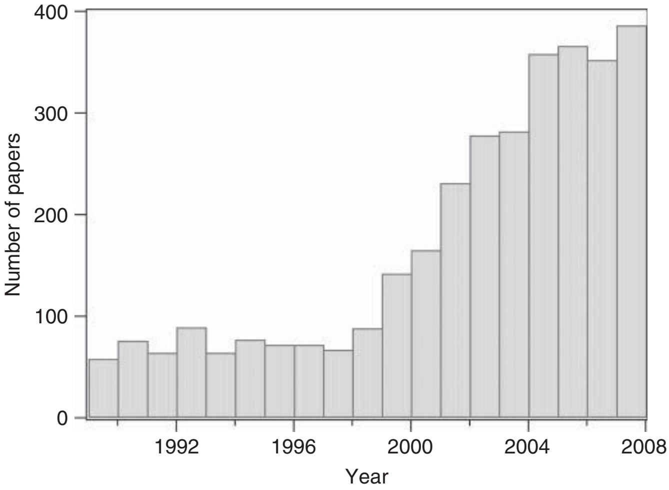

Figure 27.3 The dramatic increase in Raman pathology studies in recent years. (Data from Scisearch using "Raman <and> (pathology <or> cytopathology).")

configurations for *in vivo* bone signal intensity, variance, and power distribution, validated by measurements of exposed bone [152].

27.2.7
Single-Cell Analysis

Most recently, laser tweezer Raman spectroscopy (LTRS) has been used to obtain baseline spectra from single-tumor and healthy tissue cells [153]. PCA and PCR were used to reveal the cell structural changes or biochemical variations associated with the normal-to-cancer transition. Sabelnikov and Kempf [154] analyze the ramifications of whether a single cell picked for interrogation is representative of the whole, using a probability approach in LTRS. Spiers and coworkers [155] report on the capabilities of discriminate functional analysis of single-cell Raman spectroscopy to report on the whole-cell chemical composition of bacteria providing phenotypic classification with minimal physiological interference [153]. Zheng *et al.* [156] have shown the power of LTRS coupled with binary feedforward neural network spectral analysis for diagnosis of colorectal cancer.

27.2.8
Surface-Enhanced Raman Spectroscopy (SERS)

In the 35 years since its discovery [157], the new method of surface-enhanced Raman spectroscopy (SERS) has seen nearly exponential growth, particularly in bioanalytical applications [158]. The field has grown in spite of controversy about the detailed understanding of the enhancement mechanism, especially the variability in enhancement factors – particularly, the presence of hot spots at which the enhancement factor can be 10^9 or larger and at which single molecules have been detected [Ref 158] – which affect the use of SERS in bioanalysis. A recent article in *Science* by Dlott *et al.* [159] provides a method to measure the distribution of site enhancement factors on a given SERS substrate, establishing a methodology to achieve a greater level of understanding of whence SERS signals emanate.

The recent explosion in the use of SERS for bioanalysis was the subject of a special issue in *Chemical Society Reviews*, edited by Graham and Goodacre [160], which is an excellent resource for practitioners and newcomers. Among the articles in this special issue, Tian [161] introduces early work on SERS and then the development of electrochemical SERS to date. The importance of electronic resonance enhancement coupled with surface enhancement is discussed by Smith [162]. Mirkin [163] reviews the rational design of SERS nanostructures, and the tailoring or plasmonic substrates is detailed by Halas [164]. Another recent review of plasmonic nanostructures for SERS bioanalysis has been published by Vo-Dinh and his collaborators [165].

In addition to the traditional approach of using Raman spectroscopy, alternative measurement techniques for enhanced Raman measurements are being developed. Deckert provides an in-depth overview of tip-enhanced Raman scattering (TERS) as an alternative to the traditional approach to surface-enhanced Raman spectra, with its additional advantage of very high (beyond the diffraction limit) spatial resolution for imaging and mapping [166]. Blanch discusses combining surface-enhanced Raman spectroscopy with Raman optical activity (SEROA) to gain chiral-specific information from biochemical species [167].

Recent progress in the fundamental mechanisms and application of SERS at the single-molecule level is reviewed in articles by Aroca [168] and Kneipp [169]. The latter article also presents surface-enhanced hyper Raman scattering (SEHRS) as a tool for two-photon-excited vibrational spectroscopy, with its potential for greatly reduced phototoxicity and stress to the sample due to the longer wavelength excitation. Qian and Nie [170] discuss the considerable recent progress in understanding the mechanism of enormous enhancements of certain classes of SERS substrates and then present their use as SERS nanoparticle tags for *in vivo* imaging.

The abilities of SERS and Surface enhanced resonance raman spectroscopy (SERRS) for quantitative analysis are provided as a tutorial review by Bell and Sirimuthu [171], including the factors that need to be controlled to generate stable and reproducible SERRS calibrations. Graham and Faulds [172] discuss the use of SERRS for the analysis of specific DNA sequences by using spermine as the aggregation agent because of its abilities to produce highly enhancing aggregates of excellent reproducibility. SERS as a detection method for bioanalytes is reviewed by Porter who discusses the fundamentals, design, and applications of SERS as a viable bioassay platform [173].

Finally, Jarvis and Goodacre [174] illustrate how SERS can be used for the identification of low numbers of bacteria. Hildebrandt [175] furthers the understanding of the interfacial redox processes of proteins and Sockalingum [176] gives an interesting overview of intracellular SERS and the potential effect it has for single-cell imaging.

27.3
Terahertz Spectroscopy in Bioanalysis

27.3.1
Introduction

The terahertz (THz) region of the electromagnetic spectrum can loosely be defined as frequencies between 0.3 and 30 THz. Electromagnetic radiation with a frequency of 1 THz has a free-space wavelength of 300 μm and photon energy of 4.1 meV. At the same time, this frequency can be associated with a temperature of 47 K. Hence, a range of important low-energy interactions in physical, chemical, and biological processes involving interaction between the electromagnetic field and matter can be studied with a suitable spectroscopic technique covering the relevant spectral range. Particularly, THz spectroscopy has been widely used for the analysis of vibrational modes in molecular crystals [177–185].

As an example of a spectroscopic study of vibrational modes in the solid state, Figure 27.4a shows the absorption spectrum of the sucrose crystal together with

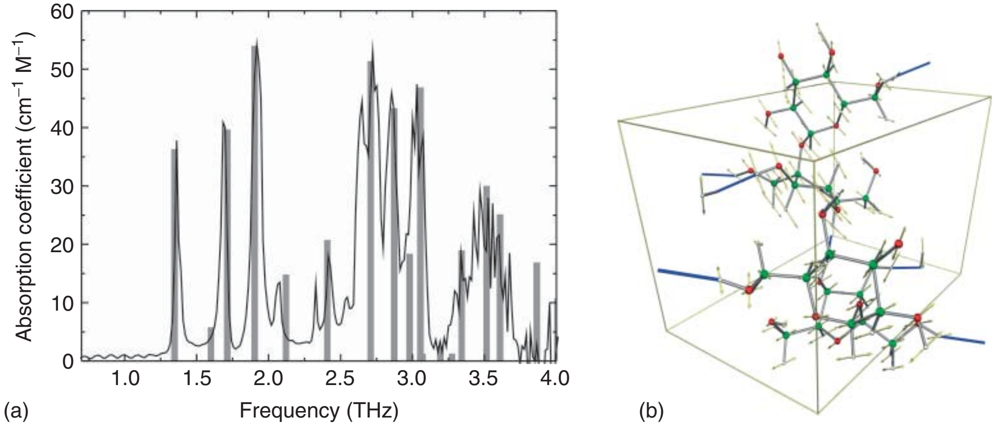

Figure 27.4 (a) Absorption spectrum of microcrystalline sucrose (solid curve) with simulated resonance frequencies (gray bars). (b) Normal-mode motion of the 1.9 THz resonance.

results of a simulation of the vibrational modes of the lattice, based on density functional perturbation theory (DFPT) [185]. The vibrational modes that contribute to the low-frequency absorption spectrum of the crystal are in general modes, which involve motion of all atoms in the unit cell, and in the general case, there is no clear distinction between molecular modes and intermolecular modes in the THz range. This is in contrast to vibrational modes in the mid-IR, which are typically localized at specific positions and functional subunits of the molecules with a relatively weak coupling to intermolecular modes.

In the THz range, the coupling between molecular modes and intermolecular modes is strongest when the intermolecular forces are relatively strong, for instance, in hydrogen-bonded crystals such as saccharides. In Figure 27.4b, the normal mode corresponding to the 1.9 THz absorption peak in sucrose is illustrated.

In crystals with weaker intermolecular forces, such as van der Waals-bonded systems, there is a correspondingly weaker coupling between the internal molecular modes and the external intermolecular modes [186, 187].

THz spectroscopy of gases reveals the rotational structure of the gas molecules. In Figure 27.5, we show the absorption spectrum of water vapor, which has been used extensively as a reference spectrum for calibration of THz spectrometers owing to the presence of water vapor in normal laboratory air, and thus in the beam path of an unpurged spectrometer. THz spectroscopy has been used extensively for the analysis of the rotational spectra of gases, including interstellar gases. THz time-domain spectroscopy, which will be described in the following, has unique capabilities that have been utilized for the detailed analysis of periodic rephasing of manifolds of rotational transition [188], collisional line broadening in gases at high pressures [189], and the study of hot molecular species in flames [190].

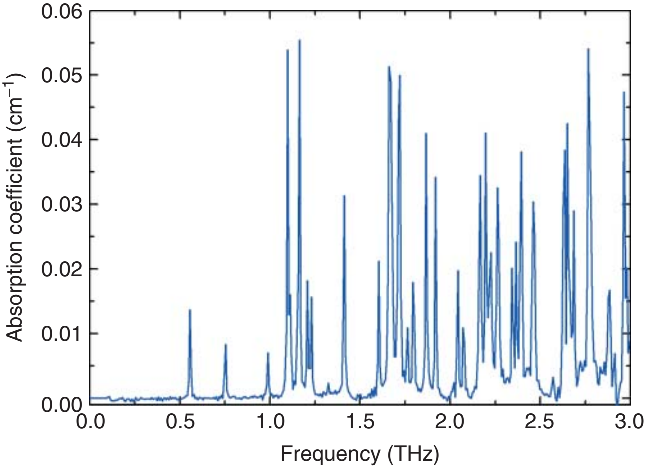

Figure 27.5 Absorption spectrum of water vapor in the THz range. Each absorption line corresponds to a rotational transition of the asymmetric top molecule H_2O.

Here, we will present an overview of a new technique known as terahertz time-domain spectroscopy (THz-TDS), which in the recent years has enabled a wealth of new studies of low-energy interactions between light and matter. In particular, the technique has recently offered unique insight into structural dynamics of biological systems, charge-transfer processes in molecules in solution, and transient behavior of photosensitive systems.

The development of the femtosecond laser in the 1980s enabled an alternative method for spectroscopy in the THz range with completely new functionalities. This method, first introduced in 1989 by Grischkowsky *et al.* [191], relies on the optical excitation of photoconductive dipole antennas and is now known as *terahertz time-domain spectroscopy*. The development of THz-TDS has been closely linked to the more general development of ultrafast laser technology, for instance, the Ti:sapphire femtosecond laser [192]. At the same time, the principles behind THz-TDS are heavily related to microwave technology as well as methods developed for FTIR. The different aspects of THz technology, components, spectroscopic methods, and imaging modalities are discussed in recent textbooks dedicated to THz science and technology [193–197].

27.3.2
Amplitude- and Phase-Resolved Detection of THz Fields

In a classical spectroscopic measurement, the intensity of electromagnetic radiation from a suitable light source is recorded in a manner that allows analysis of the spectral content of the light transmitted through or reflected from a sample. In FTIR spectroscopy, this analysis is performed interferometrically, and in a grating- or prism spectrometer, diffractive, or refractive optics is used to separate the wavelengths of the light. In all cases, the detection efficiency is determined by the dynamic range of the spectrometer and the capability of suppressing undesired background light from the beam path into the detector.

In the most basic implementation, FTIR as well as diffractive and refractive spectrometers detect only the intensity of the spectral distribution of the light. Hence, the recorded information is insufficient for the full reconstruction of the complex dielectric function of the sample material. With a sufficiently high bandwidth of the spectroscopic measurement, the Kramers–Kronig relations can, in principle, be applied for the determination of the full dielectric function. However, this procedure relies on certain assumptions about the behavior of the dielectric function outside the frequency range, and the accuracy of the analysis then naturally relies on the correctness of these assumptions.

Several spectroscopic methods exist for the direct measurement of the full dielectric function of a sample. The traditional method is dispersive FTIR [198], where the sample is placed as an integral part of one of the arms of the Michelson interferometer of the spectrometer.

27.3.3
Instrumentation for THz Spectroscopy

27.3.3.1 Coherent Generation and Detection of Broadband THz Light

Broadband, coherent THz radiation can be generated in a photoconductive switch on a semiconductor substrate excited by a femtosecond laser pulse or in a suitably phase-matched nonlinear crystal by difference frequency mixing of the frequency components of a femtosecond laser pulse. Generally speaking, the bandwidth of several THz of a femtosecond laser pulse can be used for the generation of broadband THz radiation with comparable bandwidth.

When driven by a train of femtosecond laser pulses synchronized to the laser pulses used for THz generation, photoconductive switches and electro-optic crystals can also be used for a field-resolved detection of the THz field.

In the following, we discuss the method of photoconductive generation and sampling of broadband THz radiation. We refer the reader to excellent reviews on the generation and detection of THz pulses by electro-optic methods [199–204].

The electric field from an electric dipole oscillating at a frequency of $\nu = \omega/2\pi$ can be expressed as [205]

$$E = \frac{1}{4\pi\varepsilon_0}\left[k^2\left(\hat{\boldsymbol{n}} \times \overrightarrow{\boldsymbol{p}}\right) \times \hat{\boldsymbol{n}}\frac{\mathrm{e}^{\mathrm{i}kr}}{r} + \left[3\hat{\boldsymbol{n}}\left(\hat{\boldsymbol{n}} \times \overrightarrow{\boldsymbol{p}}\right) - \overrightarrow{\boldsymbol{p}}\right]\left(\frac{1}{r^3} - \frac{\mathrm{i}k}{r^2}\right)\mathrm{e}^{\mathrm{i}kr}\right] \tag{27.1}$$

where $\overrightarrow{p}$ is the electric dipole moment, $\hat{n}$ is the unit vector in the direction of observation, r is the distance between the dipole and the observation point, and $k = \omega/c$ is the propagation constant of the electric field in free space.

If we assume that the temporal evolution of the electric dipole moment can be found by a Fourier analysis of its frequency components, then the electric field component perpendicular to the direction of observation from an electric dipole can be expressed in the time domain in the following form by a Fourier transformation of Eq. (27.1):

$$E_\theta(r,\theta,t) = \frac{1}{4\pi\varepsilon_0}\left[\frac{1}{r^3}\vec{\boldsymbol{p}}\left(t_\mathrm{r}\right) + \frac{1}{cr^2}\frac{\mathrm{d}\vec{\boldsymbol{p}}\,(t_\mathrm{r})}{\mathrm{d}t} + \frac{1}{c^2 r}\frac{d^2\vec{\boldsymbol{p}}\,(t_\mathrm{r})}{\mathrm{d}t^2}\right]\sin\theta \tag{27.2}$$

where θ is the angle between the electric dipole moment vector and the direction of observation and $t_\mathrm{r} = t - r/c$ is the retarded time. In the far field ($r \gg \lambda \gg d$, where d is the spatial extent of the electric dipole) only the last term in Eq. (27.2) survives, and hence the radiated electric field is proportional to the second temporal derivative of the dipole moment, or, the first temporal derivative of the current density $j(t)$.

This fundamental principle can be exploited for the generation of ultrabroadband electromagnetic transients with frequencies in the THz range. The frequency content of the electromagnetic field is closely linked to the dynamics of the transient current that generated the field. Consequently, a current transient that evolves on the timescale of a few hundred femtoseconds to a few picoseconds will generate a characteristic radiation signature with frequencies in the terahertz range. Such ultrafast current impulses can be generated by impinging an ultrafast laser pulse onto a biased semiconductor surface. The photons excite electrons across the electronic bandgap of the semiconductor, and the bias field subsequently accelerates the free charges, which subsequently recombine with the characteristic recombination time of the material. Using femtosecond laser pulses, current impulses with bandwidths well into the THz range can be generated in this manner. A photoconductive switch for generation of such ultrashort THz pulses is illustrated in Figure 27.6.

The metallic electrodes supply the bias field to the photoconductive gap between the electrodes. This gap is excited by femtosecond laser pulses, and the resulting

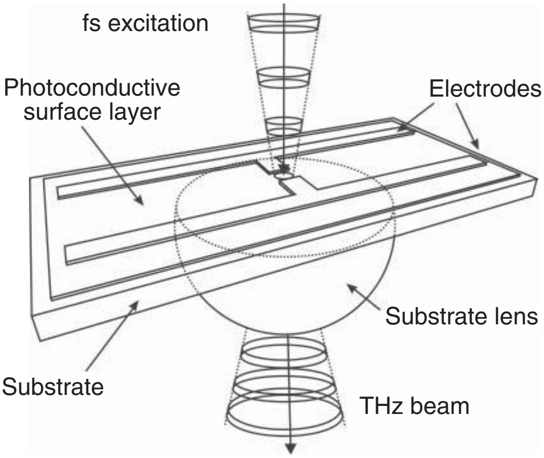

Figure 27.6 Photoconductive switches for generation and detection of ultrabroadband THz transients.

current transients generate the THz pulses that are emitted into the substrate by a THz dipole antenna structure, which in the simplest case is formed by the metalized bridge between the two electrodes. The THz radiation is collected into a collimated beam by a substrate lens attached to the structure.

27.3.3.2 **Detection of Broadband THz Transients**

Detection of the THz pulses generated in a broadband THz antenna can be detected by photoconductive sampling in an antenna structure identical to the THz emitter structure. A portion of the femtosecond laser pulse train, synchronized to the femtosecond pulse train used for the THz generation, is split off and used to excite, or gate, the detector structure. In contrast to the THz emitter antenna, the detector antenna is not biased by an external circuit. The electric field required to drive a photocurrent in the antenna is supplied by the THz pulses, which arrive in synchronism with the gate pulses. The photocurrent in the antenna circuit is then a convolution of the electric field picked up by the antenna and the transient photoconductivity induced by the gate pulse

$$j(\tau) \propto \int_{-\infty}^{\infty} E_{\mathrm{THz}}(t)g(t-\tau)\mathrm{d}t \tag{27.3}$$

The transient photoconductivity of the detector can be described by the same kinetics as discussed earlier for the generation of THz radiation. In the limit of a transient photoconductivity response $g(t)$ much faster than the duration of the THz field, the detected current is directly proportional to the THz field strength, corresponding to a frequency response of $j(\omega) \propto E_{\mathrm{THz}}(\omega)$. In the other limit, with long-lived photoconductivity, the measured current is proportional to the temporal integral of the THz field, corresponding to a frequency response of $j(\omega) \propto E_{\mathrm{THz}}(\omega)/\omega$. In the intermediate case, which is the normal case, the detected photocurrent will have a frequency response that can be described as [206]

$$j(\omega) \propto I(\omega)R(\omega)E_{\mathrm{THz}}(\omega) \tag{27.4}$$

where $I(\omega)$ is the spectrum of the excitation laser pulse and $R(\omega)$ is the frequency response of the photoexcited carriers in the semiconductor switch. Hence, the bandwidth of the detector is limited by the trapping and recombination times of the photoexcited carriers, and the transient photoconductivity can be seen as a low-pass filter function that is applied to the frequency spectrum of the THz pulse incident on the detector.

Ultrafast carrier lifetime is advantageous for a high bandwidth of the detected THz signal. Materials such as low-temperature-grown (LTG) GaAs, which have carrier lifetimes as low as a few hundred femtoseconds, are often used as active materials in photoconductive detectors. While the detection bandwidth in most systems described in the literature are in the low THz range, it was recently demonstrated that by removing all absorbing elements in the THz beam path and using the shortest possible laser pulses, photoconductive detection of frequencies approaching 100 THz is possible [206].

27.3.3.3 Ultrabroadband THz Optics

The photoconductive THz emitters described in the previous section are remarkably stable and reproducible with respect to the generated signal shape. Therefore, such emitters are well suited for spectroscopic measurements when combined with a similar THz detector. As illustrated in Figure 27.7, the THz emitter and THz detector must be excited with fractions of the same synchronized train of femtosecond pulses.

The beam of THz pulses can be transported from the emitter to the detector with either reflective or transmissive optics. The most commonly used reflective optics are off-axis paraboloidal mirrors with metallic reflectors, but elliptical mirrors can also be used, depending on the required focusing and imaging of the THz beam through the optical system. Reflective optics offer very low loss and minimal dispersion due to the high conductivity of most metals in the THz range, but may be difficult to align properly. On the other hand, transmissive optics can be aligned more easily than reflective optics, but usually suffer from frequency-dependent absorption that often leads to attenuation of the high-frequency components of the THz radiation and thus hinders high-frequency operation of the spectroscopy system.

Transmissive optics typically takes the form of lenses with spherical or aspherical surfaces. Such lenses are usually manufactured from transparent polymer materials such as polyethylene (PE) or teflon, and recently more transparent and low-dispersion materials based on cyclic olefin copolymers have been characterized [207, 208] and used. In addition, high-resistivity silicon is widely used as lens material for THz applications because of its exceptionally low loss and low dispersion [209].

High-resistivity silicon hyperhemispherical lenses are often used to couple the THz radiation from the emitter antenna into free space, and to couple the THz radiation from free space and onto the detector antenna. Hyperhemispherical lenses were first introduced by Fattinger and Grischkowsky [210, 211]. The THz radiation patterns from hyperhemispherical silicon lenses have been

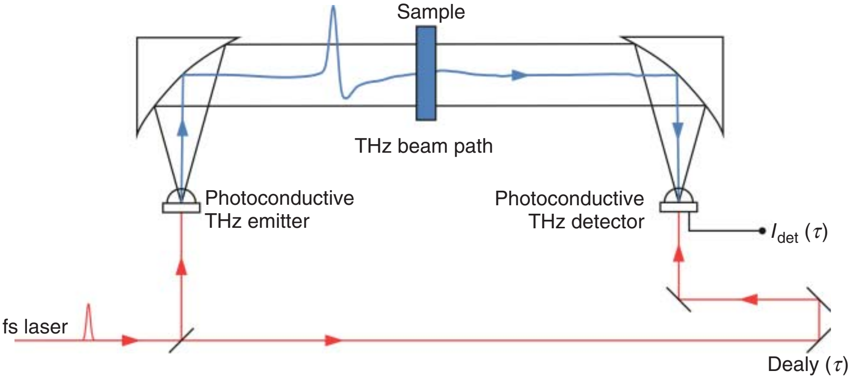

Figure 27.7 Schematic configuration of a full THz-TDS system for transmission spectroscopy, using broadband THz antennas driven by femtosecond laser pulses.

characterized [212, 213] and found to be described, at least approximately, by a fundamental Gaussian beam with beam waist at the surface of the hyperhemispherical lens. Different lens shapes (collimating, hemispherical, and hyperhemispherical shapes) have been thoroughly characterized by Rudd and Mittleman [214]. Reiten *et al.* [215, 216] performed careful measurements and simulations of the propagation of THz beams through hyperhemispherical lenses and the subsequent optical system of a THz-TDS setup. They showed that the THz beam profile emerging from a lens-coupled photoconductive emitter is accurately described by a superposition of Laguerre–Gauss modes, and also discussed the influence of spherical aberration and surface waves on the propagation. Recently, Lo and Leonhardt [217] devised aspheric lens designs with optimized focusing properties for high-resolution THz imaging applications.

27.3.4

Terahertz Time-Domain Spectroscopy (THz-TDS)

In this section, we review the most common configurations of THz-TDS and present an overview of the most widely used spectroscopic configurations, namely, transmission spectroscopy, reflection spectroscopy, and ATR spectroscopy. Each configuration has its own strengths, and we give examples of measurements with each experimental configuration. Transmission measurements are most suitable in situations with low- or medium-absorption strength of the sample. Examples include oils, solid-state materials such as molecular crystals, and powders of organic molecules. Transmission measurement requires the recording of a reference signal and a sample signal, either in the form of two different sample thicknesses (variable sample path length) or in the form of a measurement on an empty sample cell followed by a full sample cell.

Measurements in reflection are useful when the sample is a strong absorber. Reflection spectroscopy allows self-referenced measurements, where the reference signal and the sample signal can be obtained in a single scan, for instance, as reflections from the front side of a window in contact with the sample (the reference signal) and the reflection from the backside of the window in contact with the sample material (the sample signal). In such geometry, the sample and reference signals are separated in time, and by appropriate time gating of the signal, quantitative spectroscopy is possible with a single data recording.

In particular, the use of the ATR configuration can be shown to be the most sensitive method for the characterization of strongly absorbing materials with relatively low index of refraction. Examples include polar liquids, such as water, aqueous solutions, and electrolyte solutions. However, similar to transmission measurements, the ATR technique requires the recording of a reference signal followed by a sample signal.

Here, we describe the basic methods used in transmission and reflection spectroscopy, and discuss the influence of the dynamic range and the signal-to-noise ratio in a typical THz-TDS measurement. The first application of transmission THz-TDS was on water vapor in the ambient atmosphere [191] and subsequently

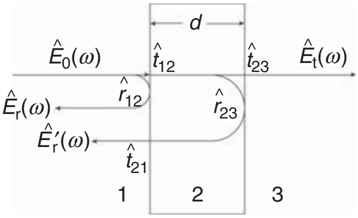

Figure 27.8 Schematic representations of the geometries for transmission and reflection spectroscopy.$E_0(\omega)$ is the incident field, $E_t(\omega)$ is the transmitted field, and $E_r(\omega)$ and $E_t{'}(\omega)$ are the fields reflected from the first and second interface of the sample, respectively.

the absorption coefficient and index of refraction of a range of dielectrics and semiconductors were reported [218].

In Figure 27.8, the general geometries for transmission and reflection measurements are illustrated.

The incident THz pulse is characterized by its spectral amplitude and phase $E_0(\omega)$, obtained by Fourier transformation of the raw experimental data and the time-domain representation of the pulse, as illustrated in Figure 27.9.

The transmitted and reflected signals are in this geometry given by

$$\begin{aligned}
\hat{E}_t(\omega) &= \hat{E}_0(\omega)\hat{t}_{12}\hat{t}_{23}\exp(-\alpha d/2)\exp(\mathrm{i}n\omega d/c),\\
\hat{E}_r(\omega) &= \hat{E}_0(\omega)\hat{r}_{12},\\
\hat{E}_r{'}(\omega) &= \hat{E}_0(\omega)\hat{t}_{12}\hat{r}_{23}\hat{t}_{21}\exp(-\alpha d)\exp(2\mathrm{i}n\omega d/c)
\end{aligned} \qquad (27.5)$$

where $\hat{t}_{12}$, $\hat{t}_{23}$, $\hat{t}_{21}$, $\hat{r}_{12}$, and $\hat{r}_{23}$ are the various complex Fresnel field transmission and reflection coefficients, as defined in Figure 27.8.

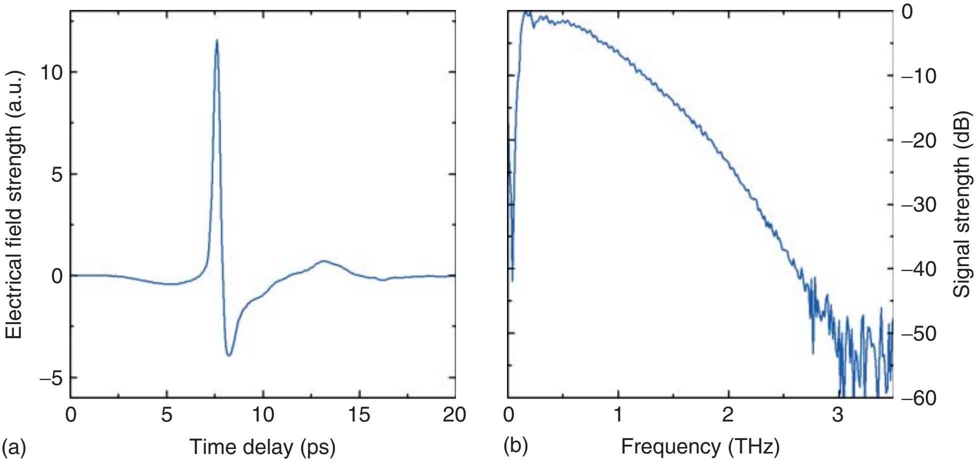

Figure 27.9 (a) THz-bandwidth transient recorded in the time domain and (b) its corresponding frequency spectrum.

Measurements carried out either in transmission and reflection can be used for the extraction of the complex index of refraction of the sample $\hat{n}(\omega) = n(\omega) + \mathrm{i}\kappa(\omega)$. Here, $\kappa(\omega)$ is the extinction coefficient, related to the absorption coefficient $\alpha(\omega)$ through $\kappa(\omega) = \alpha(\omega)c/2\omega$.

27.3.4.1 **Transmission THz-TDS**

In the simplest transmission experiment, two THz pulses–propagating through air and the sample, respectively–are recorded and their spectral amplitudes and phases are compared as

$$\frac{E_{\mathrm{sam}}(\omega)}{E_{\mathrm{ref}}(\omega)} = T(\omega)\exp(\mathrm{i}\phi(\omega)) = \hat{t}_{12}\hat{t}_{23}\exp(-\alpha d/2)\exp(\mathrm{i}(n-1)\omega d/c) \tag{27.6}$$

For simplicity, if we limit the analysis to sample materials with low absorption coefficient then the Fresnel transmission coefficients are real valued, and at normal incidence, we find

$$\begin{aligned} n(\omega) &= 1 + \frac{\phi(\omega)c}{\omega d}. \\ \alpha(\omega) &= -\frac{2}{d}\ln\left(\frac{(n+1)^2}{4n}T(\omega)\right) \end{aligned} \tag{27.7}$$

In Figure 27.10, we have shown an example of a transmission THz-TDS measurement. The sample was a mixture of the pure DNA base cytosine and PE filler material [219].

Figure 27.10a shows the time traces of the reference and sample signals, recorded after transmission through dry air and the sample pellet, respectively. Figure 27.10b shows the frequency spectra of the two signals, and Figure 27.10c shows the extracted absorbance (the product of absorption coefficient α and sample thickness d), together with a curve showing the highest detectable absorbance in the given experiment. Figure 27.10d shows the extracted index of refraction of the cytosine sample.

Figure 27.10b shows that the THz signal reaches the noise floor of the experiment at high frequencies, here at 4 THz. Naturally, at frequencies above this cutoff point, no meaningful measurements are possible, but also at frequencies below the cutoff the results might be impeded by the limited frequency-dependent dynamic range of the experiment, defined as the strength of the reference signal with respect to the noise floor of the experiment. The highest absorbance that can be measured with a given dynamic range DR corresponds to the situation where the sample signal is at the same level as the noise floor [220]. This can be expressed as

$$(\alpha d)_{\max} = 2\ln\left(\mathrm{DR}\frac{4n}{(n+1)^2}\right) \tag{27.8}$$

The curve showing the largest detectable absorbance in the given experiment is shown together with the extracted absorption coefficient in Figure 27.10c. The strongest absorption lines in the measured spectrum are clearly saturated, and the rolloff of the absorption at high frequencies is a direct consequence of the limited dynamic range of the experiment.

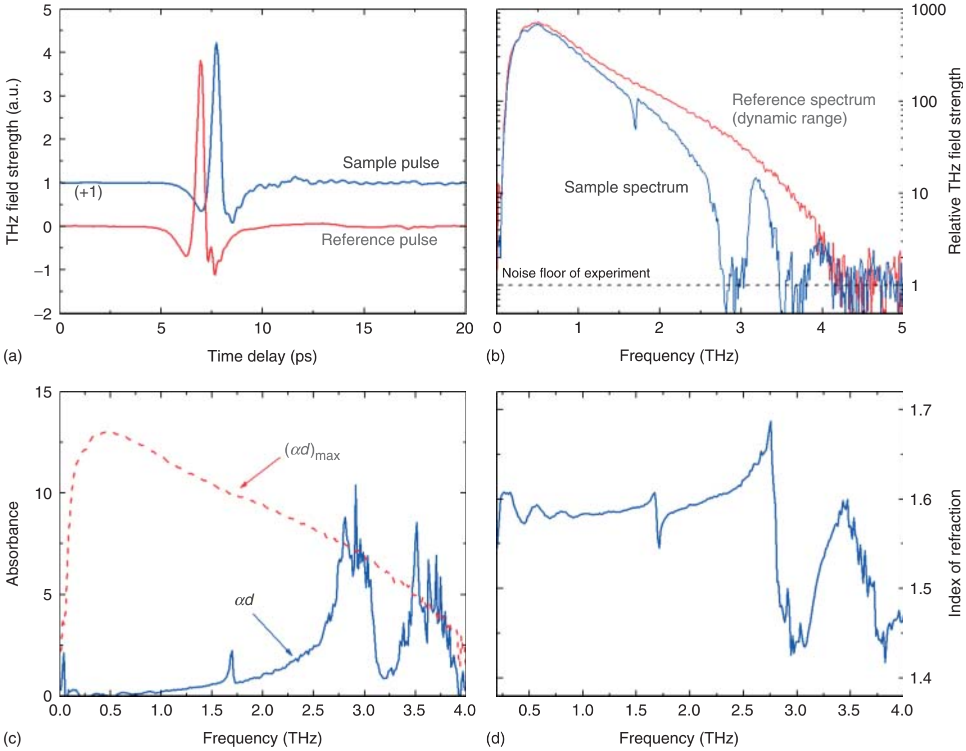

Figure 27.10 Time traces of the reference and sample pulses in a transmission THz-TDS experiment, (b) frequency spectra of the reference and sample pulses with respect to the noise floor of the experiment, (c) the extracted absorbance αd and the highest detectable absorbance αd_{max}, and (d) index of refraction of the sample material. The sample consisted of a mixture of cytosine and PE filler.

The analysis outlined gives analytical, closed-form solutions to the inversion of the equations linking the measured transmission amplitude and phase to the optical properties of the sample. However, Eq. (27.7) is only strictly valid for samples with vanishing absorption and infinite thickness. Finite absorption leads to additional phase shifts due to the complex-valued Fresnel transmission coefficients. For thin samples with high absorption (e.g., liquid water or highly doped semiconductors) the phase change due to the Fresnel coefficients becomes comparable to the accumulated phase change due to propagation through the sample. Hence, the separate calculation of the real part of the refractive index from the phase of the sample signal relative to the reference signal is no longer possible. In Figure 27.11, the effect of the additional phase shift at the sample interfaces is demonstrated. The dielectric function of liquid water was measured using a transmission cell with a water layer thickness $d = 76$ μm. The dashed lines show the result of an analysis using Eq. (27.7) to calculate the dielectric function $\hat{\varepsilon}(\omega) = \varepsilon\prime(\omega) + \mathrm{i}\varepsilon\prime\prime(\omega) = (n + \mathrm{i}\kappa)^2$, and the solid lines show the results of

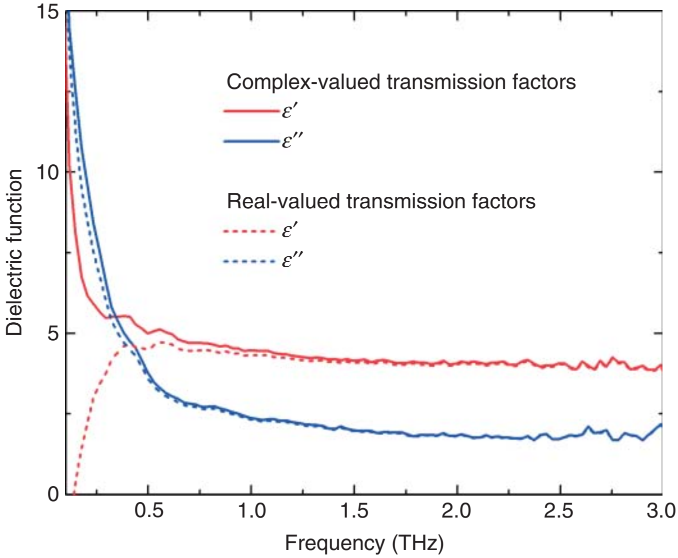

Figure 27.11 Real and imaginary parts of the dielectric function $\hat{\varepsilon} = \varepsilon\prime + \varepsilon\prime\prime$ of pure water at room temperature, extracted from transmission THz-TDS data measured with a 76 µm thick water layer using complex- (solid lines) and real-valued (dashed lines) Fresnel transmission coefficients.

a full analysis, including the phase shift due to the imaginary part of the index of refraction in the Fresnel transmission coefficients.

The correct extraction of the real part of the dielectric function is especially strongly dependent on the inclusion of the interfacial phase shifts. Although the full analysis correctly reproduces the known dielectric function of water [221–226], the simpler analysis completely fails to reproduce the sharp increase of $\varepsilon\prime$ toward its static value $\varepsilon_{\mathrm{DC}}$ at low frequencies.

The THz frequency range addresses low-energy processes (1 THz corresponds to a photon energy of 4.1 meV). In biological systems, there is a wide range of important questions that can be addressed by THz spectroscopy. Large macromolecules such as proteins and DNA have a large density of vibrational states in the THz region, because of the large masses and low-binding energies involved. For this reason, transmission THz spectroscopy has been applied to address the mechanisms, which control flexibility and conformational state of biological macromolecules [227]. As prominent examples of work on proteins, Markelz and coworkers [228, 229] have studied the influence of the conformational state of proteins on the density of states in the far-infrared, protein–ligand binding in solution [230], oxidation of proteins [231], and the dynamical transition near 200 K in proteins [232, 233]. Havenith *et al.* [234] have demonstrated a time-resolved THz-TDS technique, which is capable of studying the solvation kinetics in protein solution. THz spectroscopic studies on DNA material have focused on the difference in dielectric properties in the THz range on the binding state of DNA, as studied by Brucherseifer *et al.* [235] who later applied THz sensing in resonant waveguide structures for label-free sensing of hybridization of DNA with femtomolar sensitivity [236]. The broadband absorption differences between two types of artificial RNA could be used as contrast mechanism for free-space imaging of arrays of RNA spots [237]. Finally, the dielectric properties of water confined in nanometer-sized micelles has been studied by the Mittleman *et al.* [238, 239], who demonstrated that water in such confined environments displays strong resonances originating from vibrational modes of the nanometer-sized water pool.

27.3.4.2 **Reflection THz Spectroscopy**

Spectroscopy of liquids is typically carried out in either transmission geometry or reflection geometry, depending on the absorption strength of the liquid. The highest absorption that can be measured in a transmission experiment is limited by the dynamic range, defined as the frequency-dependent reference signal amplitude with respect to the noise floor of the experiment, of the spectrometer because the signal must be transmitted through the sample [220]. In contrast, it is the signal-to-noise ratio of the spectrometer, that is, frequency-dependent fluctuations of the signal strength, which determines the largest measurable absorption coefficient in a reflection experiment as the absorption of the sample is detected as a small additional phase of the reflected signal [220].

Owing to the rather strong absorption of polar liquids, and in particular of water, spectroscopy in the THz region of such liquids are typically carried out in a reflection geometry on bulk quantities of the liquid or by transmission through a very thin liquid layer. While THz transmission measurements of liquid water are certainly possible for thin water layers, the subsequent analysis becomes plagued with multiple reflections of the THz beam in the water cell, especially at low frequencies. In the region above 1 THz transmission, experiments are difficult owing to strong absorption, and in recent work targeting the frequency range of 1–6 THz, reflection-type spectroscopy seems the method of choice. Here, we briefly review different techniques applied for reflection THz spectroscopy.

Historically, the technique of dispersive Fourier transform spectroscopy (DFTS) [198] was the first method for accurate determination of the full dielectric function of materials in the far infrared. Afsar and Hasted [240] used DFTS to characterize the full dielectric function of liquid water in the 0.2–13.5 THz range of 6–450 cm^{-1}. In their spectroscopic setup, water was kept behind a single-crystal, high-resistivity silicon window, highly transparent to the far-infrared radiation, but with sufficiently high and constant index of refraction [218] to also serve as a useful beam splitter for the THz radiation. The liquid cell was placed in one of the arms of the modified Michelson interferometer in the spectrometer, as illustrated schematically in Figure 27.12a. Hence, phase-sensitive measurements were possible by measuring the interferogram $I(\tau)$ of the incoherent, broadband light source. This allowed a direct evaluation of both the real and the imaginary parts of the frequency-dependent permittivity $\varepsilon(\nu) = \varepsilon'(\nu) + i\varepsilon''(\nu)$ from the experimental data.

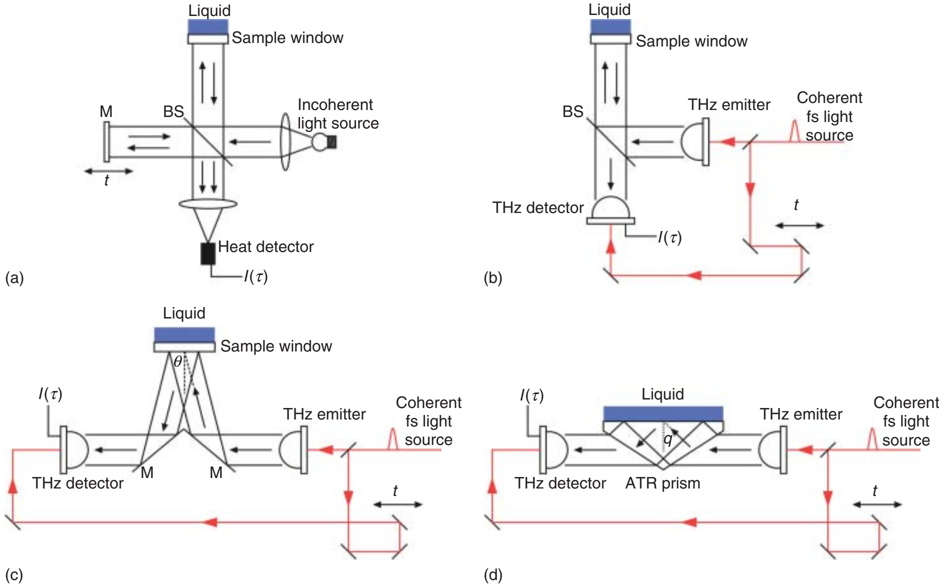

Figure 27.12 Experimental configurations for (a) dispersive Fourier transform spectroscopy (DFTS), (b) normal-incidence reflection THz time-domain spectroscopy (THz-TDS), (c) generalized reflection THz-TDS with an incidence angle theta, and (d) attenuated total reflection (ATR) THz-TDS with an internal angle theta larger than the total internal reflection angle.

In DFTS, temporally separated interferograms of the incoherent light reflected from the different dielectric interfaces in the sample arm of the spectrometer are recorded by scanning the position $\tau = 2x/c$ of the mirror in the variable arm of the interferometer. The part of the interferogram $I_{\mathrm{aw}}(\tau)$ associated with the window–air interface of the empty cell is used as a reference for the sample interferogram $I_{\mathrm{wl}}(\tau)$ from the window–liquid interface of the filled liquid cell. The ratio of the Fourier transformations of these interferograms can then, in combination with the standard expressions for the Fresnel reflection coefficients at the interfaces, be used for the calculation of the optical properties of the liquid

$$R\exp(\mathrm{i}\phi) = \frac{I_{\mathrm{wl}}(\nu)}{I_{\mathrm{aw}}(\nu)} = \frac{\hat{\boldsymbol{r}}_{\mathrm{wl}}(\nu)}{\hat{\boldsymbol{r}}_{\mathrm{aw}}(\nu)} = \frac{(\hat{\boldsymbol{n}}_{\mathrm{l}}(\nu) - n_{\mathrm{w}}(\nu))(1 + n_{\mathrm{w}}(\nu))}{(\hat{\boldsymbol{n}}_{\mathrm{l}}(\nu) + n_{\mathrm{w}}(\nu))(1 + n_{\mathrm{w}}(\nu))} \tag{27.9}$$

where R and ϕ are the measured amplitude and phase of the ratio of the Fourier transformations of the two interferograms. When inverted, Eq. (27.9) gives the complex index of refraction of the liquid, $\hat{\boldsymbol{n}}_{\mathrm{l}}(\nu) = n_{\mathrm{l}}(\nu) + \mathrm{i}\kappa(\nu) = n_{\mathrm{l}}(\nu) + \mathrm{i}\alpha(\nu)c/4\pi\nu$, assuming that the index of refraction n_{w} of the window material is known

$$\begin{aligned} n_{\mathrm{l}} &= \frac{1 - R^2(1 - n_{\mathrm{w}})^2/(1 + n_{\mathrm{w}})^2}{1 + R^2(1 - n_{\mathrm{w}})^2/(1 + n_{\mathrm{w}})^2 - 2R\cos\phi(1 - n_{\mathrm{w}})/(1 + n_{\mathrm{w}})}, \\ \alpha_l &= \frac{4\pi\nu}{c}\,\frac{2R\sin\phi(1 - n_{\mathrm{w}})/(1 + n_{\mathrm{w}})}{1 + R^2(1 - n_{\mathrm{w}})^2/(1 + n_{\mathrm{w}})^2 - 2R\cos\phi(1 - n_{\mathrm{w}})/(1 + n_{\mathrm{w}})} \end{aligned} \tag{27.10}$$

Thrane *et al.* [222] established a reflection-type THz-TDS technique with an experimental arrangement of the liquid cell similar to reflection-type DFTS [240], adapted for the technique of reflection THz-TDS, with normal incidence of the THz field onto the liquid surface. This experimental geometry is illustrated in Figure 27.12b. In the geometry shown here, the full set of spectroscopic data is obtained within the same temporal scan, by using the reflection from the interface between air and window material as the reference signal $E_r(\tau)$ and the reflection from the interface between the window and the liquid as the sample signal $E_s(\tau)$. The sample signal is separated in time from the reference signal as a result of the propagation delay of the sample signal through the window material. With normal incidence of the THz beam on the window, the ratio of the spectra of the sample and reference pulses is

$$\begin{aligned}
&\frac{\hat{\boldsymbol{E}}_s(\nu)}{\hat{\boldsymbol{E}}_r(\nu)} = \frac{t_{aw}t_{wa}}{r_{aw}} \exp\left(\mathrm{i}\frac{4\pi n_w d_w \nu}{c}\right) \frac{\hat{\boldsymbol{n}}_l - n_w}{\hat{\boldsymbol{n}}_l + n_w} \quad \Leftrightarrow \\
&R\exp(\mathrm{i}\phi) \equiv \frac{\hat{\boldsymbol{E}}_s(\nu)}{\hat{\boldsymbol{E}}_r(\nu)} \frac{r_{aw}}{t_{aw}t_{wa}} \exp\left(-\mathrm{i}\frac{4\pi n_w d_w \nu}{c}\right) = \frac{\hat{\boldsymbol{n}}_l - n_w}{\hat{\boldsymbol{n}}_l + n_w}
\end{aligned} \tag{27.11}$$

where R and ϕ are the measured spectral amplitude and phase of the ratio of the sample and reference signals, corrected for the transmission and reflection coefficients of the air–window interface and the acquired phase as a result of propagation through the window material.

Inverting Eq. (27.11) yields the index of refraction and absorption coefficient of the liquid

$$\begin{aligned}
n_l &= \frac{n_w(1-R^2)}{1+R^2+2R\cos\phi}, \\
\alpha_l &= \frac{4\pi n_w \nu}{c} \frac{-2R\sin\phi}{1+R^2+2R\cos\phi}
\end{aligned} \tag{27.12}$$

The methodology described here for the calculation of the dielectric properties of the liquid can be extended to an analysis at non-normal incidence at an angle θ of the THz beam on the sample window. This experimental geometry is shown schematically in Figure 27.12c. Compared to normal-incidence reflection spectroscopy, the configuration with non-normal incidence of the THz beam has significantly higher signal strength as the THz beam splitter is no longer required. In this situation, the generalized reflection and transmission coefficients must be used; in addition, the polarization state of the THz beam becomes important [225].

27.3.4.3 **Attenuated Total Reflection THz-TDS**

The most sensitive method for determination of the full dielectric function of a strongly absorbing liquid is offered by ATR THz-TDS [241, 242].

ATR THz-TDS has proved to be instrumental for detailed studies of the dielectric function of water and aqueous solutions as well as studies of solvation of organic molecules in water. The Tanaka group has demonstrated that spectroscopy in the THz range makes it possible to measure the size of the solvation shell of water molecules around molecules and aggregates of molecules in aqueous solution [243, 244]. Furthermore, the increased sensitivity of ATR THz-TDS compared to reflection THz-TDS has enabled the same group to study fast relaxation at several THz in water isotopes [245, 246].

In the ATR configuration, the THz beam is transmitted through a Dove prism where it undergoes total internal reflection at a facet of the prism in contact with the liquid. The geometry of an ATR THz-TDS system is schematically shown in Figure 27.12d. The angle θ refers to the internal incidence angle of the THz beam onto the interface in contact with the liquid. The highest sensitivity to small changes in the dielectric properties of the sample is obtained when that incidence angle is larger than, but close to, the critical angle for total internal reflection. The measurement is carried out by recording a reference pulse $E_\mathrm{r}(\tau)$ transmitted through the prism with air above the interface and, subsequently, a sample pulse $E_\mathrm{s}(\tau)$ is recorded with liquid in contact with the prism. The ratio of the spectra of these two signals is, as in the previous cases discussed here, analyzed in order to extract the complex index of refraction of the liquid. If we assume *p*-polarization of the THz light incident on the ATR interface, we have [242]

$$R\exp(\mathrm{i}\phi) = \frac{\hat{\boldsymbol{E}}_\mathrm{s}(\nu)}{\hat{\boldsymbol{E}}_\mathrm{r}(\nu)} = \frac{\hat{\boldsymbol{r}}^\mathrm{p}_\mathrm{wl}}{\hat{\boldsymbol{r}}^\mathrm{p}_\mathrm{wa}} \tag{27.13}$$

where R and θ again represent the amplitude and phase of the ratio of the spectra of the sample and reference pulses. Using the Fresnel reflection coefficients for total internal reflection of *p*-polarized light, Eq. (27.13) can be inverted to find an expression for the complex permittivity $\hat{\varepsilon}_1 = \varepsilon_1{\prime} + \mathrm{i}\varepsilon_1{\prime\prime} \equiv (n_1 + \mathrm{i}\kappa_1)^2$ [242]

$$\hat{\varepsilon}_1 = \frac{B \pm \sqrt{B^2 - AB\sin^2 2\,\theta}}{2A\cos^2\theta} \tag{27.14}$$

where $A = (\hat{\boldsymbol{r}}^\mathrm{p}_\mathrm{wl} - 1)^2$ and $B = (\hat{\boldsymbol{r}}^\mathrm{p}_\mathrm{wl} + 1)^2$. All typical material systems without gain show a positive $\varepsilon{\prime\prime}$ and hence the solution with $\varepsilon{\prime\prime} \geq 0$ should be chosen.

Bioanalytical NMR Spectroscopy

Perttu Permi

28.1
Introduction

Nuclear magnetic resonance (NMR) spectroscopy is likely the most versatile method for the study of biomolecules. The power of NMR originates from the fact that practically every atom with a magnetic nucleus gives rise to an individual signal in the NMR spectrum that carries spatial and temporal information of the local chemical environment of that atom. Solution conditions in high-resolution NMR experiments mimic the natural biological environment and results relate to functional assays.

Proteins, owing to their many biological functions, display versatile phenomena to investigate. In addition, there are spectroscopic reasons in favor of proteins. Proteins, as a class of molecules, give particularly well-dispersed NMR spectra because of rich local diversity in their physical–chemical structures. Proteins can also be obtained using methods of molecular biology, in large quantities enriched uniformly or selectively with ^{13}C and ^{15}N as well as deuterated or specifically reprotonated to make use of a large repertoire of heteronuclear NMR experiments. These are the main reasons why NMR spectroscopy of proteins is highly developed.

Today, NMR spectroscopy is one of the most important experimental techniques for protein structure determination – 15% of new structures published in the protein data bank (PDB) have been solved using NMR. NMR has been found to be especially useful for the studies of small- and medium-sized proteins. The structure determination process can be accomplished within 1–3 months for proteins with $<$180 amino acid residues, provided that a good quality ^{1}H, ^{15}N correlation spectrum can be obtained, which shows a properly folded protein and no sign of aggregation. Recent technological advances such as cryogenically cooled probe heads as well as breakthroughs in NMR methodology, computational methods, data analysis, and sample production have resulted in astonishingly versatile and powerful methods well documented in the original papers, recent reviews [1–7], and textbooks on NMR spectroscopy [8, 9]. Recent progress has demolished many obstacles earlier hindering the studies of larger proteins. To date, the largest systems studied on the amino acid residue scale has been the

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

110 kDa homooctameric *Staphylococcus aureus* 7,8-dihydroneopterin aldolase [10] and the 81.4 kDa *Escherichia coli* malate synthase G (MSG) containing 723 residues [11]. In addition, the number of membrane protein structures solved by solution-state NMR in detergent micelles has been steadily increasing during the past 5 years. It is very likely that molecular complexes with a molecular size approaching 1000 kDa are feasible under certain conditions.

The most important recent innovations in the field of NMR include the introduction of weakly aligned systems [12] and transverse relaxation-optimized spectroscopy (TROSY) [13]. These discoveries have significantly expanded the realm of high-resolution NMR spectroscopy by including new directional and range-independent information and by significantly enlarging the set of molecules amenable to NMR. Many of the NMR methods that were originally developed for proteins have been amended suitably for studies of other classes of molecules, in particular, nucleic acids and carbohydrates.

28.2
Protein Sample

28.2.1
Solubility and Stability

Successful NMR spectroscopy begins from successful sample preparation [14]. Usually, it is very difficult to compensate for a poorly ‘‘behaving’’ molecule by spectroscopic means. Indeed, the preparation of a highly soluble labeled protein sample is often the limiting factor, not the spectroscopy, in the studies of proteins and their complexes by NMR. Problems with samples manifest themselves typically as low signal-to-noise ratio (SNR) or fast transverse relaxation, that is, broad lines or multiple signals. These can be signs of poor solubility, oligomerization, aggregation, conformational isomerism, or perhaps paramagnetic ion impurities, all deleterious to carrying out detailed NMR studies. However, low-quality spectra may also be indicative of interesting phenomenon perhaps itself worthy of an investigation.

There has been a manifold increase in the SNR of NMR over the decades as a result of the progress in instrumentation and methodology. Nevertheless, NMR remains a comparatively insensitive method, owing to minute nuclear magnetic moments, compared with many forms of optical spectroscopy. Therefore, fairly large amounts of material are required for experiments. Even though compounds in a nanogram scale can be detected using special NMR probes, detailed structural studies, for example, determination of three-dimensional structures, need at least a few hundred micromolar protein solutions in few hundred microliter volumes. Proteins, that are obtained by overexpression in bacterial or eukaryote hosts and subsequently purified by affinity, ion exchange or gel filtration, and so on, come in large quantities and are usually sufficiently pure for NMR spectroscopy. Small molecule impurities are easy to detect and often indifferent to heteronuclear NMR spectroscopy, unless occurring in much higher concentrations than the solute of interest or unless they happen to possess a particular activity on the system of interest.

The high solubility of a biomolecule required for NMR cannot be taken for granted. The spectral characteristics might be compromised even without an apparent aggregation seen as weak signals or broad lines. Often it is not obvious if or how unspecific binding or aggregation or oligomerization that leads to increase in rotational correlation times can be avoided. Temperature, pH, and ionic strength are among the easiest parameters to vary in search of appropriate solvent conditions. Knowledge of the protein's properties, such as isoelectric point (pI), acquired during the production and purification may provide valuable clues about the conditions and additives, that is, cosolvents that may improve the spectral appearance. Some of the commonly used cosolvents include surfactants, such as CHAPS, octylglucoside, and SDS; alcohols such as trifluoroethanol; zwitterionic compounds such as glycine and also denaturants such urea and DMSO are sometimes applied. Ligands or inhibitors of enzymes or cofactors of proteins may improve the spectral appearance. Chimeric constructs have also been used to improve the behavior [15]. Nevertheless, it is difficult to take into account all aspects that have an influence on the spectral appearance and suitable conditions are often found after trial and error.

The presence of more than one conformation may give rise to multiple signals or broadened lines due to exchange and may significantly reduce SNR, complicating assignment and interpretation of the spectra. The solvent conditioning may alter the equilibrium toward a single conformation, provided that there is some evidence or even hypothesis of conformational heterogeneity, for example, proline cis–trans isomerism or flexibility in the catalytic site due to the lack of ligand or hinge motions in a multidomain structure may help to understand and eventually to solve the problem of conformational isomerism by protein engineering [16]. Of course, it should be kept in mind not to change the solvent conditions or to engineer the protein to render the original biological question meaningless. Functional assays help to judge the appropriateness of the solvent conditioning or protein engineering. NMR itself, for example, when used to follow reaction kinetics, can be used to assess functional properties.

A stable sample is a necessity for extensive studies, such as the determination of three-dimensional structure, which require several weeks of measurement time.

Bacterial growth, owing to nonsterile conditions, in the sample tube can be largely eliminated by using sodium azide (NaN_3) in 0.02% (w/v). Proteins are also subject to degradation by proteolytic enzymes that may be present in the sample in minute amounts after the purification. Application of a ''cocktail'' of inhibitors against the common proteases eliminates largely the enzymatic breakdown. Exposed cysteine residues not paired in disulfide bonds may with time form intermolecular disulfide bonds generating dimers or higher oligomers depending on the number of exposed cysteins. Dithiothreitol (DTT) in a stoichiometric excess to cysteines can be used to keep *all* cysteins in the reduced state. Alternatively, the unpaired cysteines could be mutated often to serines to avoid the problem of unnatural pairing. Deamidation of asparagine (Asp) over time is a potential problem in certain sequences, but can be avoided by engineering the corresponding sequence.

In practice, it is difficult to take into account or rationalize all aspects that influence the sample solubility and stability. Fortunately, the protein stability and solvent conditions are easy to monitor, in particular, by heteronuclear correlation spectroscopy. Amide resonances are sensitive reporters of changes in the protein structure or in the solvent conditions. Mass spectroscopy that requires very little material is a very practical method to monitor the protein sample. Once optimal conditions are found, experiments should be conducted promptly.

28.2.2
Isotope Labeling

The purpose of isotope labeling is to produce the molecule of interest enriched with isotopes of preferred nuclear magnetic properties in order to extract more information or to facilitate the interpretation of the information and more frequently to make the study feasible in the first place. In many applications, it is advantageous to increase the proportions of ^{13}C and ^{15}N that are both spin-$\frac{1}{2}$ nuclei, from their natural abundance of 1.1% and 0.4% respectively, as high as possible to nearly 100% for the detection. The labels facilitate assignment by multidimensional heteronuclear correlation spectroscopy. In other applications, selective labeling provides means to simplify the interpretation, for example, to distinguish intermolecular correlations from intramolecular signals or segmental labeling [17, 18], for example, to reduce the number of signals.

In large systems, perdeuteration is the efficient way to slow the transverse relaxation [19–22] and specific reprotonation serves to maintain crucial information [23]. The labels allow measurements of dihedral angles via scalar couplings [24] and projection angles via cross-correlation rates [25] as well as internuclear directions via residual dipolar couplings (RDCs) [26]. Furthermore, site-specific spin labels, that is, paramagnetic electrons, can be used to extract long-range distance information [27]. Today, isotope labeling is an integral part of biomolecular NMR spectroscopy [3].

28.2.2.1 ^{13}C and ^{15}N Labeling

Uniform ^{13}C and ^{15}N labeling provides improved signal dispersion and editing by multidimensional experiments or filtering by isotope or spin state as well as various routes for coherence transfer and ways to measure scalar and dipolar couplings. Solvent suppression in heteronuclear correlation experiments is also much easier than in homonuclear correlation experiments. Uniformly labeled proteins are customarily obtained via overexpression in bacteria grown in a culture medium having enriched metabolites as sole sources of carbon and nitrogen. For bacterial expression, ^{13}C-glucose (or ^{13}C-acetate) and ^{15}N-ammonium chloride or sulfate are commercially available and commonly used. The use of the minimal medium easily leads to reduction in growth and to a reduced yield compared to the use of rich medium. The choice of a host strain and vector and at times also the codon usage have to be optimized to reach a yield that is sufficient, given the current price of ^{13}C-glucose. The ^{15}N-compounds are inexpensive and thus can be used for testing much of the performance of the protein. More recently, rich growth media with isotope labels have become commercially available to facilitate the uniform enrichment. To make proteins with posttranslational modifications expression in eukaryote hosts primarily in yeast is reaching sufficient expression levels [28].

For studies of protein complexes, intermolecular correlations can be distinguished from intramolecular correlations by filtered heteronuclear experiments provided that one of the components is labeled selectively and differently from the other. This approach is also useful for large protein complexes to acquire simplified spectra to alleviate the assignment. For the same end, segments of polypeptide chain can selectively be labeled by ^{13}C and ^{15}N using inteins, splicing enzymes [18]. The inteins also provide the way to obtain cyclic peptides with labels that are significantly less expensive than labeled amino acids from the solid-state peptide synthesis.

Nowadays, *E. coli* is the primary organism for production of recombinant, isotopically enriched proteins. *E. coli* cells are easy to handle and by far serve the most economic way of producing uniformly ^{15}N, ^{13}C (^{2}H)-labeled proteins. Conventional labeling strategy, based on NH_4Cl and glucose precursors, yields homogeneously labeled proteins and is a very powerful method leading to high protein yield. Unfortunately, the protein expression in *E coli* has several limitations, for example, the proteolytic degradation of the target protein, the solubility problems, and improper protein folding, as a result of distinct folding machinery and posttranslational modifications between eukaryotics and prokaryotics. Additionally, only proteins that do not interfere with host cell physiology can be produced.

During the past few years, cell-free *in vitro* protein synthesis has become an important protocol in production of isotopically labeled proteins. The commercially available cell-free protein expression systems are based on *E. coli* or wheat germ cell extracts, where the necessary components for protein translational machinery are purified from the aforementioned organisms. Cell-free methods overcome many problems encountered in the protein production in *E. coli* cells. Proper folding of the mammalian protein can be achieved by using the eukaryotic protein translation/folding machinery extracted from wheat germs. Advantages of the cell-free protein production method rise from its open system nature, where components assisting the biosynthesis, folding, and stability of the protein, can be utilized during the protein synthesis. Although uniformly labeled proteins can be expressed in *E. coli* by simple protocols, selective labeling of the proteins is not achieved accurately. Severe scrambling of the isotopes is observed during the expression, due to the metabolism of the living organism. On the contrary, the metabolism of the amino acids the cell-free system is restricted, which enables highly selective labeling of the proteins. In addition, the usage of precursors, such as amino acids with selective isotope labeling, is also very flexible.

In addition, DNA and RNA molecules are, nowadays, obtained with labels from the cell-free synthesis using uniformly labeled ribonucleotide triphosphates (NTPs) [29–32].

28.2.2.2 **Deuteration**

Perdeuteration has become an indispensable means for circumventing problems of transverse relaxation (T_2) inherent to large biomolecules and their complexes [22]. Protons because of their large nuclear magnetic moment are the main cause of dipolar relaxation of protons themselves as well as the directly bound heteronucleus. The relaxation problem can largely be reduced by uniform deuteration. Perdeuterated proteins are obtained by growing host microorganisms in deuterium oxide (D_2O) often concurrently with ^{15}N and/or ^{13}C labeling. The expression levels in D_2O are usually comparable to that in H_2O, but the growth is compromised. When the labeled protein is dissolved in H_2O, the amide deuterons are exchanged for protons, which serve as the main source of magnetization for coherence transfer in heteronuclear correlation experiments, and also for the direct detection of the signal during the acquisition. The high degree of labeling is advantageous to reduce the transverse relaxation of the aliphatic carbons and amide protons in TROSY at high magnetic fields [13, 33]. Obviously, perdeuteration reduces significantly the distance information available via interproton nuclear Overhauser enhancements (NOEs). A compromise between the favorable relaxation properties and the extent of NOE data may be found by adjusting the degree of deuteration with the D_2O content in the culture medium. Suitable degree of random fractional deuteration is often $>50\%$.

Alternatively, an important portion of the conformational restrictive NOEs can be recovered by relabeling for protonated methyl rotors of aliphatic residues [23]. This is accomplished using either selectively labeled amino acids that are more readily incorporated during the expression than *de novo* synthesized amino acids or more affordably by using selectively protonated nonglucose carbon sources. It depends on the metabolism of a particular metabolite how the protons become incorporated in specific positions in the amino acids. The methyl group of pyruvate is a precursor for the methyls of alanine, valine, leucine, and γ rotor of isoleucine. More recently, protonated methyl rotors of valine, leucine, and isoleucine have been derived using α-ketoglutarate. It has been demonstrated that these labeling strategies are sufficient to obtain short-range distance data for determination of three-dimensional structures when the reduced distance information from highly perdeuterated proteins is compensated partly by using the directional restraints and hydrogen bond restrains. More sophisticated labeling strategies are designed to reprotonate $C\alpha$ to be used as the sole source of magnetization for experiments in D_2O.

The TROSY effect is not limited to IS spinning systems only. Substantial improvement in sensitivity and resolution can also be obtained for I_3S spin moieties of methyl groups, provided that one of the methyl groups of Ile$\delta1[^{13}CH_3]$, Leu$[^{13}CH_3/^{12}CD_3]$, and Val$[^{13}CH_3/^{12}CD_3]$ are selectively protonated in an otherwise highly perdeuterated protein [34].

The Stereo-array isotope-labeling (SAIL) scheme is an optimal isotopic labeling method in which cell-free translation system is used for assembling proteins from synthetic stereo-isotope-labeled amino acids [35]. The leading principle is to maximize sensitivity and resolution of protein spectra without losing vital NOE distance information from side chains. This is accomplished by stereospecific labeling of methylene $^{13}CH_2$ and methyl $^{13}CH_3$ moieties with ^{13}CHD and $^{13}CHD_2$ units. One of the prochiral methyl groups in Leu and Val residues is quenched by replacing the $^{13}CH_3$ moiety with $^{12}CD_3$. In addition, six-membered aromatic rings are labeled with alternating $^1H-^{13}C$ and $^2H-^{12}C$ moieties. Advantages of the SAIL labeling are significant. The resolution in NMR spectra is improved because more than 50% of carbon-bound protons are replaced by deuterons. These protons are mainly originating from methylene groups, which, without stereospecific assignment of geminal protons, contribute solely to spectral overlap in uniformly ^{13}C-labeled samples. Additional improvement in both resolution and sensitivity can be obtained through diminished ^1H and ^{13}C transverse relaxation rates and reduced long-range $^1H-^1H$ scalar coupling interactions. Moreover, coherence transfer efficiency can be optimized and improved owing to the absence of heterogeneous spin moieties.

28.2.3
Dilute Liquid Crystals

Perhaps surprisingly, biomolecules as large as proteins tumble in water so stochastically that it is difficult to observe any degree of a molecular alignment [36]. It is only proteins with prosthetic groups of high-magnetic anisotropy susceptibility, such as globins with hemegroups, which acquire a noticeable degree of alignment in isotropic milieu [37]. In general, it is first when molecules are dissolved in a dilute liquid crystal that they assume a minute, but measurable degree of molecular alignment [12]. The molecular alignment arises from the interaction between the molecule of interest and the liquid crystal particles. The steric hindrance, that is, the shape of the molecule, determines the size and direction of alignment [38]. In addition, the surface charges on the biomolecule, the charge texture on the liquid crystalline particle, and the ions or cosolvents in the solution may give a contribution to the size and direction of alignment.

The molecular alignment manifests itself as RDCs and chemical shift anisotropy (CSA) that carry information about directions and molecular shape. The preferred degree of molecular alignment is small on the order of 10^{-3} to retain essentially all characteristics of high-resolution NMR spectra. Otherwise, a full span of dipolar couplings and CSAs would render the spectrum of complex molecule hopelessly uninterpretable. RDCs reveal the directions of internuclear vectors and frequency shifts the directions of the components of CSA tensors [39]. The information content is highly complementary to the torsion angles available from three-bond scalar couplings and to the interproton distances available from NOEs when determining the three-dimensional structure. Furthermore, the anisotropy data implicitly contain information about the molecular shape via simulations [38]. The directional dependence of dipolar couplings and chemical shifts is easy to interpret and to compare with values computed from known three-dimensional structures. In this way, structures and conformational changes and formation of quaternary structures are easy to examine and to analyze without extensive structure determination.

A number of aqueous liquid crystalline media suitable for inducing a weak alignment of biomolecules are known [6]. It should be understood that the choice for a particular liquid crystalline system depends on the properties of the biomolecule, liquid crystalline particles and temperature, ionic strength, and eventual cosolvents. Some of the critical factors affecting the formation of the liquid crystal and the size and direction of the solute alignment may be difficult to anticipate beforehand and preliminary experiments are often required to find a suitable system. Furthermore, the set of aqueous liquid crystals for aligning biomolecules is likely to continue to expand as the search for novel media is currently in progress.

28.2.3.1 **Liquid Crystal Composed of Organic Compounds**

Certain amphiphatic molecules arrange themselves in discoidal-bilayered structures known as *bicelles*. The bicelles have highly anisotropic magnetic susceptibility and thus the property to align themselves in the magnetic field with the plane normal perpendicular to the field [40]. This results in a uniaxial medium suitable for aligning solute molecules. Bicelles can be prepared, for example, from a mixture of (1 : 3) dry dihexanoylphosphatidylcholine and dimyristoylphosphatidylcholine and dissolved in water to a concentration >3% (w/v) [41]. The long-chain lipid is thought to make the bilayer and the short-chain lipid confines and protects the perimeter of the disk. The solubilization is best carried out at low temperature near 0 °C, where the viscosity is low and components mix properly. The liquid crystalline phase is stable in the temperature range of ∼30–50 °C, depending slightly on the exact composition of the medium. The correctly prepared phase should be uniform and transparent. The presence of the liquid crystalline phase is easy to confirm by measuring the deuterium quadrupolar splitting of D_2O or from the shifted phosphor signals of the phosphatidylcholine head groups (Figure 28.1).

The size of the alignment can be tuned by varying the concentration of the liquid crystal, however, above the critical concentration required for the liquid crystalline phase to form [41]. The tuning is a convenient way to adjust the range of RDCs and CSA optimal for the measurements. Provided that the alignment is induced not only exclusively by the molecular shape but also by the electric interactions between the surfaces of the solute and liquid crystal particle, the ionic strength of the solution will influence both the size and the direction of the alignment. This phenomenon can be exploited by ‘‘doping’’ the bicelles with a small amount of charges. In this way, it is possible to create several nonredundant alignments and to collect nonredundant data for the structure determination.

Liquid crystal phases can be prepared, also, by dissolving various polyethylene glycols, referred to as *CmEn compounds* such as C12E5, to water >3% (w/v) [42]. A small amount of short-chain alcohol such as hexanol helps to form the phase by stabilizing the exposed edges of the lamellae. The liquid crystalline phase is found in the temperature range from 30 to 40 °C. However, the actual composition of polyethylene glycol or their mixtures or any of their derivatives may noticeably alter the phase diagram and transition temperatures. The phase transitions to and from

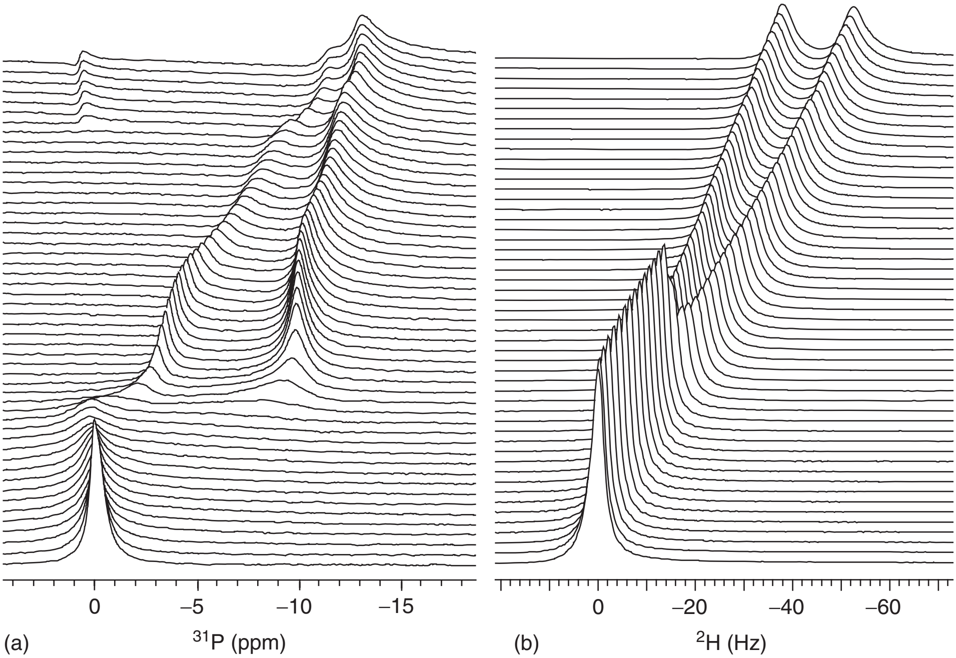

Figure 28.1 Deuterium (a) and phosphorus (b) spectra as a function of temperature of a liquid crystal.

the liquid crystalline phase, again depending on the composition, show hysteresis as a function of temperature. Another lamellar phase can be prepared from cetylpyridinium bromide/hexanol/sodium bromide [43]. The liquid crystalline phase is stable and robust, tolerating different buffer conditions, temperature ranges, and concentrations.

28.2.3.2 Liquid Crystals Prepared from Biological Material

Many particles of biological origin are also suitable for making lyotropic liquid crystals. For example, filamentous phages most notably Pf1, fd, and tobacco mosaic virus (TMV) readily align their long axis along the magnetic field [44–46]. The full degree of alignment of Pf1 is obtained already at modest field strengths, for example, at the field of a 300 MHz NMR spectrometer. The liquid crystalline phase is stable over a wide range of temperatures >5 °C, and it does not depend on the concentration as the phage particles align individually unlike bicelles and lamellae, where a critical concentration has to be exceeded. It is in the nature of the phages to carry high charge on their surfaces. Consequently, electric interactions often play a role in the alignment, in addition, to the molecular shape. The presence of electric contributions can be often deduced by varying the salt concentration. The Pf1 particles are negatively charged and therefore suitable for work with DNA, which is also negatively charged. On the other hand, an attractive Coulombic interaction may lead to an exchange-dominated alignment [47]. Likewise, when using particles of biological origin more specific interactions may come into the play and express themselves readily at very dilute concentrations of liquid crystalline particles as very large dipolar couplings.

The low pI ~4 of Pf1 implies that particle aggregation becomes a problem in acidic conditions. The bacterial phages can be produced in an infected bacterial culture and harvested after cell lysis and purified by precipitation and finally in a salt gradient by an ultracentrifuge.

Fragments of purple membranes (PMs) of *Halobacterium salinarum* align in the magnetic field [48]. The amount of the alignment can be tuned by varying the concentration of PMs and the solute alignment is also affected by salt that screens electric interactions between the negatively charged membranes and solutes. At tens of millimolar concentrations of monovalent ions, however, the PM membranes undergo transition to a gel, where the membrane patches can no longer be oriented with the magnetic field. An order of magnitude lowers the concentration of the divalent salt, which is required for a similar phase transition to gel.

28.2.3.3 **Oriented Matrices**

A cross-linked polyacrylamide gel customarily used in electrophoresis can be compressed or strained to bring about an oriented medium suitable for weakly aligning biomolecules [49]. The oriented matrix is robust, that is, insensitive to the solvent conditions, such pH, temperature, and cosolvents, which makes it suitable medium to study, for example, denatured proteins. Furthermore, the matrix is expected to be insensitive to the surface charge of the biomolecule. The direction of the medium is determined by the direction of the strain, not by the magnetic field, which opens possibilities to acquire data of a sample in different orientations with respect to the magnetic field. The main disadvantage of the polymeric systems is that the solute molecule has to be included in the solution before the polymerization or driven to the matrix by electrophoresis or diffusion.

Oriented matrices can also be prepared from the liquid crystal composed of membranes and bacterial phages by the polymerization to the acrylamide gel. The resulting "frozen" medium is no longer a liquid crystal, but an oriented matrix whose director is independent of the magnetic field.

28.3
Proton NMR Experiments

The large magnetic moment of proton, a spin-½ particle, and its high natural abundance are the reasons for the historical predominance of ^{1}H NMR spectroscopy. There are numerous homonuclear ^{1}H experiments, however, and some of them have proved to be most applicable to biomolecular NMR spectroscopy and are mentioned here. The emphasis is on the principles of the experiments, their processing, and information content. The reader is encouraged to consult textbooks (8 and 9) for the proper description of the experiments using the appropriate nomenclature that is not possible to introduce in this context. Furthermore, directions for operating an NMR spectrometer and procedures for setting up experiments including calibrations are usually found in textbooks or spectrometer manuals and are not discussed in this context.

In general, all present day pulse sequences employ pulsed field gradients (PFGs) for selection of desired coherences and/or for removal of artifacts. Furthermore, phase-sensitive experiments are preferred over their magnitude mode counterparts as a result of the superior resolution and possibilities to analyze the multiplet patterns for coupling constants. For the quadrature detection, the States-TPPI protocol [50] is often the most advantageous to displace artifacts to the edges of spectra. For small proteins and peptides and for many other biomolecules, the basic proton correlation experiments are the most practical and require no isotope labeling. Many of the elements of the basic proton correlation experiments are also embedded in many heteronuclear experiments.

28.3.1
One-Dimensional NMR Experiment

Customarily, studies of a biomolecule by NMR spectroscopy will begin by recording a one-dimensional (1D) proton spectrum. The 1D spectrum allows consideration of the SNR for further studies. Signals must be easily visible above the noise from a spectrum acquired by averaging 32 scans or preferably less for two-dimensional correlation experiments to be feasible (Figure 28.2). For equimolar concentrations, larger proteins have lower apparent SNR because of their larger linewidths compared to those of smaller proteins and peptides.

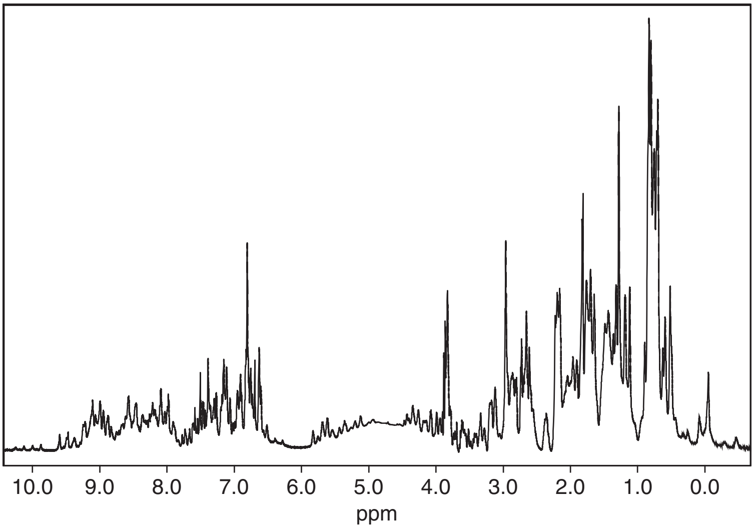

Figure 28.2 One-dimensional spectrum of a 3 mM human SH3 domain of TEC protein dissolved in H_2O/D_2O.

One-dimensional spectra of peptides and small proteins usually permit to judge from the linewidths, if aggregation or exchange processes are likely to compromise the performance. For larger proteins, in particular, it may be difficult to find sufficiently isolated signals in the 1D spectrum to measure linewidths. Furthermore, the proton linewidths of a large protein may not be adequate to evaluate feasibility of further experiments. Feasibility of larger proteins for NMR studies is better judged on the basis of heteronuclear experiments and at least an ^{15}N-labeled sample is required.

The overall dispersion of the signals seen in 1D is an important attribute of the structural characteristics of a protein. Well-structured proteins display signals over large spectral regions, in particular, the chemical shift dispersion in amide, alpha, and methyl proton resonance regions is indicative of the structure. On the contrary, resonances of unstructured or unfolded proteins lump together and have values similar to those found in short (random-coil) peptides. For example, amide proton dispersion in an unfolded protein is about four to five times smaller than in a well-folded protein of a similar size. One dimension can be used to monitor various effects, such as pH, temperature, ionic strength, or cosolvents on SNR and dispersion of signals, or on stability of a protein. It is also possible to estimate structural integrity of protein mutants with respect to wild-type proteins. So-called water-suppressed longitudinal encode decode (water-sLED) sequence [51] with its various variants is a powerful tool for studying translational diffusion and hydrodynamic radii of macromolecules and hence, aggregation state as well as folding/unfolding of proteins in solution [52]. Furthermore, one-dimensional, relaxation- and diffusion-edited proton NMR can also be used for screening of small molecule ligands that bind to a target [53]. The rate of diffusion of a small molecule is much higher than that of a macromolecule, for example, protein. A molecule that binds to a target protein can be readily identified from a cocktail of small molecules by recording 1D diffusion-edited spectra from a cocktail with and without a target protein. Subtracting these two spectra from each other reveals only signals whose rate of diffusion have changed on binding to a slowly diffusing target protein.

However, when using nondeuterated cosolvents the solvent signal suppression may become problematic. Owing to the high concentration of water, it is necessary to record the 1D proton spectrum using solvent suppression. The same applies to other nondeuterated solvents. There are various ways to reduce the solvent lines to a level comparable to the signals of the solute to utilize the full dynamic range of the detection of the NMR spectrometer. Saturation of the water line by selective radiation during the recycle delay is a simple, effective, and robust method. Therefore, the presaturation method is commonly in use. The main disadvantage of the method is that the solute signals near the solvent signals are also easily saturated to complicate the assignment. Even a partial saturation will compromise the quantitative spectroscopy. In addition, the exchangeable protons such as amide protons are subject to the saturation transfer that diminishes their signal intensity.

More selective schemes for solvent suppression employ selective pulses, spin-lock purge pulses, and field gradient pulses. Some of these methods aim to saturate the water signal in milliseconds rather than during the recycle delay, while others are designed to maintain the water magnetization in equilibrium. To destroy the water magnetization, selective pulses are used to generate orthogonal components for the solvent and solute magnetizations and subsequently to destroy the solvent signal by rf inhomogeneity or to dephase the solvent coherence by PFGs. To place the water magnetization along z-axis during the acquisition, selective pulses or binomial sequences are employed for selective excitation and PFGs are used to destroy any residual transverse magnetization caused by pulse imperfections [54]. In this way, radiation damping is largely avoided and also noticeable gains in the signal intensity of exchangeable protons are obtained. Although sensitivity loss by saturation transfer from water protons to labile amide protons is drastically diminished when PFGs are used for dephasing of water magnetization, significant sensitivity gain can be obtained by minimizing saturation of water magnetization. To this end, the so-called water flip-back procedure is employed, that is, water magnetization is turned back to positive z-axis before acquisition. This approach has now routinely been applied in protein NMR also in case of more complicated pulse sequences. A very recent innovation dubbed *selective optimized flip-angle short-transient heteronuclear multiple-quantum coherence* (*SOFAST-HMQC*) prevents excitation of water magnetization, which dramatically shortens longitudinal T_1 relaxation time of amide protons enabling the use of much faster repetition rates in NMR experiments (Section 28.5.4).

Post-acquisition methods are used to improve the *appearance* of the spectrum. The filtering of the low-frequency components by convolution is one of the most widely used methods to suppress the residual solvent signal [55]. The filtered dataset is constructed by subtracting the data ‘‘smeared’’ by the filter function from the original FID (Figure 28.2). If the solvent signal is away from the carrier frequency, that is, high-frequency components are to be removed, then the original data are initially digitally frequency shifted to zero by multiplication with an exponential function and subsequently filtered and finally restored to the original position by multiplication by the complex conjugate of the exponential function. A flat baseline is obviously an important merit of a spectrum of any dimensionality. There are various reasons for a poor baseline. The baseline will have an offset and curvature, if the signal phase at the beginning of the acquisition period or the indirect dimension is not a multiple of 90°, and if the sampling delay is not adjusted to zero, that is, $t_0 = 1$, or to the inverse of twice of the spectral width, that is, $t_0 = 1/(2 \times \mathrm{sw})$. The Hahn echo can be used to adjust the initial sampling delay for the acquisition dimension.

For the indirect dimensions in two- or higher-dimensional spectra, the phase evolution during, for example, off-resonance pulses and mixing periods must be taken into account to set the initial sampling delay correctly. The baseline distortions may also result from corrupted data points at the beginning of the acquisition period. These can be corrected by reconstruction of the initial points by a backward linear prediction. A receiver gain that is too high compared with the dynamic range of the analog-digital converter (ADC) will result in signals with ‘‘wiggles.’’ In addition, a finite rise time of audio filters may cause a baseline roll.

In modern spectrometers, this is circumvented by oversampling, that is, by using a sampling signal with the maximal frequency of the ADC and reconstructing the signal mathematically afterwards for processing.

28.3.2
Correlation Experiments

The principle purpose of correlation experiments is to establish a one-to-one mapping from the signal to its source, that is, to the particular atomic nucleus in the molecule. This assignment task involves identification of the members in the coupling network, referred to as the *spin system*. In addition, correlation experiments as such or with modifications are suitable for measurements of scalar and dipolar couplings.

Correlation in the two dimensions is the most natural dimensionality because the spin–spin interactions are pairwise. Three-dimensional or experiments of higher dimensionality are constructed from concatenated two-dimensional (2D) experiments. Homonuclear three-dimensional experiments, such as TOCSY-NOESY (total correlation spectroscopy-nuclear Overhauser enhancement spectroscopy), are not considered here because in many cases the multidimensional heteronuclear experiments are superior.

For all homonuclear experiments, there are certain common guidelines to follow. When preparing a correlation experiment, it is the expected lineshapes and widths that determine the lengths of acquisition and indirect dimension and the processing. Narrow in-phase lines allow considerable degree of freedom for the setup of experiments, whereas broad antiphase lines are the most difficult. The repetition rate of the acquisition for signal averaging should be adjusted properly to reach optimal SNR or to obtain quantitative spectra.

28.3.2.1 **COSY-Type Experiments**

Correlated spectroscopy (COSY) is the first 2D NMR experiment realized [56, 57] and it is still among the most useful NMR experiments. COSY generates cross peaks in the 2D spectrum at the intersection of resonances of coupled spins (Figure 28.3). In proteins, cross peaks are observed for geminal protons, that is, over two bonds, and vicinal protons, that is, over three bonds, and in small peptides, couplings over four bonds may also be detected. Thus, the COSY spectrum allows the identification of spin systems for the assignment.

However, apart from peptides, the overlap and degeneracy in chemical shifts is likely to prevent obtaining entire spin systems exclusively from the COSY spectrum, for which additional experiments are required.

The COSY spectrum also provides information about the coupling constants in the fine structures of cross peaks. The value of the three-bond scalar coupling is related to the torsion angle via the Karplus equation [58] and knowledge of the couplings together with NOEs provides stereospecific assignment. The coupling can be determined from the frequency separation of the antiphase absorptive doublet. For two-coupled spins, that is, without a passive coupling partner such

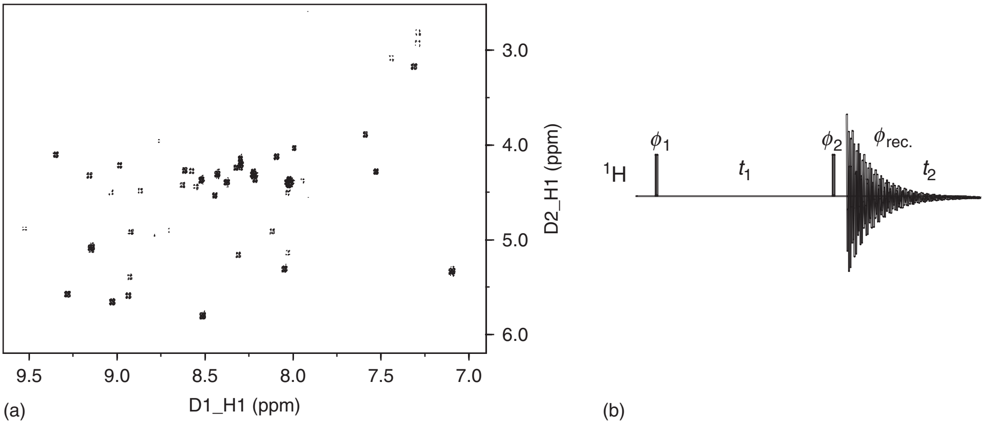

Figure 28.3 (a,b) COSY spectrum of a 1 mM SH3 sample in H_2O/D_2O (90/10 v/v).

as the ^3JHNHα of residues other than glycines (that have two Hα) the lobes of the cross peak are separated along the directly observed direction by the coupling constant. However, if the linewidth increase is comparable to the coupling constant or even larger, the positive and negative lobes of the antiphase line began to cancel each other more and more, thereby increasing the apparent separation of the multiplet components. This aberration from the true coupling value has to be taken into account when measuring coupling constants. Analyses of the antiphase lines for extracting the true separation of the multiplet components require that the spectrum to be processed to maintain Lorentzian lineshapes. In practice, when the linewidth is twice as large as the coupling constant or more, it is difficult to obtain accurate values. Therefore, scalar coupling constants are preferably measured by heteronuclear experiments. Owing to the self-cancellation of the broad antiphase lines, the sensitivity of the experiment also decreases with increasing molecular weight. COSY is, otherwise, among the most sensitive experiments for peptides and small proteins.

The COSY pulse sequence is very simple, consisting of the recycle delay, the first 90° pulse succeeded by the incremental delay t_1, and the other 90° pulse followed by the acquisition period t_2 (Figure 28.3). The phases of the pulses and the receiver are cycled according to CYCLOPS and axial peaks are suppressed by inverting the phases of the first pulse and receiver. The residual axial peaks are moved to the edges of the spectrum by the States-TPPI protocol. A product operator analysis shows that the cross peak has an antiphase lineshape and that the diagonal peak differs by 90° and thus cannot be phased simultaneously for absorption. The nature of the antiphase lines requires that the data in the indirect dimension t_1 are collected for a sufficiently long time, at least longer than $1/(4J)$, otherwise the signal intensity is reduced because of self-cancellation of the antiphase lines. For the measurement of couplings, the acquisition dimension t_2 can well be longer than $1/(2J)$ as the recycle delay can be shortened correspondingly. The COSY spectra are customarily processed for resolution using sine bell weight functions.

The analysis of coupling constants requires that the F_2 slices have been adequately zero filled, for example, to about 0.5 Hz per point.

There are a number of variant COSY experiments and extensions to COSY. One of the main goals of the descendants has been to remove the dispersive tails of the diagonal peaks that may obscure the near-diagonal cross peaks. The double-quantum filtered (2QF) COSY experiment [59] also yields a spectrum with absorptive antiphase lines for the diagonal peaks of the coupled spins and the attenuated diagonal resonance of the uncoupled spins. The drawback of 2QF-COSY over COSY is the twofold decrease in sensitivity. In addition, the total acquisition time for a concentrated sample may become long because of the longer phase cycle. The PCOSY experiment is designed for the same purpose as 2QF-COSY, but offers greater sensitivity.

E-COSY is an abbreviation for methods to generate coupling patterns exclusively with the active components. The fine structure of the E-COSY cross peak is a superposition of two-quantum (2Q) and three-quantum (3Q) COSY peaks so that the two components that stem from the passive couplings cancel each other to leave a simplified coupling pattern. The active coupling can be measured directly from the antiphase separation on either of the multiplets as usual and the passive couplings can be measured from the displacements of the two antiphase multiplets. Importantly, the method will not be subject to the errors as a result of finite linewidths. Furthermore, the E-COSY experiment serves to determine the relative sign of the passive couplings. The same principle is used in heteronuclear experiments. The pre-TOCSY COSY experiment aims to recover resonances attenuated by the solvent presaturation. The mixing sequence before the first 90° pulse serves to transfer the magnetization to Hα that are near the irradiated water line.

Relayed COSY [60] is a straightforward extension to COSY. An additional coherence transfer delay is inserted in the pulse sequence before the acquisition period with the purpose of relaying coherence from the second spin further to a third spin. This will result in a spectrum with a cross peak between the first and the third spin even if they are not directly coupled, but only via the second spin. The chemical shifts are monitored before, that is, t_1, and after, that is, t_2, the coherence transfer steps. The mixing time for the second coherence transfer depends, of course, on the couplings; for proteins, the delay from 20 to 40 ms usually makes a good compromise between transfer efficiency and relaxation losses. There is no new information compared to COSY, however, in the case of degenerate shifts; R-COSY provides means to assess if the spins belong to the same spin system. The acquisition and processing of R-COSY is similar to that of COSY.

28.3.2.2 **Multiple-Quantum Spectroscopy**

Multiple-quantum (MQ) spectroscopies offer complementary information to COSY to elucidate scalar coupling networks [61]. The multiple-quantum transitions are observed indirectly during t_1. A 2Q experiment is commonly used to circumvent problems in COSY due to diagonal peaks, self-cancellation of signals, and solvent suppression.

The idea is to generate the 2Q coherence that evolves with the frequency sum of the chemical shifts $\Omega_1 + \Omega_2$ of two coupled spins I_1 and I_2. The active coupling J_{12} will not evolve during t_1. During the acquisition, cross peaks appear along F_2 at frequencies of Ω_1 and Ω_2 with the absorptive antiphase splittings corresponding to J_{12} and along F_1 at a frequency of $\Omega_1 + \Omega_2$ with absorptive in-phase lineshape along with a dispersive antiphase component that add constructively. These cross peaks are referred to as *direct peaks*. In addition, three-spin coherences that originate from the J_{12} and J_{13} couplings and from the J_{13} and J_{23} couplings become observable and result in cross peaks along F_2 at frequencies of Ω_3 and along F_1 at frequencies of $\Omega_1 + \Omega_2$. These cross peaks with double antiphase dispersive nature along F_2 and with dispersive antiphase and absorptive in-phase components along F_1 are referred to as *remote peaks*. In general, the direct and remote peaks can be distinguished from each other by the opposite lineshape along F_2. Considering the lineshapes, the acquisition and processing parameters along t_2 are similar to those used in COSY, whereas along the indirect dimension t_1 it is not necessary to collect data extensively and cosine apodization is appropriate.

28.3.2.3 **Total Correlation Spectroscopy**

TOCSY, also known as the homonuclear Hartmann–Hahn (HOHAHA) experiment, provides all relayed connectivities within a spin system [62, 63]. The primary intention in TOCSY as in other relayed experiments is to establish connectivities in less-crowded spectral regions to facilitate the assignment of spin systems.

The key idea in TOCSY is to transfer in-phase magnetization from spin to spin throughout the spin system by an isotropic mixing sequence rather than to rely on transferring antiphase coherence during free precession periods. During the mixing sequence, the system is governed by the strong coupling Hamiltonian. The intensity of a cross peak will depend on the topology of the spin system, that is, the ways spins are coupled, the various coupling constants, and properties of the mixing sequence. There are several mixing sequences. The DIPSI-2 sequence [64] is better than WALTZ-16 or MLEV-17 when relaxation is neglected. The actual performance of a mixing sequence over the others depends on the implementation and accuracy of calibrations.

Dipolar couplings during the mixing period may give rise to the rotating-frame Overhauser effect (ROE). Attenuation of the in-phase TOCSY peaks due to the ROE peaks of opposite sign can be particularly important for larger proteins, but can be largely eliminated by interrupting the mixing train so that laboratory-frame NOEs with opposite sign to ROEs can develop to cancel each other. These sequences are referred to as *clean TOCSY*. Furthermore, adiabatic mixing sequences (WURST-8) [65] have low sensitivity to RF field inhomogeneity and miscalibration of the field strength. The sensitivity-enhanced TOCSY pulse sequence retains two orthogonal components of magnetization for postacquisition reconstruction of the spectrum to achieve a gain of $\sqrt{2}$ in SNR (Figure 28.4).

The evolution during the indirect dimension and acquisition are not constrained by the scalar couplings because the peaks in TOCSY are mostly in-phase and only resolution should be considered both when setting the acquisition and indirect

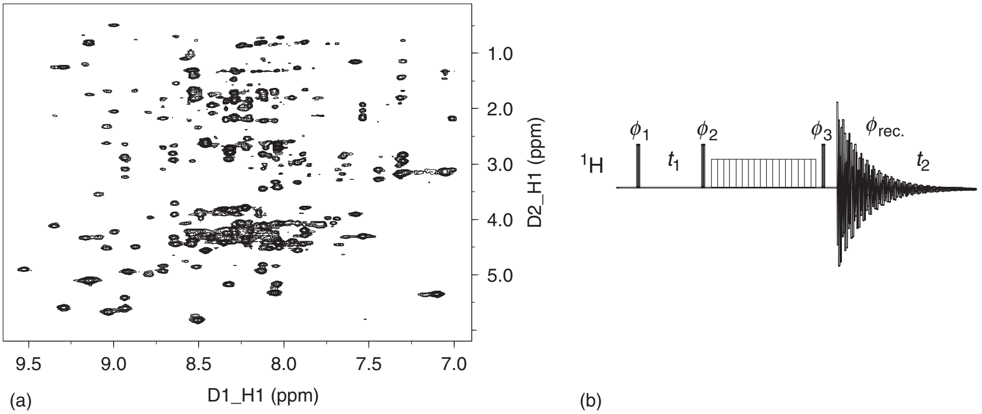

Figure 28.4 (a,b) TOCSY spectrum of a 1 mM SH3 sample in H_2O/D_2O (90/10 v/v).

dimensions and weight functions in processing. It is seldom worthwhile to collect t_1 longer than $1.5 \times T_2$, where T_2 is the transverse relaxation time. The length of the isotropic mixing sequence is subject to two opposing conditions. On one hand, a long mixing sequence is preferred to obtain a correlation between the spins at the opposite ends of the network and, on the other hand, all correlations are preferably observed. These constraints are difficult to meet simultaneously and therefore usually two or more TOCSY spectra with mixing times from 30 to 120 ms depending on the relaxation are collected. The interpretation of TOCSY is subject primarily to two concerns. As the experiment provides correlations along the network of spins, it may remain uncertain which nucleus in the spin system gives rise to which signal, in particular, when chemical shifts are not unambiguous. The other concern is that cross peaks may not always be observed because of the intensity variation of the signal as a function of the mixing time.

Furthermore, if TOCSY is used to estimate coupling constants it must be kept in mind that the signal intensity depends on *all* couplings in the spin system. Short mixing times transfer mostly via a single scalar coupling and are more reliable for coupling constant measurements.

28.3.3
Cross-Relaxation Experiments

The elucidation of the scalar coupling network by the correlation experiments is, apart from small molecules, not enough for the unambiguous, sequential, and stereospecific assignment. The complementary information of spatially adjacent protons is obtained via cross-relaxation experiments, the laboratory-frame NOESY, and the rotating-frame nuclear Overhauser effect spectroscopy (ROESY). These experiments also provide the distance restraints for the structure determination and help to recognize exchange processes.

28.3.3.1 Nuclear Overhauser Enhancement Spectroscopy

The NOESY experiment is composed of the frequency-labeling part, that is, t_1 flanked by two 90° pulses, ensued by the magnetization transfer via dipolar couplings during the mixing period τ_m before the read pulse for the acquisition t_2 (Figure 28.5). During the mixing period, relaxation processes govern the longitudinal magnetization. The autorelaxation results in the diagonal peak and the cross-relaxation results in the cross peaks in the NOESY spectrum. Both peaks are absorptive in-phase in both dimensions. The phase cycling will remove coherences higher than zero.

Consequently, in addition to the longitudinal magnetization, the cross peak may have an undesirable zero-quantum contribution. The zero-quantum peak is antiphase in both dimensions just as a COSY peak, but dispersive with respect to the NOE peaks. The intensity of the zero-quantum peak depends on the chemical shift difference of the spins in question and the mixing time. Furthermore, the transverse zero-quantum term relaxes during the mixing period faster than the desirable longitudinal magnetization.

Therefore, the zero-quantum artifacts are usually observed when the mixing time is short, but can further be suppressed by varying the length of the mixing time, a procedure known as *z-filtration*. However, for short mixing times it may be difficult to vary the mixing time enough without introducing problems in the interpretation due to the averaging.

When setting the NOESY experiment, it is worthwhile to make sure that the baseline is flat and the total measuring time will yield adequate SNR. The recycle delay should be $3 \times T_1$, where T_1 is the longitudinal relaxation time, otherwise the intensity of the cross peaks can be affected by the steady-state conditions. The length of the mixing time is subject to contradictory demands. A long mixing time, on the order of T_1, will give high intensities for the cross peaks and have small zero-quantum artifacts. On the other hand, multiple magnetization transfers, referred to as *spin diffusion*, will affect the intensity and obscure the interpretation.

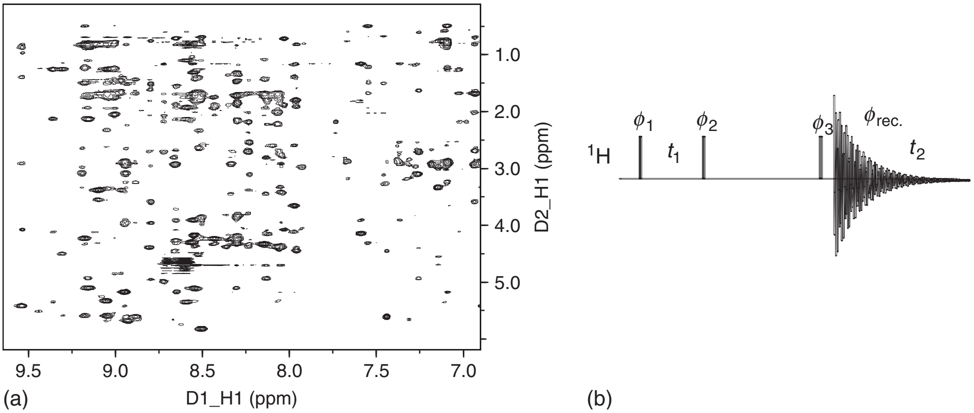

Figure 28.5 (a,b) NOESY spectrum of a 1 mM SH3 sample in H_2O/D_2O (90/10 v/v).

Therefore, a compromise depending on the size of the protein has to be made or a series of NOE spectra is to be collected for more precise calibration of intensities to distances. For large proteins, the dipolar relaxation is effective and short mixing times are appropriate, whereas for small proteins or peptides longer mixing times are required. Furthermore, the cross-relaxation rate constant depends on the rotational correlation time and changes its sign at short correlation times, thereby making the observation of NOEs for small molecules difficult unless there is a freedom to change temperature so as to affect the rotational correlation time. For proper integration of the cross peaks during processing, window functions for the resolution enhancement are to be applied with a caution because signals differing in their linewidths will then not retain relative intensities.

Otherwise, the in-phase absorptive peaks allow considerable freedom for choosing lengths of acquisition and indirect dimensions and their apodization. Chemical exchange, not too slow compared with the mixing time, can result in cross peaks in the NOESY spectrum. The chemical exchange peaks are hard to distinguish from the NOE peaks, but they have a different sign from the ROE peaks. Furthermore, coupled exchange and spin diffusion can result in complicated spectra.

28.3.3.2 **Rotating-Frame Nuclear Overhauser Effect Spectroscopy**

The ROESY experiment [66, 67] follows the cross relaxation in the rotating frame that is established by locking the spins with a train of rf pulses. During the spin lock any components of magnetization orthogonal to the rf field are dephased by the inhomogeneity of the rf field. The longitudinal magnetization is governed by rotating-frame relaxation rates. The rotating-frame cross-relaxation rate constant is positive for all correlation times, which makes ROESY particularly, suitable for studies of small peptides. The ROESY cross peaks depend, in addition, on the resonance offset from the carrier. The offset dependence appears as phase error along F_1 and F_2, which can be removed during processing. However, the intensity of cross peaks for the off-resonance spins will have an opposing NOE contribution in addition to that by ROE. The offset dependence has to be taken into account in quantitative analysis of the cross-peak intensities. The ROE mixing time is usually kept shorter than the corresponding NOE mixing time because the ROE buildup is twice as fast as the NOE buildup. The in-phase absorptive cross peaks and diagonal peaks, but of opposing sign to each other, allow considerable freedom in setting the parameters for the acquisition and indirectly detected dimensions and their processing.

The ROE experiment is potentially subject to artifacts rising from isotropic mixing. The TOCSY transfer will reduce the intensity of the ROE cross peak and obscure the quantification. In particular, consequent TOCSY and ROE transfers have the same sign as the authentic ROE peaks and may easily be misinterpreted. Therefore, as long as the long spinlock is not sufficiently strong to match the Hartmann–Hahn condition, there is need to watch only for artifacts for those spins that have closely similar chemical shifts or shifts that are placed on opposite sides with respect to the carrier. Eventual artifact-related problems can be noticed by taking spectra with different carrier positions and varying the strength of the spinlock.

Contrary to the NOE experiment, the cross peaks of the ROE experiment are of opposite sign with respect to the chemical exchange peaks. This is a particularly valuable property in studies of complex formation where peaks rise both from cross relaxation and chemical exchange. Furthermore, the assignment of stereospecific restraints to the methylene protons that are often subject to spin diffusion can be facilitated by the ROESY measurement. The ROE cross peaks that stem from the relayed transfer have opposite sign with respect to the direct transfer and thus the methylene ROE signals do not tend to have equal values.

28.3.4
Heteronuclear NMR Experiments

Heteronuclear NMR experiments have many virtues over the homonuclear ^{1}H experiments when labeled samples are available for the measurements. It is for the high-molecular-weight proteins and protein complexes that the heteronuclear experiments are imperative. Compared with homonuclear experiments, heteronuclear methods provide improved resolution via increased dimensionality, editing and filtering possibilities, and various ways for coherence transfer and measurement of scalar and dipolar couplings to increase the information content. It is in the nature of amino acids in folded proteins to contain distinguishable nuclei that are coupled to each other with various strengths of couplings that lays the foundation for the rich repertoire of heteronuclear experiments. Furthermore, relaxation measurements of ^{15}N and also ^{13}C are much more amenable to interpretation than those of protons. Today, heteronuclear experiments are indispensable for biomolecular NMR spectroscopy.

28.3.4.1 Basic Heteronuclear Correlation Experiments

Many heteronuclear multidimensional correlation experiments appear superficially complicated, but actually comprise simple building blocks for coherence transfer and for recording chemical shift and/or coupling evolution. These basic elements are simple and robust. The usual protocol begins by transferring proton magnetization to the heteronucleus, that is, ^{15}N or ^{13}C, which is subject to further actions, and finally the coherence is returned to the proton for detection. This indirect detection scheme is superior in sensitivity over direct methods because of the proton's large gyromagnetic ratio and favorable relaxation properties. The most frequently used experiments are the heteronuclear multiple-quantum coherence (HMQC) [68, 69] and heteronuclear single-quantum coherence (HSQC) experiments [70] More recently, it was discovered that significant gains in SNR for large proteins at high magnetic fields is obtained by selecting particular multiple components for the detection to result in TROSY [13]. Polarization transfer in high-molecular-weight systems has been further improved by designing novel pulse-sequence elements such as CRIPT and CRINEPT, which utilize elevated cross-correlation rates for magnetization transfer [71].

28.3.4.1.1 **Heteronuclear Multiple-Quantum Coherence** The HMQC experiment begins with a coherence transfer from a proton to the heteronucleus during a delay matched to $2\tau = 1/(2J)$, $J\mathrm{HN} = 94$ Hz, and $J\mathrm{HC}\alpha = 140$ Hz, to result in a MQ coherence that evolves during t_1. The heteronuclear coupling is not active under MQ coherence during t_1, but the ^{1}H chemical shift evolution must be refocused by a 180° proton pulse. The MQ coherence is transferred to the proton for detection. Before the acquisition, antiphase dispersive components can be purged by a 90° proton pulse. During the acquisition t_2, heteronuclear decoupling is employed. Homonuclear scalar couplings during the coherence transfer periods will cause a phase error along F_1. The size of the error is fairly small, but it depends on the size of the coupling and cannot be simply compensated. The HMQC experiment is very simple with only few pulses and it is therefore a favored building block in more complicated experiments.

28.3.4.1.2 **Heteronuclear Single-Quantum Coherence** The HSQC experiment (Figure 28.6) is based on the INEPT (insensitive nuclei enhanced by polarization transfer) sequence [72], which converts proton magnetization to the antiphase single-quantum (SQ) coherence that evolves during t_1. The scalar coupling evolution is refocused by a 180° proton pulse or decoupled. Homonuclear scalar couplings do not contribute to the lineshape along F_1. The reverse transfer from the heteronucleus to the proton is analogous. Homonuclear scalar couplings during the coherence transfer periods will affect the amplitude of the peak and cause an antiphase dispersive contribution along F_1, which can be purged by a 90° proton pulse just before the acquisition. During the acquisition t_2, the heteronucleus is decoupled.

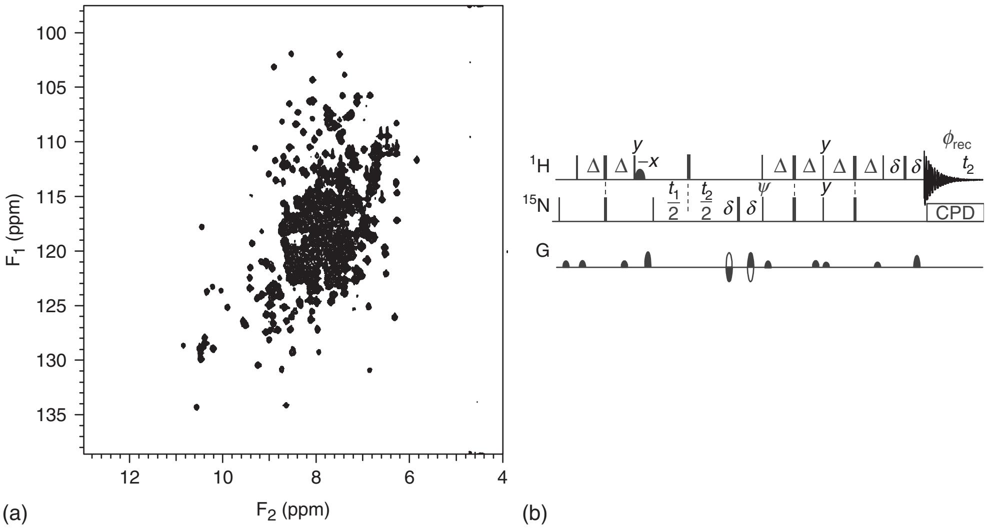

Figure 28.6 (a,b) ^{1}H–^{15}N HSQC spectrum of a 1 mM maltose-binding protein in complex with beta-cyclodextrin in H_2O/D_2O (93/7 v/v).

The decoupled HSQC experiment employs the refocused INEPT sequence to generate an in-phase SQ coherence that is desirable, for example, for measurements of heteronuclear relaxation rates. The transfer function of the refocused INEPT depends on the proton multiplicity, that is, the number of protons bound to the heteronucleus. This can be used to edit the spectrum or when an overall maximal transfer efficiency is required, $2\tau = 1/(3J)$ makes a good compromise. The constant time (CT) HSQC has an evolution period $t_1 = \mathrm{CT}$ fixed in length. This brings in two advantages. The homonuclear couplings do not modulate the signal during t_1 and consequently there is no homonuclear multiplet structure along F_1. This is particularly useful for fully ^{13}C-enriched samples to remove the ^{13}C–^{13}C couplings of aliphatic carbons that cannot be selectively decoupled. The other advantage is the narrow lines. The linewidth along the indirect dimension does not depend on the transverse relaxation rate, but is mainly determined by the window function used for processing. The transverse relaxation rate appears as only a constant factor that scales the intensity. The optimum trade-off between intensity and resolution depends on each particular case. Another favorable feature of the experiment is that when the CT delay is set to $1/(J_{\mathrm{CC}})$, the sign of the emerging signal depends on the number of adjacent carbons owing to the $\cos^n(\pi J_{\mathrm{CC}}\mathrm{CT})$ modulation ($n =$ number of carbons). Therefore, carbons that have an odd number of directly bound aliphatic carbons are in opposite phase with respect to the carbons having an even number of adjacent carbons. The CT scheme can also be implemented into a number of sophisticated triple-resonance experiments to facilitate the protein side-chain assignment procedure.

28.3.4.1.3 **Transverse Relaxation-Optimized Spectroscopy** At high-magnetic field strengths the CSA interaction of ^{15}N is a comparable source of relaxation as the dipole–dipole (DD) interaction. The same is true for the amide proton CSA and DD. Therefore, the four multiplet components of the amide spin pair have different relaxation rates depending on whether the DD and CSA mechanism interfere constructively or destructively. When other sources of relaxation such as those due to remote protons are negligible, the differential relaxation effect on the multiplet components is large and also in practice attainable at high magnetic fields for large perdeuterated proteins. It is the most slowly relaxing multiplet component that is of a particular interest and it is possible to filter away the other multiplet components for spectral simplification. This is the essence of the TROSY [13]. The resulting spectrum is superior to an HSQC experiment under the aforementioned conditions. The pulse sequence resembles superficially that of the sensitivity-enhanced HSQC. Obviously, neither proton during t_1 nor ^{15}N during the acquisition t_2 should be decoupled to maintain the multiplet components. It is the latter part of the pulse sequence used for the reverse transfer from ^{15}N to ^{1}H including the gradient selection that chooses the most slowly relaxing multiplet component for detection (Figure 28.7).

The intensity of TROSY component can be further boosted by sensitivity enhancement and more importantly by taking advantage of the ^{15}N steady-state

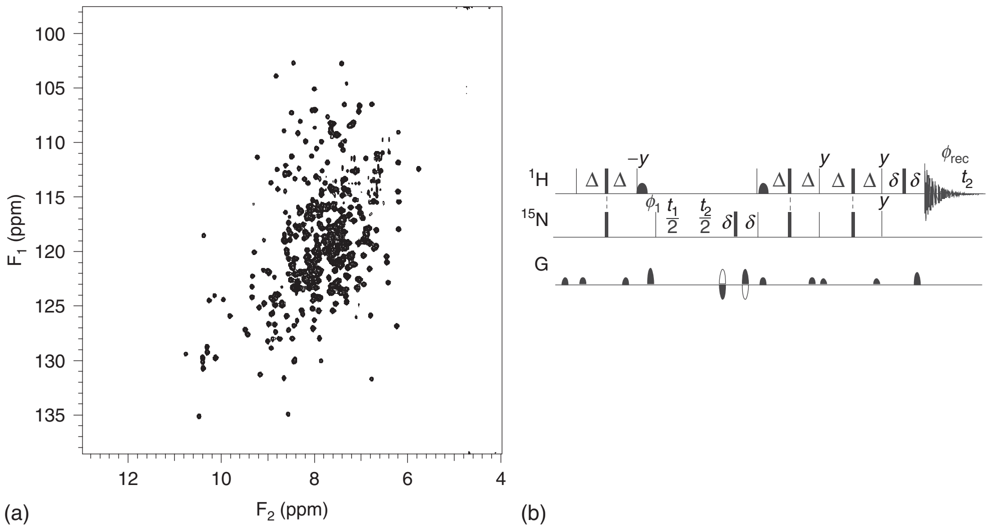

Figure 28.7 (a,b) ^{1}H–^{15}N TROSY spectrum of a 1 mM maltose-binding protein in complex with beta-cyclodextrin in H_2O/D_2O (93/7 v/v).

magnetization [73]. The TROSY principle has been implemented in many heteronuclear correlation experiments such as those used for the main-chain assignment and measurement of scalar and dipolar couplings that exploit coherence transfer between the amide nuclei before the acquisition. The TROSY principle works also for the CH pairs in aromatic rings and side-chain NH_2 groups [74]. TROSY has significantly increased the molecular size limit of proteins and their complexes feasible to NMR studies [75, 76].

Transverse Relaxation Optimized Polarization Transfer Polarization transfer in HSQC and TROSY experiments is based on the aforementioned INEPT sequence. INEPT utilizes scalar spin–spin couplings in order to create antiphase coherence between proton and nitrogen. Although the transfer based on INEPT is highly sensitive in small proteins, it rapidly becomes inefficient with increasing molecular weight. Another polarization transfer scheme, CRIPT [71] utilizes transverse relaxation optimization during the polarization transfer step by omitting the 180° pulse on nitrogen in the middle of the transfer delay. Thus, fast and slow relaxing spin states are not interchanged during the transfer period resulting in suppression of the fast relaxing doublet component, while the slowly relaxing component sustains. There are few characteristic features in CRIPT that differ from the INEPT-based transfer. Polarization transfer is obtained solely through cross-correlated relaxation DD and CSA interactions. In addition, only 50% of the available ^{1}H polarization can be transferred to heteronucleus, albeit the transfer efficiency does not depend on rotational correlation time of the molecule (τ_c). The optimal transfer time, however, depends on molecule's τ_c owing to the decay of the fast relaxing doublet component. Sensitivity of the CRIPT transfer has been improved (20–30%) by a sophisticated TROPIC sequence developed using the optimal control theory [77].

Another transverse relaxation-optimized polarization transfer scheme is CRINEPT [71]. It takes a full benefit from cross-correlated relaxation based transfer, but also maintains scalar-coupling-mediated transfer. This results in a significant improvement in polarization transfer efficiency. However, as no refocusing ^{1}H pulse is applied during the CRINEPT step, there is an inherent loss of sensitivity owing to ^{1}H chemical shift modulation during the CRINEPT transfer.

Interestingly, the TROSY or polarization transfer is not limited to the ^{1}H–^{15}N spin pair. The TROSY principle can be utilized in ^{1}H–^{13}C methyl correlation experiments as well [78]. Half of the originating proton magnetization relaxes slowly in both ^{13}C and ^{1}H domains during the methyl-TROSY experiment, which is essentially a methyl-HMQC pulse scheme. The pulse sequence selects a central line of the MQ methyl triplet during t_1 and transfers it to the slowly relaxing proton coherence for acquisition. In this way, dramatic sensitivity improvement of methyl correlations in very large proteins and complexes has been obtained. The isotopic-labeling scheme, where methyl groups of structurally and biologically important residues, that is, Leu, Val, and Ile (δ_1 only) are selectively protonated in otherwise perdeuterated proteins, plays a crucial role in the success of the methyl-TROSY experiment. It ensures that dipolar relaxation pathways from external protons are minimized, enabling cancellation of intramethyl ^{1}H–^{1}H and ^{1}H–^{13}C dipolar interactions. Methyl TROSY has been especially valuable in studies of high-molecular-weight systems including the 670 kDa 20S proteasome [79].

Application of Heteronuclear NMR Experiments for Studying Protein Dynamics One of the most fascinating attributes of solution-state NMR spectroscopy is its unique sensitivity toward molecular dynamics. In comparison to many other spectroscopic methods, NMR provides simultaneously a very broad range of timescales ranging from picoseconds to seconds (up to hours in H/D exchange experiments) and nearly atomic resolution, enabling site-specific characterization of macromolecular dynamics. Motions of proteins take place in various timescales, most of which can be studied by NMR spectroscopy through use of various relaxation probes or parameters. Fast internal motions, that is, interaction of surface atoms with water, side-chain rotations, or Brownian tumbling of small proteins, take place in the picosecond–to-nanosecond timescale, which can be readily probed by T_1, T_2, and heteronuclear ^{15}N NOE experiments [80]. These are in the essence ^{15}N-HSQC or ^{15}N-TROSY experiments, which include an implemented period for probing, for example, T_2 relaxation within the ^{15}N-HSQC experiment.

Local unfolding and catalysis-related motions in enzymatic reactions or conformational exchange, in general, take place in the microsecond-to-millisecond timescale, which can be characterized through analysis of $T_{1\rho}$ and T_2 relaxation times. These can be readily probed by Carr–Purcell–Meiboom–Gill (CPMG) relaxation dispersion methodology [81]. Relaxation dispersion NMR spectroscopy enables full characterization of both kinetics and thermodynamics of the exchange process [82]. It is even possible to determine the structures of very low populated excited states, which are invisible in traditional NMR spectra but can be accessed by using relaxation dispersion spectroscopy [83]. Kinetic molecular processes taking place in slow or very slow (millisecond-to-subsecond) timescales, for example, protein folding and proton–deuterium exchange, can be studied with exchange spectroscopy or real-time NMR spectroscopy. Real-time NMR spectroscopy has been plagued by inherently slow data collection in indirectly detected dimensions, which makes application of 2D NMR techniques for studying protein kinetics in the second timescale impossible. Fortunately, a novel SOFAST-HMQC technique opens the avenue for kinetic studies in the second timescale [84]. There is a gap between the sub-nanosecond and microsecond timescales, which is not accessible by T_1, $T_{2,}$ and heteronuclear NOEs or CPMG methodology. RDCs are sensitive to motions taking place in the picosecond-to-millisecond timescales, which ideally bridges the gap between the supra-nanosecond and microsecond timescales, facilitating studies of secondary structure fluctuations and domain movements occurring in the microsecond-to-millisecond timescale. This renders RDCs very suitable for their characterization.

28.3.4.2 Edited and Filtered Experiments

The basic heteronuclear experiments are easy to combine with the two-dimensional homonuclear experiments to produce three- or four-dimensional edited spectra. In this terminology, editing means selection of the protons that are attached to the heteronucleus. The main purpose of these experiments is to reduce the signal overlap of the homonuclear two-dimensional experiments.

Combinations of NOESY with HSQC (or HMQC) and TOCSY with HSQC are among the most useful edited three-dimensional experiments [85, 86]. For example, the NOESY-HSQC (Figure 28.8) begins by the NOESY sequence and is followed directly by the HSQC sequence. It is important to acquire enough data points (typically 128 and 2048) along the proton dimensions (t_1) and (t_3), whereas

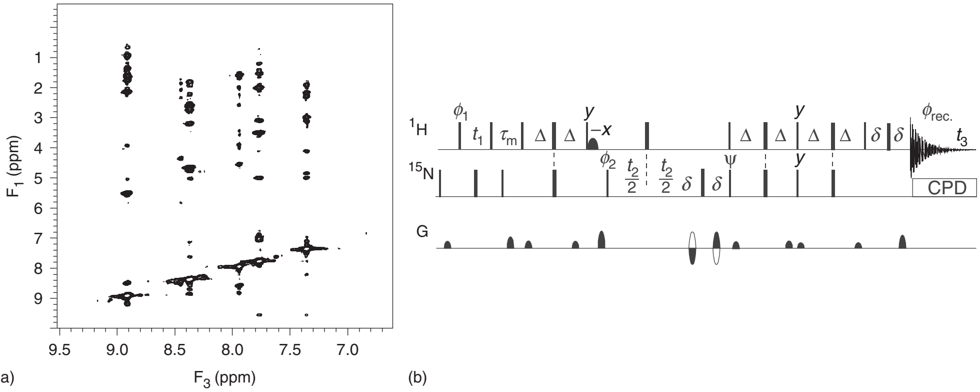

Figure 28.8 (a,b) Plane ^1H–^1H of ^1H–^{15}N-NOESY-HSQC spectrum of a 1 mM SH3 sample in H_2O/D_2O (90/10 v/v).

fewer increments (typically 32) along the ^{15}N editing dimension (t_2) will suffice. The F_1-F_3 plane at each F_2 displays the homonuclear correlations just as in the two-dimensional spectrum, but edited with respect to the heteronucleus. It will take about one day to acquire a spectrum with good SNR.

Clearly, the homonuclear and the heteronuclear experiments could be combined in the reverse order, that is, HSQC-NOESY and HSQC-TOCSY. The main advantage in these schemes relates to ^{15}N-edited experiments in which the narrower amide proton spectral width is sampled during t_1 and the full proton spectral width is collected during t_3. On the other hand, water suppression is more effective when HSQC follows NOESY. In addition, the sensitivity enhancement can be incorporated to the NOESY-HSQC experiment. For the TOCSY-HSQC or HSQC-TOCSY, this does not matter because both the TOCSY and HSQC sequences can be implemented with sensitivity enhancement. It should be mentioned that the TOCSY type of transfers is more effective between ^{13}C nuclei than between protons and therefore HCCH-TOCSY experiment is preferred when a doubly labeled sample is available.

Even if the heteronuclear editing provides a big advantage over the 2D homonuclear experiments, this is not enough when two protons with a mutual correlation have degenerate chemical shifts. This can be of importance, in particular, in NOESY that contains a large number of cross peaks. The 4D HMQC-NOESY-HMQC experiment provides editing in two dimensions to alleviate the overlap problem. The NOESY part is flanked by two HMQC sequences. Obviously, the two HMQC parts can be chosen to edit with respect to the same or different heteronucleus, that is, ^{15}N or ^{13}C. The total acquisition times tend to be long, taking several days to achieve sufficient resolution along the indirect dimensions. This can be alleviated by employing nonlinear sampling to indirectly detected dimensions (Section 28.3.5.3).

For studies of intermolecular interactions, filtered experiments are valuable. The essence of filtered experiments is to distinguish protons on the basis of the heteronucleus to which it is bound. In the terminology, filtering means rejection of the protons that are bound to the heteronucleus. Therefore, provided that the heteronuclei in the subunits that make the quaternary complex are labeled differently, that is, either the target protein or the ligand is labeled, it is possible to employ filtering experiments to distinguish, for example, intermolecular proton NOEs from intramolecular NOEs. While for the heteronuclear-edited experiments, it is sufficient to have only modest degree of labeling, it is mandatory for the filtered experiments to have very high degree of labeling, that is, >98%. The most robust filters are of the double spin echo type.

However, it should be kept in mind that none of the filter sequence will work properly, if the labeling degree is not close to 100%. Leakage of signal may lead to misinterpretation.

28.3.4.3 **Triple-Resonance Experiments**

The assignment of signals is, of course, a prerequisite for any detailed interpretation of NMR spectra. The advent of triple-resonance experiments [87] for double-labeled and, more recently, for perdeuterated proteins, has been very important to work out the assignment problem. The fundamental principle of all triple-resonance experiments is a directional relay of the magnetization from nucleus to nucleus via the scalar coupling network concurrent with a multidimensional detection of the resonance frequencies. In this way, it is possible to correlate several nuclei with enough dispersion to avoid degeneracy even for large proteins. Today, many of the triple-resonance experiments are well established (e.g., Refs. [1, 5, 88, 89]). The principles of how to use them are described later, whereas a more thorough discussion can be found in the reviews. In addition, the triple-resonance experiments are the skeletons for experiments designed to measure scalar and dipolar couplings.

The assignment of resonances to the chemical structure commences from the main-chain atoms HN, N, CA, CO, and CB. The experiments, that is, the pulse sequences for this purpose appear superficially complex, but are in fact built from concatenated parts of heteronuclear polarization transfers. The magnetization is often derived from the amide proton and also from the amide nitrogen when using TROSY. Subsequently, the polarization is relayed to amide nitrogen and further to carbons. Three-dimensional spectra are produced by acquiring frequencies of the amide proton directly and recording indirectly the frequencies of amide nitrogen and either aliphatic carbon or carbonyl carbon (or both, in four-dimensional experiments).

It is the coupling network that dictates the possibilities to select correlations to be observed. The key idea is to produce a mutually complementary pair of spectra, for example, HNCA and HN(CO)CA. The former displays both intra- and interresidue correlations and the latter exclusively the intercorrelations. Alternatively, an exclusive intraresidue HNCA can be recorded [90, 91] The pair of spectra, displaying both intra- and intercarbon resonances for each amide nuclei resonance, allow one to trace the polypeptide backbone from one residue to another. The sequential walk is interrupted at prolines and, at times, potentially due to exchange broadening.

The other commonly used pair of experiments also involves resonances of CB, that is, HNCACB and HN(CO)CACB. Of course, these experiments are less sensitive as the total intensity is divided among CA and CB, but extension of magnetization transfer to CBs facilitates the sequential assignment significantly. Besides that, signal dispersion of beta carbons is superior to that of CAs. The CB resonances carry vital information on residue type, which can be utilized for establishing certain anchor points during the assignment. Particularly, alanine, serine, and threonine residues have very distinctive CB chemical shifts. These residues and their respective linear combinations in the sequence, together with glycine that does not have a CB, form robust templates for the sequential assignment.

The third pair of experiments is the HNCO and HN(CA)CO. The principle is the same as that mentioned earlier, but now the carbonyl carbon frequencies are used instead of CAs or CBs. The former experiment, which correlates amide proton and nitrogen with carbonyl carbon of the preceding residue, is the most sensitive triple-resonance experiment, whereas the latter is among the least sensitive, making this pair unbalanced. Certain modifications to the latter experiment improve the performance, however, at the cost of nonuniform performance for the various amino acid residues.

Today, there are many variants of the basic sequences. The most important modifications are the transverse relaxation-optimized experiments suitable for perdeuterated proteins, the sensitivity-enhanced versions, and the CT implementations for improved resolution. Furthermore, there are many experiments based on the basic sequences designed to measure scalar dipolar couplings and RDCs, often also implemented with spin-state selection as exemplified in Figure 28.9.

The assignment of side-chain resonances is a more laborious undertaking. The proton-detected versions of the aforementioned experiments such as HN(CACB)HAHB and HBHA(CO)NH reveal the protons at the stem of the side chain.

Assignment of the protein's aliphatic side chains can readily be obtained using H(CC)(CO)NH and (H)CC(CO)NH experiments [92]. These experiments correlate either aliphatic ^{1}H or ^{13}C frequencies in the first indirectly detected dimension, after which the magnetization is relayed through aliphatic carbons and carbonyl carbon to the amide nitrogen of the sequential residue. After ^{15}N frequency

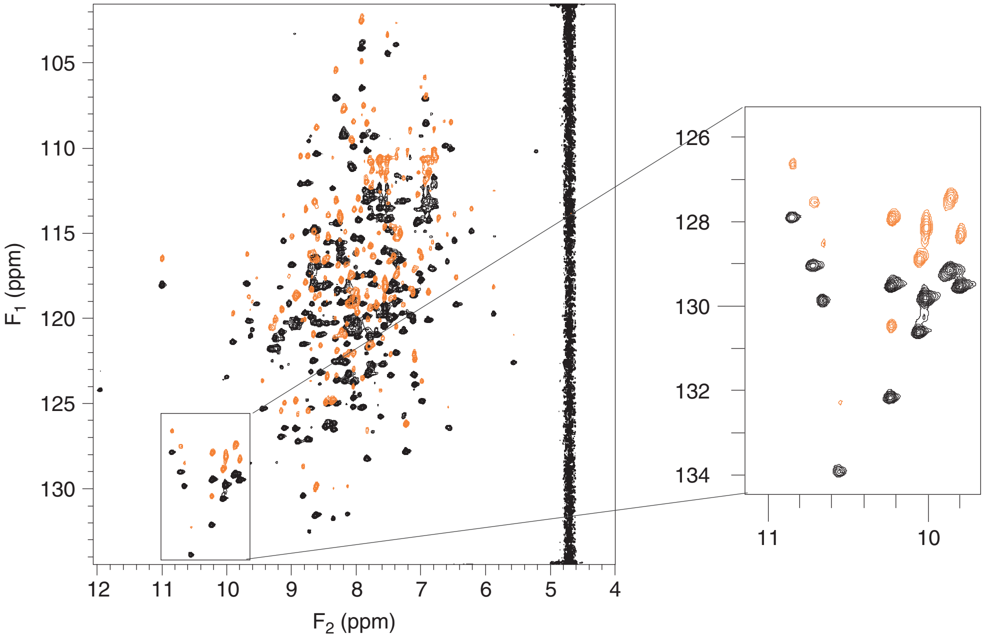

Figure 28.9 Spin-state edited ^{15}N–^{1}H correlation spectra of a 1 mM cellulase sample in H_2O/D_2O (90/10 v/v) recorded at 40 °C in a dilute liquid crystal composed of filamentous phages with an 600 MHz NMR spectrometer using the gradient selected TROSY sequence, modified to select TROSY (black contour) and semi-TROSY (red contour) spin states. The displacement of the multiplets contains in addition to the 94 Hz scalar-coupling-residual dipolar contributions. The inset shows linebroadening of the semi-TROSY component in ^{15}N dimension.

labeling, the coherence will be transferred to the directly bound amide proton for detection. In this way, provided that assignment of the protein main chain has been accomplished earlier, side-chain resonances can be assigned in a trouble-free manner for small- and medium-sized proteins. Inherent sensitivity of these C,C-TOCSY-NH experiments is low owing to relatively long transfer periods from side-chain protons/carbons to main-chain amide protons. HCCH-TOCSY and HCCH-COSY experiments, which correlate protons and carbons with their neighbors in aliphatic side chains, provide superior sensitivity in comparison to NH-detected counterparts. These spectra are, however, more tedious to assign.

Assignment of aromatic side chains is more troublesome owing to significant frequency difference between aromatic and aliphatic carbon resonances, which renders TOCSY transfer inefficient between aromatic and aliphatic carbons. Further difficulties are due to modest cross-peak dispersion among aromatic ring protons and carbons in combination with broad linewidth. For small- and medium-sized proteins, aromatic rings can be connected to the protein backbone by (HB)CB(CGCD)HD and (HB)CB(CGCDCE)HE experiments, which establish connectivities between CBs and aromatic ring protons [93]. There are also sophisticated experiments for the assignment of tryptophans and histidines [94] as well as polar side chains of Arg, Gln, Glu, Asn, and Asp [95–97]. Special techniques have been developed for the assignment of proline-rich sequences, which are abundant in many intrinsically unfolded proteins [98].

28.3.5
Methodology for Fast Data Collection

Traditionally, biological NMR spectroscopy has been limited by sensitivity, that is, experimental time of a key triple-resonance experiment such as HNCACB has been several days in order to accumulate spectrum adequately to meet a useful SNR. In total, this results in several weeks of expensive spectrometer time during which the stability of the sample can be of serious concern. Recent advances in NMR instrumentation, especially development of cryogenically cooled probe heads and higher polarizing magnetic fields, have improved the attainable SNR tremendously. The cryogenically cooled probe head decreases the thermal noise and resistance that originates in detector coils and preamplifiers by cooling them to 10–30 K. This results in an increase of SNR in NMR spectrum by a theoretical factor of 4. In biomolecular NMR applications, where the protein of interest is usually dissolved in aqueous solution comprising ionic buffer and some salt, this theoretical factor of 4 is not reached. Instead, sensitivity improvement by a factor of 3 is typically obtained. Nevertheless, owing to the $\mathrm{SNR} \sim \sqrt{t}$ relation, where t is the effective experimental time or more accurately the number of transients used for accumulating the NMR spectrum, the overall experimental time can, in principle, be reduced by an order of magnitude in cryogenically cooled probe heads, which has marshaled NMR spectroscopy of small- and medium-sized proteins to a new era – the sampling-limited regime. Thus, the overall duration of the NMR experiment is no more limited by the time required to obtain a feasible SNR, but instead to collect adequate number of time points to attain appropriate resolution in multidimensional experiments. Data collection or sampling in this way is a very slow process as each indirectly detected dimension has to be browsed in a point-by-point manner resulting in unnecessarily long experimental times, where expensive spectrometer time is wasted for obtaining adequate resolution. In recent years, several approaches have been introduced, which try to overcome the issue of sampling-limited regime. These methods, although referred here generally to as *fast acquisition NMR methodology* reach the same goal often in conceptually different ways. At least two main categories exist: approaches that (i) employ sparse sampling of NMR data and (ii) increase pulsing rate, that is, shorten the repetition delay between experiments. New methodologies belonging to the first category are reduced dimensionality (RD) and projection reconstruction techniques as well as experiments utilizing nonlinear or nonuniform sampling. Methods belonging to the second category are mainly SOFAST-HMQC experiments and their applications.

28.3.5.1 **Reduced Dimensionality Techniques**

The G-matrix Fourier transform (GFT) projection NMR spectroscopy speeds up data collection by obtaining high-resolution spectral data from low-dimensional projections. The technique is based on RD NMR methodology, which had already been introduced in the early 1990s [99], where two nuclei are jointly sampled in indirectly detected dimension. Therefore, conventional N-dimensional data can be ‘‘reduced’’ to be presented in an $(N-1)$-dimensional subspace. One of the two jointly sampled dimensions is detected as a simple cosine modulation, which creates a chemical shift doublet to this domain. Another dimension is detected in a conventional phase-sensitive manner. This then enables a phase-sensitive detection of a pair of peaks, which can be found as the sum and the difference of jointly sampled chemical shifts. The GFT projection NMR spectroscopy is a generalization of the RD NMR methodology [100]. Therefore, along with one phase-sensitively detected dimension, there is 2^n-fold repeated joint sampling of n indirectly detected chemical shift evolution periods. In addition, by taking linear combinations of these 2^n subspectra, we can generate separate, phase-sensitively detected spectra comprising peaks with a given linear combination of shifts. By using the GFT approach, even five- or six-dimensional data sets can be recorded using relatively short experimental times. For small proteins, overall time saving by a factor of 10–100 can be obtained. However, the experiment suffers from an inherent sensitivity loss by a factor of $(1/\sqrt{2})^n$ in comparison to the parent N-dimensional experiment. This can be partly compensated by symmetrization of subspectra.

28.3.5.2 **Projection Reconstruction Technique**

The projection reconstruction technique in NMR is related to a three-dimensionalX-ray imaging in anatomy, that is, a three-dimensional image is reconstructed from a set of plane projections taken from various angles of the object. By considering the NMR frequency space as a three-dimensional object, which is made of well-resolved discrete signals, a similar reconstruction of the three-dimensional spectrum can be obtained by collecting small number of 2D projections of the three-dimensional spectrum at different angles [101]. The full three-dimensional spectrum can then be reconstructed from the 2D projections. The peak lattice can be obtained using two orthogonal projections, but at least one or more tilted projections needs to be collected in order to select true cross peaks out of multiple possibilities. These tilted projections can be readily obtained by joint evolution of chemical shifts using fixed ratios, which defines the tilt angle. Although the projection reconstruction technique utilizes joint incrementation of two evolution parameters, similar to the RD approach, the data processing is different. It provides spectra with a familiar outlook, resembling the traditional three-dimensional spectrum. More importantly, sensitivity per unit time of the projection reconstruction method is identical to the conventional three-dimensional spectrum. Time savings on a spectrometer are significant, at least an order of magnitude in comparison to a conventional three-dimensional experiment.

28.3.5.3 Nonlinear Sampling

The principal idea behind nonlinear sampling, referred also to as *nonuniform* or *sparse sampling*, is to record multidimensional experiments through sparse and yet random sampling. In the sampling scheme, only a small subset of optimally selected data points are collected and the complete spectrum is then reconstructed by using nontraditional spectral-processing schemes such as nonuniform Fourier transform, maximum entropy, or multidimensional decomposition (MDD) [102–104]. For three-dimensional triple-resonance spectra, time savings by a factor of 5 can be readily obtained, enabling collection of data for protein backbone assignment within one day. By combining a nonlinear sampling scheme with the real-time targeted acquisition approach, additional time savings can be realized [105]. Fully automated data collection and on-line spectral processing during acquisition enables optimization of experimental time by following result-oriented criteria, that is, by stopping the experiment when the predefined spectral quality, completeness, or sensitivity, is adequate. This approach can be extended even further, that is, utilizing real-time data acquisition, hyperdimensional spectroscopy [106], and automated assignment, which results in blistering speed in backbone assignment of small proteins – the total time required for data collection and backbone assignment of 8.6 kDa human ubiquitin is ∼1 h [107].

28.3.5.3.1 **Selective Optimized Flip-Angle Short-Transient Heteronuclear Multiple-Quantum Coherence** RD and projection reconstruction techniques address the issue of sampling-limited data collection by joint sampling of several time domains and/or by collecting a limited set of 2D projections of a three-dimensional spectrum from various angles. The band-SOFAST-HMQC experiment is a conceptually very different approach [108, 109]. It hinges on standard sampling in indirectly detected dimensions but utilizes shortened longitudinal relaxation times of sample protons, which enables the use of very short interscan delay. Therefore, the repetition rate of the experiment can substantially be increased, resulting in significant time saving in overall experimental time. The key idea of the SOFAST-HMQC experiment is to avoid perturbation of protons, which are not directly detected. These protons serve as a reservoir for dipolar interactions (NOE effect) with the protons of interest, which reduces spin–lattice (T_1) relaxation time of detected protons substantially. Thus, the equilibrium spin polarization will be restored at a higher rate, enabling the use of a higher repetition rate in the pulse sequences. In comparison to the conventional HMQC, homonuclear J-modulation is not active during t_1 evolution period of SOFAST-HMQC as the 180° (^{1}H) pulse is band selective.

The general idea of fast pulsing in a manner of SOFAST-HMQC experiments can be used for acquiring three- or four-dimensional spectra with increased pace. With a suite of fast band-selective excitation short-transient (BEST) triple-resonance experiments [110]. High-quality 3D spectrum can be obtained within 10 min, provided that a sufficiently concentrated protein sample and a cryogenically cooled probe head are available.

29
Direct Optical Detection in Bioanalytics

Günter Gauglitz and Nicholas J. Goddard

29.1
Introduction

Apart from fluorescence techniques and the use of labeled compounds, direct optical detection of the biomolecular interaction process has increasingly gained interest in recent years. Especially, the monitoring of protein–protein interaction is in the focus of recent research. It takes advantage of direct optical detection since it reduces the problems with loss of bioactivity and requires no labeling. Accordingly, quite a few reviews dealing with optical biosensors for nonlabeled targets [1–5] have been published as well as an overall review of strategies for label-free optical detection. The latter is not just an overall review on optical biosensors covering only immunosensors but also refers to biosensors dealing with nucleic acids and whole-cell systems [6]. All these upcoming applications are discussed in a feature article in *Science* [7], ''Who needs labels,'' covering proteomics in life science technologies. These publications state the feasibility of direct optical detection as well as the advantages and disadvantages compared to microarrays based on labeled systems [8], and as optical techniques have to compete with optical microarray techniques using labeled systems that are commercially available [9]. Stimuli-responsive application is certainly done preferably by using direct optical techniques [10], and will help gain more information in the signaling chain or even to discriminate between agonists and antagonists [11].

In the meanwhile, quite a few commercially available systems for nonlabeled screening are available [12]. Further references to other commercialized products using different principles for direct optical detection are given in the related subchapters later. In addition, some specific realizations are discussed later.

Non-optical screening platforms relying on label-free screening such as impedance assays, acoustic systems, or micro-electromechanical sensors are also discussed in literature [13], but are not part of this chapter.

In principle, most of these direct optical detection techniques perform spectroscopy on biomolecules at the surface. In addition, they can monitor the interaction between a thin biomolecular layer containing recognition sites and a ligand or an analyte in solution. Typically, the behavior of radiation in

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

reflectance is used. Thereby, in general, changes in the so-called optical thickness are monitored. This optical thickness is a product of the refractive index n and physical thickness d of this interaction layer. According to the Fresnel equation, white light interference or effects caused by changes in the evanescent field form the principle of these optical techniques [14].

The principles of both these approaches to use reflected radiation (inner or outer reflectance) is explained, demonstrating the advantages and disadvantages, and various applications are outlined.

29.2
Optical Fundamentals

29.2.1
Optical Absorption

The attenuation factor α links the imaginary part K of the complex refractive index n to the loss per unit length:

$$I_x = I_0 \mathrm{e}^{-\alpha x} \quad \text{or} \quad \ln \frac{I_x}{I_0} = -\alpha x \tag{29.1}$$

where I_0 is the initial intensity and I_x is the intensity after the light has propagated a distance x through the absorbing medium at wavelength λ, and

$$\alpha = \frac{4\pi K}{\lambda} \tag{29.2}$$

However, the Lambert–Beer law states that

$$\log \frac{I_0}{I_x} = \varepsilon c x \tag{29.3}$$

where ε is the molar extinction coefficient ($\mathrm{m}^2\ \mathrm{mol}^{-1}$) and c is the concentration ($\mathrm{mol\,m}^{-3}$). Combining Eqs. (29.1–29.3) yields

$$K = \frac{\varepsilon c \lambda \ln 10}{4\pi} \tag{29.4}$$

Thus, we can calculate the imaginary part of the complex refractive index of a dielectric medium if we know the extinction coefficient and the concentration of the absorbing species. If the lower index medium in a total internal reflection (TIR) configuration has a complex refractive index, that is, it is lossy, then the reflection coefficient is reduced from unity, even for angles of incidence above the critical angle.

29.2.2
Theory of Total Internal Reflection

29.2.2.1 Reflection and Refraction

At a dielectric interface, we can have both reflection and transmission, as shown in Figure 29.1 [14]. The following conditions must be satisfied:

$$\theta_3 = \theta_1$$

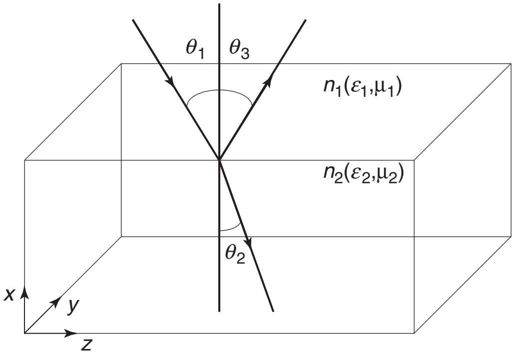

Figure 29.1 Reflection and refraction of light at the interface between two dielectric media having different refractive indices.

$$\frac{\sin\theta_2}{\sin\theta_1} = \frac{n_1}{n_2} = \left(\frac{\varepsilon_1}{\varepsilon_2}\right)^{1/2} \tag{29.5}$$

where n is the refractive index, ε is the permittivity, and μ is the permeability of the dielectric media. The incident, reflected, and refracted rays are coplanar (located in the x-z plane, the plane of incidence, in Figure 29.1). Transverse electric (TE), perpendicular (⊥) or s-polarized light has its electric vector perpendicular to the plane of incidence (x-z plane) in Figure 29.1, while transverse magnetic (TM), parallel (||) or p-polarized light has its magnetic vector perpendicular to the plane of incidence.

29.2.2.1.1 **The Fresnel Equations** The Fresnel equations describe the reflection and transmission coefficients at the interface of two optical media. The polarization of the incident light affects the magnitude of these coefficients. It is possible to derive expressions for the intensities of the reflected and refracted rays. These differ for the TE and TM polarizations as follows:

$$R_{\mathrm{TE}} = \frac{\sin^2(\theta_2 - \theta_1)}{\sin^2(\theta_2 + \theta_1)} = \frac{\left(n_1\cos\theta_1 - \sqrt{n_2^2 - n_1^2\sin^2\theta_1}\right)^2}{\left(n_1\cos\theta_1 + \sqrt{n_2^2 - n_1^2\sin^2\theta_1}\right)^2} \tag{29.6}$$

$$T_{\mathrm{TE}} = \frac{\sin 2\theta_1 \sin 2\theta_2}{\sin^2(\theta_2 + \theta_1)} = \frac{4n_1\cos\theta_1\sqrt{n_2^2 - n_1^2\sin^2\theta_1}}{\left(n_1\cos\theta_1 + \sqrt{n_2^2 - n_1^2\sin^2\theta_1}\right)^2} \tag{29.7}$$

$$R_{\mathrm{TM}} = \frac{\tan^2(\theta_1 - \theta_2)}{\tan^2(\theta_1 + \theta_2)} = \frac{\left(n_2^2\cos\theta_1 - n_1\sqrt{n_2^2 - n_1^2\sin^2\theta_1}\right)^2}{\left(n_2^2\cos\theta_1 + n_1\sqrt{n_2^2 - n_1^2\sin^2\theta_1}\right)^2} \tag{29.8}$$

$$T_{\mathrm{TM}} = \frac{\sin 2\theta_1 \sin 2\theta_2}{\sin^2(\theta_1+\theta_2)\, cos^2(\theta_1-\theta_2)} = \frac{4n_1 n_2^2 \cos\theta_1 \sqrt{n_2^2 - n_1^2 \sin^2\theta_1}}{\left(n_2^2 \cos\theta_1 + n_1\sqrt{n_2^2 - n_1^2 \sin^2\theta_1}\right)^2} \tag{29.9}$$

These expressions are only valid for non-normal incidence ($\theta_1 > 0$). For the special case of normal incidence, these expressions become

$$R = \left(\frac{n_1 - n_2}{n_1 + n_2}\right)^2 \tag{29.10}$$

$$T = \frac{4n_1 n_2}{(n_1 + n_2)^2} \tag{29.11}$$

Note that the polarization has no effect at normal incidence, as it is not possible to distinguish a particular plane of incidence.

29.2.2.1.2 **Total Internal Reflection (TIR)** If we have the condition $\theta_2 = \pi/2$, then the transmission coefficients for both TE and TM polarized light go to zero, because the term sin $2\theta_2$ becomes zero. Thus, the transmission coefficient is zero when $\theta_2 = \pi/2$. In this case,

$$\sin\theta_{\mathrm{c}} = \frac{n_2}{n_1} \tag{29.12}$$

and the angle of incidence at which this condition is true is called the *critical angle*. Since the sine function can only produce values from -1 to $+1$ for real angles, we can see that for this condition to be satisfied $n_2 < n_1$. In other words, TIR can only occur when light travels from a high index to a lower index medium. For angles of incidence greater than or equal to the critical angle, TIR occurs regardless of the polarization.

29.2.2.1.3 **Evanescent Waves** When the angle of incidence at a high–low refractive index boundary is greater than the critical angle, light is totally internally reflected. It can be shown that, although there is no energy transmitted across the interface, an electromagnetic wave, the evanescent wave, is present on the other side of the boundary. This wave propagates parallel to the interface and decays away exponentially with the distance from the boundary. The penetration depth of the evanescent wave is given by

$$d = \frac{\lambda}{2\pi\sqrt{n_1^2 \sin^2\theta_1 - n_2^2}} \tag{29.13}$$

where λ is the vacuum wavelength of the light. The penetration depth is the distance over which the intensity of the evanescent field decays to $1/e$ of its original intensity. This means that, except near the critical angle, the penetration of the evanescent wave into the optically rarer medium is no more than a wavelength. For example, if we take an SF10 prism ($n = 1.732$) in contact with water ($n = 1.333$) at a wavelength of 633 nm (HeNe laser), then the critical angle is 50.32°. If our angle of incidence is 60°, the penetration depth is approximately 146 nm.

While the evanescent field does not propagate into the rarer medium, it does propagate parallel to the interface and can interact with the lower index medium. Thus, if the lower index medium is absorbing, fluorescent, or scattering, some of the radiation will be absorbed, and the reflectivity will be reduced from unity. In the case of fluorescent or scattering media, fluorescence emission or scattered light from the evanescent field will be observed.

29.2.2.2 **Attenuated Total Internal Reflection (ATR)**

The small decrease in reflectivity observed when light is reflected by TIR at the interface between nonabsorbing and absorbing media is termed "attenuated total internal reflection" (ATR). If the light is scanned over a range of wavelengths, an absorption spectrum can be generated. Figure 29.2 illustrates the effect of the imaginary part of the refractive index on the reflectivity in a simple TIR configuration. When the imaginary part of the complex refractive index is quite small (0.001), the reflectivity curves deviate significantly from the curves for the no-loss situation only around the critical angle. At higher loss values, the curves deviate strongly from the no-loss values.

Figure 29.3 shows log(reflectivity) for internal reflection at the interface between dielectric media having a refractive index of 1.5 and $1.0 + iK$ for two angles of incidence, 60°, and the critical angle (41.8°). It can be seen that the TM polarization gives slightly higher sensitivity and that operating at the critical angle for $K \approx 0.1$ also gives higher sensitivity. Above these values of K, the reflectivity is a nonlinear function of K.

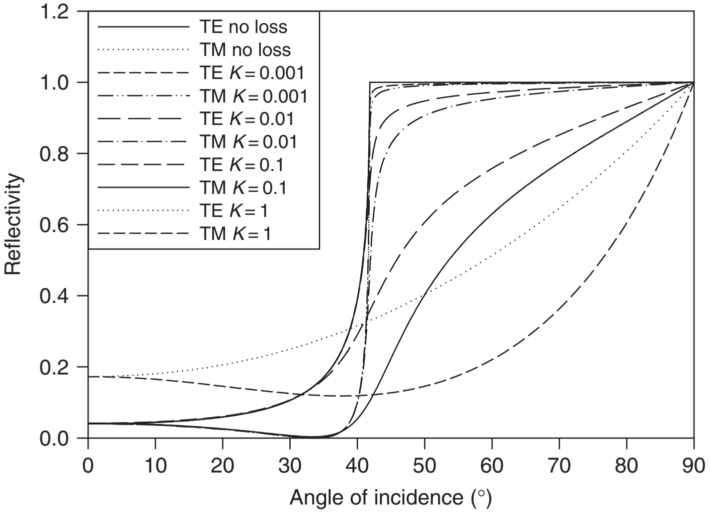

Figure 29.2 Reflectivities calculated for angles of incidence between 0 and 90° for internal reflection at the interface between dielectric media having refractive index 1.5 and $1.0 + iK$.

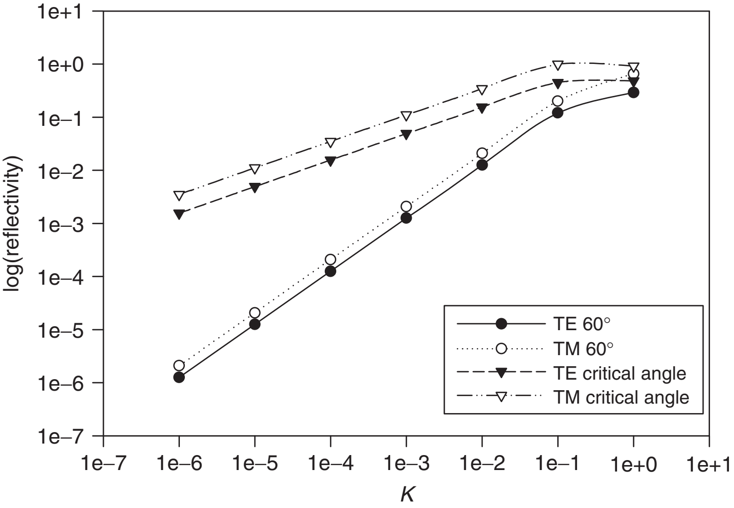

Figure 29.3 log(reflectivity) for internal reflection at the interface between dielectric media having refractive index 1.5 and $1.0 + iK$ for two angles of incidence, 60° and the critical angle (41.8°).

29.2.2.3 Effective Path Length and Sensitivity

We can use the preceding calculations to determine an effective path length for a material having a given value of K. This is calculated as a fraction of the path length of the material in a conventional spectrophotometer. Equation (29.4) can be rewritten as

$$\varepsilon c = \frac{4\pi K}{\lambda \ln 10} \tag{29.14}$$

In addition, we can use the reflectivity of the ATR configuration to calculate an effective absorbance or optical density:

$$A = \log \frac{I_0}{I} = -\log R \tag{29.15}$$

The ratio of the sensitivities for the ATR and conventional systems allows us to calculate an effective path length:

$$r_s = \frac{-\log R}{\varepsilon c l} = \frac{-\lambda \ln 10 \log R}{4\pi K l} = \frac{-\lambda \ln R}{4\pi K l} \tag{29.16}$$

For example, if we use ATR at the interface between dielectric media having a refractive index of 1.5 and $1.0 + 0.00001i$, we can calculate that $\varepsilon c = 86.24\,\text{m}^{-1}$ or $0.8624\,\text{cm}^{-1}$. Operating at the critical angle for such a system, using TM polarization, we obtain a value for R of 0.97487, which gives a value of 0.011055 for $-\log(R)$. This shows that the sensitivity of the ATR configuration is approximately 1/78 (0.011055/0.8624) of that of a conventional spectrophotometer, or the effective path length is 1/78 cm compared to a conventional 1-cm cell.

Although the effective path length is considerably shorter for a simple ATR configuration, the volume of material sensed is very small, since the penetration depth into the sensed material is generally very small. If we assume a circular input beam of radius r for both the conventional and ATR configurations, then the input beam will form an elliptical spot at the interface between the two media whose area is given by

$$A = \frac{\pi r^2}{\cos \theta_1} \tag{29.17}$$

The volume of material sensed is given by the product of the area of the spot and the penetration depth d:

$$V = \frac{\pi r^2 \lambda}{2\pi \ \cos \ \theta_1 \sqrt{n_1^2 \sin^2 \theta_1 - n_2^2}} \tag{29.18}$$

And, for the conventional cell the volume sensed is given by

$$V = \pi r^2 l \tag{29.19}$$

where l is the path length of the cell. The ratio of these two volumes is

$$r_{\mathrm{V}} = \frac{\lambda}{2\pi \mathrm{l} \ \cos \ \theta_1 \sqrt{n_1^2 \sin^2 \theta_1 - n_2^2}} \tag{29.20}$$

One obvious way to increase the sensitivity of ATR systems is to increase the number of reflections. This can be achieved by using a thin transparent slab and coupling the light in and out through the end faces of the slab. Many different configurations have been devised utilizing this method, including schemes where the light enters and exits by the same face and single- and double-sided slabs. If the reflectivity for a single TIR is R, then for n reflections the total reflectivity is R^n. ATR slab waveguides in IR-transparent materials such as silicon, germanium, zinc selenide, and KRS-5 are commercially available for fourier transform infrared (FTIR) instruments.

29.2.2.4 **Waveguides**

We can utilize the phenomenon of TIR to construct a waveguide. If we have a slab of transparent dielectric of a higher refractive index than its surroundings, light can be waveguided in the slab. Even a simple microscope slide can act as a slab waveguide if light can be coupled into it in such a way as to exceed the critical angle on reflection at the boundaries of the slab. Figure 29.4 shows a simple ray model of the propagation of light along the waveguide at a characteristic angle of incidence by successive reflections. To minimize losses, TIR is used as the reflection mechanism.

It might appear that θ can adopt any angle, but this is not the case. Consider an observer moving along the z-axis who sees only the transverse (x-direction) motion. For a self-consistent picture, this observer must see the ray having the same phase every time the ray reaches him or her. If this were not the case, over a large number of reflections the phase shifts would cancel out, giving an intensity of zero. For this not to occur, the total phase shift over a complete cycle from $x = 0$ to $2a$ and back to

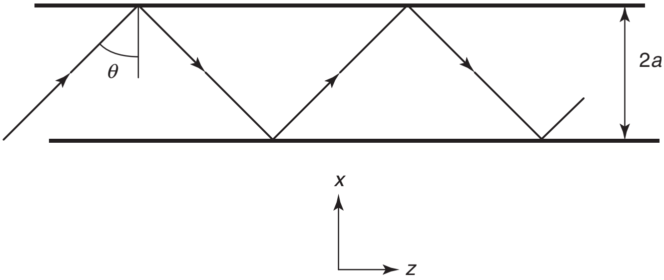

Figure 29.4 A simple model of a slab waveguide showing the propagation of light in a zig-zag path.

0 must again be an integral multiple of 2π. This is termed the *transverse resonance condition*.

If 2a is large compared to the wavelength of the light, then there will be a large number of angles θ that satisfy the transverse resonance condition. As the thickness of the waveguide is reduced, the number of possible solutions decreases until, in the limit, there is only one angle at which the light can propagate. Each discrete angle of propagation is termed a *mode,* and below a critical thickness (the cut-off thickness) no waveguide modes can be supported. Waveguides are termed *monomodal* if they can only support one mode, or multimodal if they can support more than one mode. Since a thin, monomodal waveguide will support the largest number of internal reflections, we find the sensitivity of monomodal waveguides to be higher than that of multimodal waveguides. Since the thickness of a monomodal waveguide is typically less than a wavelength, these waveguides are too fragile to be used without a thick substrate for support. This reduces the sensitivity, as only one side of the waveguide is exposed to the sample to be analyzed.

A guided mode in a waveguide also produces an evanescent field in the lower index layers outside the waveguide. In essence, some of the light is traveling outside the high-index waveguiding layer. The effective refractive index (N) of the waveguide depends on the bulk refractive indices of the waveguide and the cladding, and the relative proportions of the light in the waveguide and the cladding layers. This means that the effective index is always between the waveguide and the cladding indices.

The other implication of this is that if the refractive index of the cladding layer changes, the effective index of the waveguide changes also, which can be detected by a change in phase. Thus, waveguides are sensitive to changes in refractive index as well as to absorption outside the waveguide layer. To maximize this sensitivity, we need to increase the amount of light in the evanescent field. To do this, we require a large difference between the waveguide and the cladding refractive indices, and the waveguide should be thin enough to support only a single mode. Because of the nature of the equations that determine the supported modes of a waveguide, exact analytical solutions are not possible and numerical solutions are required. Figure 29.5 shows the sensitivity of a planar waveguide to changes in the external bulk refractive index as a function of waveguide thickness, Figure 29.6 shows the

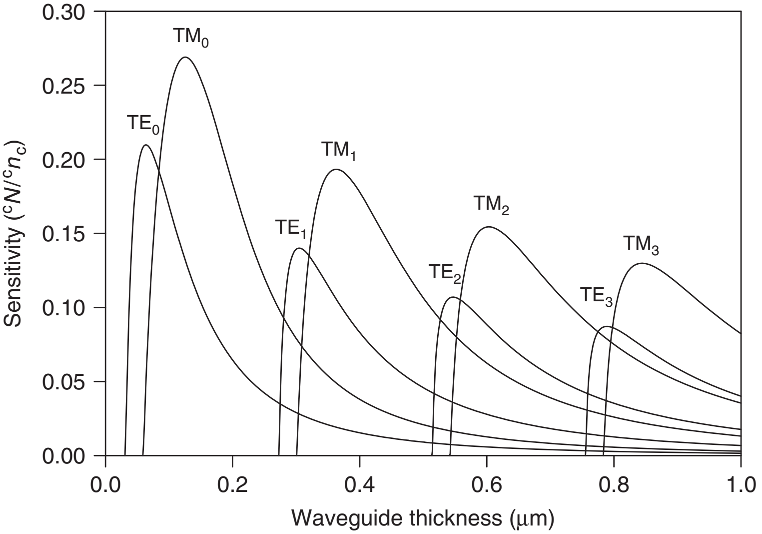

Figure 29.5 Graph of the sensitivity (ratio of the change of waveguide effective index to change in refractive index of cover layer) as a function of waveguide thickness for the first four TE and TM modes. Substrate index 1.46, waveguide index 2.00, and cover layer index 1.333, calculated for illumination at 660 nm.

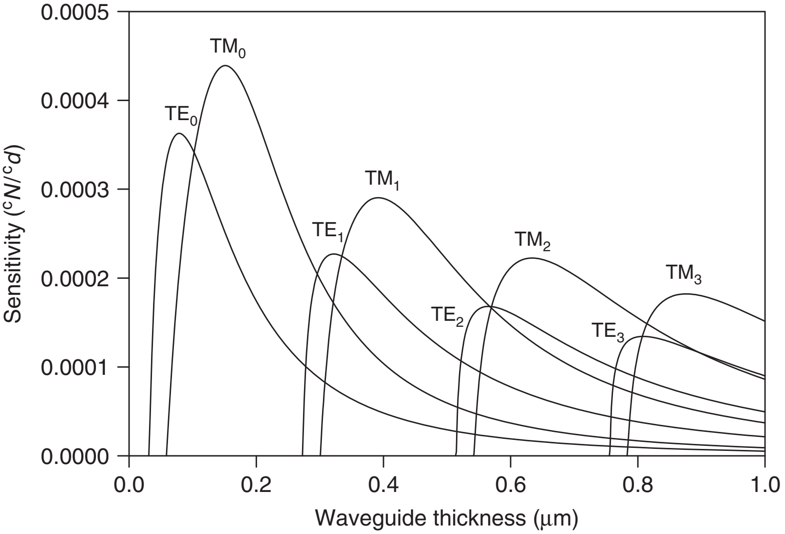

Figure 29.6 Graph of the sensitivity (ratio of the change of waveguide effective index to change in thickness of a thin adlayer) of the waveguide as a function of waveguide thickness for the first four TE and TM modes. Substrate index 1.46, waveguide index 2.00, adlayer index 1.45, and cover layer index 1.333, calculated for illumination at 660 nm.

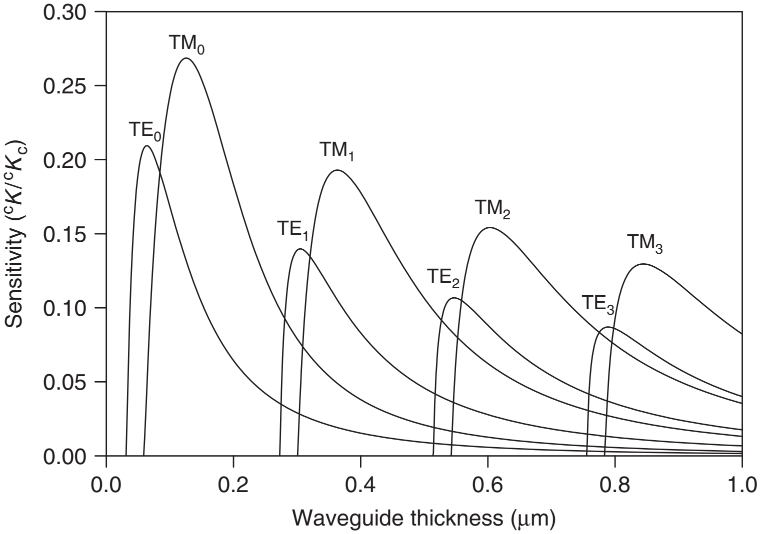

Figure 29.7 Graph of the sensitivity (ratio of the change of the imaginary part of waveguide effective index to change in the imaginary index of the cover layer) as a function of waveguide thickness for the first four TE and TM modes. Substrate index 1.46, waveguide index 2.00, and cover layer index 1.333 calculated for illumination at 660 nm.

sensitivity of the waveguide to changes in thickness of an adsorbed layer on the surface as a function of waveguide thickness, and Figure 29.7 shows the sensitivity of the waveguide to losses in the cover layer.

These graphs clearly show that there is an optimum waveguide thickness that maximizes sensitivity to refractive index changes for a particular mode, that these optimum thicknesses are different for TE and TM modes, that TM modes are generally more sensitive than TE modes, and that the zero-order modes are the most sensitive. The general form of all three graphs is the same, as they effectively measure the fraction of the light present in the evanescent field that is interacting with the material being sensed.

The calculations in the preceding paragraphs have been performed for a simple planar slab waveguide of infinite extent but finite thickness sandwiched between a semi-infinite substrate and cover layers. Other waveguide configurations are possible, most notably the cylindrically symmetrical case of a high refractive index rod surrounded by a lower index cladding. This is the fiber-optic configuration used widely in telecommunications.

The number of different optical methods depending on the optical thickness $n \times d$ (refractive index times physical thickness) is large. The following sections demonstrate that it is difficult to decide whether a device can be classified as a fiber or a waveguide, having read-outs influenced by evanescent fields, gratings, the waveguide structure, interferometric effects, or even a combination of these. Therefore, perhaps the best classification can be achieved by discriminating whether changes in refractive index or changes in the physical thickness of the layer are predominantly responsible for the measured effect. Thus, micro-refractometry or micro-reflectometry characterize the detection principle.

29.3
Measurement Configurations of Refractivity

29.3.1
General

There are various possible configurations that utilize evanescent waves for biomolecular sensing and spectroscopy [15–17]. Waveguides (either planar or in an optical fiber) can be used as prism couplers, grating couplers, mode couplers (interferometers), and in surface plasmon resonance (SPR), and FTR experiments. Grating couplers use a grating fabricated in either the substrate or waveguide to couple light in and out of the waveguide. As the surface refractive index changes, the in-coupling angle also changes, resulting in a change of the angular position of the out-coupled light on an appropriate detector. In this mode, grating couplers work very much like SPR and resonant mirror (RM) sensors. They can also be used purely as a means of coupling light in and out of the waveguide to permit detection of absorption or fluorescence changes. Interferometers (such as Mach–Zehnder, Michelson, or Young devices) use a separate reference channel that does not undergo the chemical binding stage to act as a phase reference. A periodic change in intensity at the output is observed, caused by interference between the sensing and reference channels as the refractive index on the sensing channel changes. A problem with interferometers is that the output can be ambiguous, as a large change in refractive index can take the output through more than one cycle. These devices are generally very sensitive.

Dual polarization sensors make use of the phase changes between the TM and TE modes propagating in a waveguide. If equal intensities of TE and TM are excited at the input, the polarization state of the output will depend on the relative phase shift between TE and TM at the output. Since the sensitivity of the waveguide is different for TE and TM modes, a change in refractive index on the waveguide surface will result in a change in polarization at the output. Similar to interferometric sensors using the evanescent field, the output is cyclic and can result in ambiguous outputs. The sensitivity is very high.

In FTR experiments, a leaky high index waveguide is used, which permits in- and out-coupling at well-defined coupling angles. The coupling angle depends strongly on the cover layer refractive index. They can also be used to monitor absorption, as the reflectivity is a strong function of the loss in the cover layer.

All these sensors are based on changes in the effective refractive index of the waveguide and use various forms of in-coupling and read-out techniques. A short review and comparison of these principles has been published [18a]. Design and fabrication of a complete optical interconnection scheme including the optoelectronic package, laser incoupling, and read-out has recently been published [18b].

29.3.2
Fiber Optics

Optical fibers are cylindrical waveguides consisting of a high-index core surrounded by a low-index cladding layer. Because of their low losses, fiber optics is widely used in the telecommunications industry, although the properties of telecommunications fiber optics make them poor sensors. Specially designed fiber optics can be used as biosensors, using a thin or no cladding layer on a monomode fiber core to permit interaction of the evanescent field with the material to be sensed [19–21]. Conventional fiber optics has also been widely used for sensing applications, but in the majority of cases, it has been used as a convenient means of delivering and collecting light for conventional spectroscopies.

29.3.3
End-Fire Coupling

End-fire coupling, as its name implies, is carried out by focusing a laser beam into a diffraction-limited spot centered on the waveguiding layer. Although end-fire coupling is conceptually very simple, it is not easy to perform in practice. One example where end-fire coupling has been successfully used in biological sensing applications is the difference interferometer [22–25].

If we consider Figure 29.6, we can see that there are waveguide thicknesses at which the difference in sensitivity between the TE and TM modes is at a maximum. If linearly polarized light is launched at 45° to the plane of the waveguide, equal intensities of the appropriate TE and TM modes will be launched. Since end-fire coupling will generally excite more than one mode, the waveguide thickness is chosen such that only monomode operation will be possible at the excitation wavelength and the difference in sensitivity between the TE and TM mode is maximized. As the surface refractive index changes, the retardation of the TE and TM modes will change by different amounts, changing the relative phase of the TE and TM modes, and hence the polarization state of the out-coupled light. When the TE and TM components are in phase, the out-coupled light will be polarized in the same direction as the in-coupled light. As the phase difference between TE and TM increases, the out-coupled light will become elliptically polarized, reaching circular polarization when the phase difference reaches $\pi/2$. At a phase difference of π, the light will be linearly polarized again, but at 90° to the polarization of the in-coupled light. As the phase difference increases further, the light will again become circularly polarized at $3\pi/2$, but with the opposite handedness, while at 2π the cycle will be complete and the out-coupled light will be polarized identically as the in-coupled light. This cycle can be followed using an appropriate arrangement of beam splitters, polarizers, and detectors, returning the TE–TM phase difference after processing the detector outputs. Since the phase difference is a cyclical function of the surface refractive index, this device does not give an unambiguous measurement of the surface refractive index. It can track slow changes in refractive index, but can only track the index successfully if the index change causes a phase change smaller than ±π between successive samples of the output. Because the path lengths employed in this type of sensor can be quite large (~10 mm), the sensitivity is quite high. Effenhauser *et al.* [26] were able to detect 10^{-11} M concentrations of human immunoglobulin G (IgG) using anti-human IgG antibodies with a difference interferometer configuration and a thin titanium dioxide waveguide. In studies with a bidiffractive grating coupler system, Kubitchko *et al.* [27] have used nanoparticles to enhance the sensitivity for the detection of analytes such as the thyroid-stimulating hormone (TSH). Without amplification, the detection limit was 430 pM, and with amplification by a latex-conjugated sandwich antibody, the detection limit dropped to 0.11 pM, which is the range of clinical interest (0.3–667 pM TSH).

29.3.4
Grating Couplers

A grating structure at the substrate–waveguide or waveguide–cover layer interface can be used to couple light into the waveguide [28]. A major advantage of this method is that the waveguide can be fabricated on a simple planar substrate and coupling can take place through the bottom of the substrate. Careful design of the waveguide and grating can permit the use of TM-polarized light at the Brewster angle, which eliminates reflection at the bottom surface of the substrate.

Dubendorfer and Kunz [29] employed a chirped grating coupler design, where the grating period varies continuously along the width of the coupling area. This means that light will only couple into the waveguide at the location where the grating equation is satisfied. Thus, the position in space of the out-coupled beam is a simple function of the surface refractive index. They were able to detect refractive index changes of 5×10^{-6}, corresponding to changes in surface loading of 5 pg mm^{-2}. An interesting read-out based on a rotating sample was compared to polyelectrolyte layers and biotin/streptavidin interactions in comparison to other waveguide devices [30].

Using grating couplers, the first instrumentation was developed by Tiefenthaler and Lukosz [31] based on optical principles realized by Lukosz and Tiefenthaler [32] in the small and medium sized enterprise (SME) *artificial sensing instruments* (*ASI*) in Zurich and found application in research. Tiefenthaler's goniometer has been modified by a precision-sensitive CCD (charge-coupled device) array, which avoids mechanical angle-scanning the optimum coupling angle [33]. Another possibility is a bi-diffractive coupler, which represents a ''mixed grating'' [34]. A second angle of out-coupling is achieved, which differs from that of normal reflection. By these means, the signal-to-noise ratio increases drastically, and the set-up is simpler than the *ASI* instrumentation. To reduce grating costs, embossed polycarbonate gratings as disposable chips can be considered. Varying either the grating constants across the chip or the waveguide height in which the grating is embedded, the resonance to the refractive index varies across the waveguide [35, 36]. Nowadays, the OWLS 210 from *MicroVacuum Ltd.* [37], an optomechanical grating coupler, is commercially available and provides biomolecular interaction applications [38a,b]. Details of the technology can be found in [39].

Best known is the *Corning Epic*, a broadband source grating coupler with a high-throughput platform that is used for biochemical and cell-based screening [40]. This system has been used to examine regulations of cell functions [41] or label-free cell-based screening of GPCR (G protein-coupled receptor) agonists and antagonists [42a]. Review on the screening of cellular targets using this system in comparison to other label-free platforms is given in [42b]. Since a few years, based on the Corning Epig System, Perkin Elmer offers a Multimode Plate Reader called EnSpire™ as the only bench-top plate reader available with optical label-free technology. Other modes of detection that are available in this configurable system include Alpha technologies, ultra-sensitive luminescence, fluorescence intensity, and absorbance in microplates up to 384 wells [42c].

Different optical principles of grating couplers have been reviewed in detail [33, 43].

29.3.5
Photonic Crystals

Photonic crystals have a periodic dielectric structure with a periodicity lower than the wavelength of radiation [44]. A one-dimensional ‘‘photonic crystal’’ just represents a simple grating. Therefore such devices can be considered as special types of grating couplers. A broadband source coupler system available from *SRU Biosystems*, described as a cost-effective platform for low to ‘‘ultrahigh’’ throughput, provides biochemical and cell-based applications [45]. On the basis of a former grating approach [46] below each well of a kind of microtiter plate a grating array and a scanning fiber read-out head are placed. The authors call this system the *BIND-system* [47]. *SRU* uses photonic crystals, given by periodical laterally resolved changes in refractive index on a polyester sheet (up to 1536 wells) [48]. Newer instrumentation even allows a combination of label-free and enhanced fluorescence detection [49a]. Publications use this system for interaction studies at membranes for regulations in neurosciences [49b]. Epic and BIND are compared for cellular-based screening [50].

These devices have been recently compared to other evanescent field techniques. Various arrangements and applications are given [1]. Recently, parameters for label-free biosensors have been theoretically calculated [51] and applications to ultrasensitive DNA detection are published [52].

29.3.6
Bragg Gratings

By embedding gratings in fibers by interchanging areas of different refractive indices (Figure 29.8), the grating conditions select a frequency to be reflected inside the core of the fiber [53]. Thus, a dip in intensity is formed in the bandwidth of the transmitted radiation, whereas the back propagating radiation exhibits a

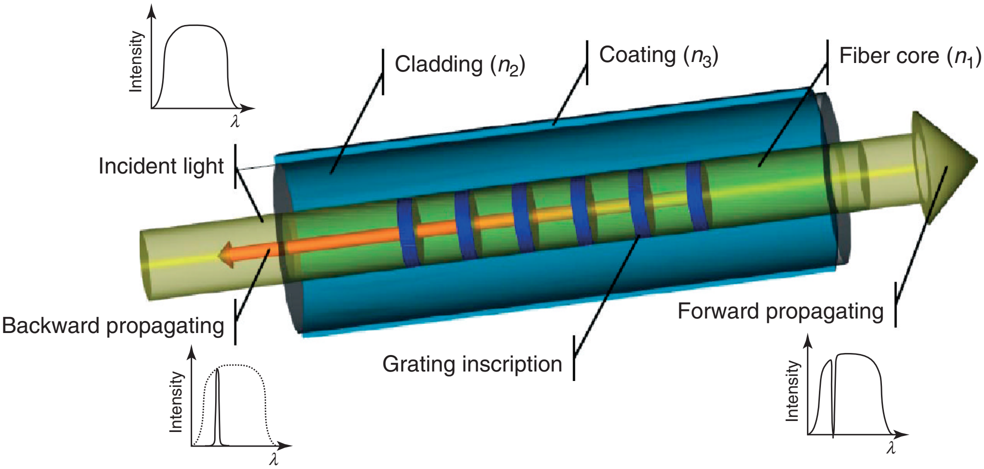

Figure 29.8 Fibers with Bragg grating, according to Meixner [56].

single line. Although Bragg gratings were first used in telecommunication and in temperature measurements, biosensing applications were published in the meantime. Maguis *et al.* [54] demonstrated the possibility of label-free immune sensing with BSA/anti-BSA interactions. These modified fibers are also used for locally resolved remote control. Changes of the refractive index in the coating or cladding can be read-out sensitively. Kashyap [55a] also proposed a Bragg grating assisted plasmon-polariton fiber for biomedical applications. A variety of applications of Bragg gratings and technical modifications have been published in the last years: for the determination of composition of fuel and biofuel [55b], label-free DNA detection [55c], or measuring of human osteoblastic cells [55d]. New possibilities to fabricate Bragg gratings are given in [55e].

29.3.7
Backscattering

A coherent single wavelength laser focuses onto a waveguide (or capillary) and a small sensing area, and results in another interference device. The reflected interference pattern is analyzed with respect to the wavelength using a detector, and monitors shifts dependent on changes in the refractive index. A newer review is given in [57], whereas various optical set-ups and applications are provided in [1]. One of the first applications of this approach is in packed-capillary high-performance liquid chromatography [58]. Label-free molecular interaction determination with nanoscale interferometry can be achieved on channels molded in PDMS (poly-dimethyl-siloxane) as perspective in proteomics [59a]. The use of nanoparticles in combination with back-scattering interferometry has been patented recently [59b] as well as using aptamer–protein interaction for biosensing [59c].

A variation of this principle is an arrangement on an optical disk comparable to a ''CD-player'' [60], which was commercialized by Quadraspec. This company changed its name in 2010 to Perfinity Biosciences Inc. and focused on protein sample preparation [61]. Recent achievements have been reviewed [62] and the detection of prostate-specific antigen in patient sera by a fluorescence-free BioCD protein array is given [63].

29.3.8
Resonant Mirror (RM)

The RM device consists of a high-index substrate (lead glass with a thickness of ~1 mm, $n_d = 1.72825$), a thin low-index spacer (about 1000 nm of magnesium fluoride or silica), and a very thin monomode waveguiding layer (about 100 nm of titanium oxide, zirconium oxide, hafnium oxide, or silicon nitride). It can be used to monitor the refractive index and the absorbing or fluorescent species within the evanescent field above the waveguide [64].

Light incident above the critical angle on the substrate/spacer interface is coupled into the waveguiding layer via the evanescent field in the spacer layer when the propagation constants in the substrate and waveguide match. For monochromatic light, this occurs over a very narrow range of angles, typically spanning <10 arcmin. The device has been termed the *resonant mirror* because it contains a resonant cavity (the waveguide), and it acts as a nearly perfect reflector for light incident above the critical angle. Since the waveguiding layer acts as a resonant cavity, the light reflected from the RM device undergoes a full 2π phase change as we scan across the resonance. To detect the resonance position, a phase reference must be provided, which is substantially constant in phase. This could be provided by splitting off part of the input beam and recombining it with the light from the sensor, but this is difficult with regard to instrumentation, and means that the object and reference beams travel by widely separated paths. Ideally, the two beams should travel by identical paths so that phase-shifting effects (such as temperature changes) are common to both beams. This can be accomplished in the RM sensor by using the TE mode as reference for the TM resonance and vice versa. This is only feasible because the resonance positions for TE and TM are widely separated.

The resonance positions may be determined in two ways:

1) in angle, using monochromatic input light covering a range of input angles (angular scan mode) [64];
2) in wavelength, using broadband input light at a fixed input angle (wavelength scan mode) [65].

To determine the resonance angles or wavelengths at which light couples into the waveguiding layer, linearly polarized light at 45° to the plane of the waveguiding layer is applied to the device, exciting equal intensities in the TE and TM modes. The output light from the device is passed to a crossed analyzer, which only passes light that has undergone a π phase change in the sensor device. In the angular measurement mode, the input light is a converging monochromatic wedge beam, covering a sufficiently wide range of input angles to permit the resonance angle (for the fixed wavelength) to be determined for the required range of surface refractive indices. In the wavelength measurement mode, the input light is a well-collimated beam of white light, covering a sufficiently wide range of wavelengths to permit the resonance wavelength (at the fixed input angle) to be determined.

Buckle *et al.* [66] used the RM to monitor antigen/antibody and enzyme/substrate/inhibitor interactions using several methods for immobilization of the biomolecules at the sensor surface. Sensitivities in the nanomolecular range were reported. Watts *et al.* [67] used the RM sensor to monitor the binding of microbial cells to antibodies immobilized on the surface of the sensor. They detected the binding of *Staphylococcus aureus* (Cowan-1 strain) to human immunoglobulin G (hIgG), covalently immobilized on the sensor surface via aminopropylsilane, at concentrations between 8×10^6 and 8×10^7 cells cm^{-3}. By employing a sandwich assay using a hIgG–gold particle conjugate, detection limits were reduced by a factor of 1000. It appeared feasible to detect between 4×10^3 and 1.6×10^6 cells cm^{-3} in spiked milk samples. Newer approaches use porous silicon for the measurement of very low DNA concentrations [68].

Some instruments based on the RM were commercially available (the *IASys* system of Thermo Labsystems/Affinity Sensors) [69], which used the angular scan mode to determine the resonance angles. According to the Internet, however, the product field of this company has changed.

29.3.9

Surface Plasmon Resonance (SPR)

Surface plasmon waves are excited in thin metal films when appropriate coupling conditions are met. The surface plasmon wave is an oscillation of the free electrons in the metal under the influence of the electric field of the light [17]. For sensor applications, the Kretschmann configuration [70–72] is most often used, where a thin metal layer (usually 50 nm gold) is deposited on a glass prism and light is coupled into the metal film at the coupling angle. This configuration is shown in Figure 29.9. Only TM polarized light shows this behavior where the mode is localized at the metal–cover layer interface. TE polarized light does not show this behavior. Since the metal film is very lossy (it has a large imaginary component of the complex refractive index), the reflected light is very strongly attenuated at the coupling angle. The coupling angle is a very strong function of the cover layer refractive index. Thus, as material binds to the metal layer there is a change in the angle at which the drop in reflectivity occurs. This is the basic sensing mechanism for SPR biosensors, as shown in Figure 29.10.

Instrumentation for SPR sensors generally comprises a monochromatic light source (a filtered incandescent lamp, LED, or laser) followed by a cylindrical lens to provide illumination over a wide range of angles. A CCD detector is then used to monitor the position of the dip in intensity (angle measurement mode), which indicates the coupling angle. Alternatively, a collimated beam of white light may be used at a fixed angle of incidence, and the wavelength position of the dip determined

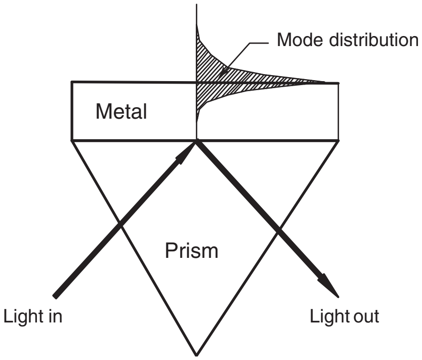

Figure 29.9 The Kretschman configuration for excitation of SPR in a thin metal layer.

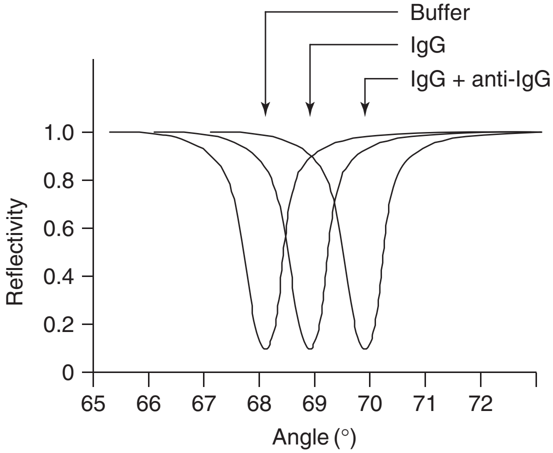

Figure 29.10 Illustration of the shift in resonance angle at various stages in the adsorption of biomolecules to the metal surface.

(wavelength measurement mode). Systems of this kind have no moving parts, and thus can follow very rapid changes in the angular position of the reflectivity dip. The metals most often used are gold or silver, but copper can also be used. These metals all have the high conductivity needed to give a relatively narrow dip in reflectivity, making the task of following small changes in the position of the dip easier.

Former reviews demonstrate the development in instrumentation, parallelization and application [73–78]. Instrumentation is reviewed in [79], and many new systems are considered for the future [80a]. Recent instrumentation and application are reviewed from a nanotechnology standpoint of view [80b]. Combination of SPR with Bragg gratings is gaining increasing interest [80c,d].

Since its commercialization, SPR has been used for the detection of a large variety of biomolecules. Reviews on the applicability of SPR detection have appeared rather regularly, discussing biomolecular interactions of proteins, nucleic acids, lipids, and carbohydrates, and demonstrating the fast growing interest in biomolecular interaction analysis (BIA) [81–86].

SPR has also shown some usefulness in the study of conformation changes of adsorbed proteins. For instance, Boussaad *et al.* [87] have used multiwavelength SPR to study conformational and electronic changes induced by the electron transfer reaction in cytochrome c, and Sota and Hasegawa [88] studied the acid-induced denaturation of an immobilized protein. DNA hybridization has also been studied by SPR [89]. Through many studies, much new knowledge has been acquired on the kinetics of antigen–antibody reactions at surfaces [90].

Besides, some other interesting applications have been published, dealing with global conformational transitions in human phenylalanine hydroxylase [91], examining peptides from the GH loop of the foot-and-mouth disease virus [92], measuring gentamicin residues [93], and determining penicillin residues in milk [94].

More recent applications deal with the detection of pathogenic microorganisms [95], review high-throughput label-free interaction analysis [96], even combining SPR microscopy and imaging to analyze kinetics quantitatively [97]. Refractometry can also be achieved using micro-optical fluidic systems [98]. Fragment-based screening is also possible using SPR [99], and the possibility of quantitative analysis of small molecule interactions with nucleic acids is demonstrated [100]. Recently, the benefits of SPR in food analysis have been reported [101a]. Development of portable and miniaturized SPR, even paper-based, opens new fields of simple applications [101b].

29.3.9.1 **Commercial SPR Biosensors**

Commercial systems using SPR sensing methods have become available from a number of suppliers. These systems range from large multichannel laboratory bench instruments to simple single-channel integrated devices in an integrated-circuit style package.

As the first direct optical detection technique, Pharmacia Biosensor AB (founded in 1984) commercialized SPR for studying biomolecular interactions; *Biacore®* was launched in the fall of 1990. Acquired by GE Healthcare in 2006, Biacore now offers a family of instruments for monitoring interaction processes in single channel fluidics and arrays. The Biacore system is based on the Kretschmann configuration, and is a multichannel instrument that has been extensively used for biological assay work and for monitoring both thermodynamic (dissociation constants) and kinetic (on and off rates) parameters of a wide range of biomolecular interactions. The present product range [102] of Biacore includes dual-channel instruments with varying specifications and the *Biacore Flexchip*, described as an array-based parallel kinetic profiling instrument with 400 spots on the sensor surface [103]. In a huge database, the newest publications can be found [104], dealing with a large number of interesting applications. The marketing concept of label-free protein interaction has been explained recently [105].

A competitive alternative to the Biacore, the *IBIS* series of biosensors, has been developed in the Netherlands at the Twente Technical University [106], which is based on the conversion of angle data into a time interval by the use of a vibrating mirror system [107]. An imaging application is given in [108].

The *Spreeta*™ device, formerly manufactured by Texas Instruments (now by Sensata Technologies in Attleboro, MA), is a low-cost miniaturized SPR sensor platform that allows real-time quantitative concentration, affinity, and kinetic analysis of biomolecular interactions [109]. Elkind *et al.* [110] describe the use of the Spreeta device as a refractive index sensor for a direct assay for human creatine kinase MB (CK-MB, a marker for heart attacks) using adsorbed anti-CK-MB antibodies, obtaining a change in index of $\sim 4 \times 10^{-4}$ for the binding of 100 ng ml^{-1} of CK-MB. They were also able to assay trinitrotoluene (TNT) using a competitive assay format by immobilizing a trinitrobenzene–bovine serum albumin adduct to the sensor surface, detecting 7 ng ml^{-1} of TNT. Sesay and Cullen [111] have used the Spreeta sensor to monitor endocrine disrupting chemicals (EDCs) in aqueous samples. The sensor surface can be regenerated by using a strong domestic detergent (Persil biological liquid) to remove all the biological material. The detection range was 10–150 ng ml^{-1}. The most recent published evaluation of the device is from 2003 [112].

Other companies have entered the market in recent years, such as *Reichert Life science* [113] and *BI Biosensing Instruments* [114]; the latter provides a large number of customer applications such as those described in [115], dealing with wild-type and mutant p53 proteins in cancer cell lysates and performed with a dual-channel SPR instrument. *Analytical* μ*-Systems*, a Department of Mivitec GmbH, offers to measure interaction of biomolecules (antigen–antibody and others) and binding constants with the *BIOSUPLAR 6 system* [116, 117].

Surface plasmon resonance imaging (SPRi) systems developed by *GenOptics* [118], a technology innovator in SPR, are now distributed worldwide by *HORIBA Jobin Yvon* [119]. With *ESPRIT, SPRINGLE*, and *TWINGLE*, *Ecochemie* in the Netherlands [120], a daughter of *Metrohm Autolab*, has brought a product family to the market dedicated to label-free measurement of biomolecular interaction processes, even in combination with electrochemical analysis. This business was outsourced to *Kinetic Evaluation Instruments BV* in the Netherlands [121]. This method is called *ESPR* (electrochemical surface plasmon resonance).

XanTec in Düsseldorf specializes in biosensor and bio-chip development [122], selling with their SPR Biosensor *SR7000DC* various chips and applications. *GWC Instruments* in Madison [123] offers Fourier transform and imaging SPR with applications to life science and material research, *Sierra Sensors* sells not only quartz micro balance sensors but also SPR equipment [124], and *DKK-TOA Corporation* [125] in Japan has entered the market with model *SPR-20. Biolin Scientific* [126] in Sweden in principle concentrates on quartz micro balance instrumentation. However, SPR is also part of their business, since this company acquired former *KSV Instruments* (Helsinki), which had long years of expertise in SPR development. These SPR *Navi*™ products are further developed by *BioNavis* [127] with applications in life sciences and material sciences. Recently, *Accurion* (former named *Nanofilm*) in Goettingen has developed an ellipsometric platform in combination with a SPR kit [128a]. It is called *nanofilm_SPR_microlab* and uses a cell design tailored for imaging ellipsometry and imaging SPR in the ellipsometric mode [128b].

29.3.9.2 Fiber and Waveguide SPR

Fiber-optic devices are attractive in many applications because they can be very small physically and provide remote operation and electrical isolation from the associated instrumentation. For these reasons, many designs for fiber-optic SPR sensors have been developed. They all rely on phase matching between the optical mode in the fiber and the surface plasmon wave. Since the control over the coupling angle is lost in a fiber, wavelength scanning is often employed. Slavik *et al.* [129] have shown that a wavelength-scanned fiber-optic SPR sensor can detect very low concentrations of proteins. They used a single-mode optical fiber with a cut-off wavelength of 724 nm, which was polished down to remove all but 500 nm of the cladding. The resulting device was coated with 65 nm of gold to support surface plasmons, and then with 19 nm of tantalum pentoxide to adjust the sensor's operating range to refractive indices between 1.329 and 1.353. This device was capable of detecting 40 ng ml^{-1} of human IgG using anti-human IgG antibodies immobilized on the sensor surface by cross-linking with glutaraldehyde.

A similar behavior is observed when a thin metal layer is coated on a planar waveguide. Harris and Wilkinson [130] have developed the theory of waveguide-coupled SPR sensors. Brecht and Gauglitz [131] have compared the performance of a waveguide-coupled SPR sensor against a grating-coupled waveguide, a channel waveguide interferometer, and a thin-film reflectance sensor for the detection of pesticides using a competitive assay format with anti-triazine antibodies. Instead of using a full spectrum scan, the intensity at a fixed wavelength was monitored. The limit of detection for triazine was found to be 0.15 ng cm^{-3}. Newer developments of fiber/SPR combination have been mentioned in Section 29.3.9.

29.3.9.3 Sensitivity and Applications of SPR-Based Biosensor Instruments

In a recent review by Homola *et al.* [73, 132], the analytical characteristics of various SPR instrumentation configurations have been compared with respect to the type of coupling (prism or grating) and the mode of measurement (angular, wavelength, and intensity read-out). In principle, the prism-coupler (Kretschman) configuration was assessed as being capable of yielding the highest sensitivity (in terms of refractive index change) in comparison to a grating-coupler-based set-up, particularly when the method of interrogation was based on intensity measurements. Lekkala and Sadowski [133] have used the Kretschmann configuration in conjunction with lock-in amplifiers for the highly sensitive detection of intensity changes at near-resonance conditions. The system was used for the optimization of antibody orientation on various lipid-modified surfaces [134].

Although the intrinsic sensitivity of SPR measurements (without any amplification schemes) had been initially assessed to be of the order of 1 nM or 150 μg l^{-1} for IgG [135], lower detection limits for small analytes have been reported [27, 136]. In most studies, equilibrium dissociation constants ranged from nanomolar to micromolar, with a few studies in the picomolar range [137, 138]. The resolution of

SPR measurements has, to some extent, been improved by using well-designed reference surfaces and sophisticated data-processing techniques [139]. SPR has been combined with other techniques, such as mass spectrometry [140] and atomic force microscopy (AFM) + electrochemistry [141]. Particularly, the combination of multichannel SPR with MALDI-TOF (matrix-assisted laser desorption/ionisation-time of flight) can be regarded as a powerful tool for proteomics research (Chapter 24).

In general, SPR-based biosensors have detection limits around 50 pM or 100 pg cm^{-2}. This is not always sufficient for the detection of low molecular weight analytes where concentrations fall below picomolar levels [142]. In such cases, amplification of the signal by sandwich assay formats or binding inhibition assays is presently the only solution. Already in 1988, Mandenius and Mosbach [143] had used quartz particles to amplify ellipsometric measurements of biospecific interactions. Similar labels, which have a large effect on the refractive index near the surface, will be suitable for use with SPR. For instance, Lyon et al. [144a] have described the use of colloidal Au nanoparticles to enhance the SPR response, through strong optical coupling between the film and the particle, achieving detection limits for human IgG down to 6.7 pM using a sandwich immunoassay format. Besides a large shift in incident angle, the colloidal gold gives a broadening of the plasmon resonance peak and an increase in minimum reflectance.

Combination of SPR with TIR increases sensitivity [145]. It was demonstrated that combining SPR and TIR devices to form a collinear, heterodyne interferometric system provided an enhanced sensitivity of real-time phase detection. Spatial variations of orientation of the reflected beam were also overcome. A refractive index sensitivity of $\approx 2 \times 10^{-7}$ was achieved. Small-angle applications in heterodyne interferometry use the two polarization states [144b]. Combination of surface plasmon resonance and total internal reflection ellipsometry (SPR-TIRE) is used for *in situ* monitoring of the growth of poly(*N*-isopropylacrylamide) brushes [144c].

29.3.10
Mach–Zehnder Interferometer

This optical detection principle combines interferometry with evanescent field effects. In substrate, waveguides are embossed, forming a bifurcation as shown in Figure 29.11a. In-coupled radiation, preferably from a laser, is split into two arms, one of which is covered with the biosensitive layer whereas the other serves as reference. The result is a phase shift ($\Delta\Phi$) dependent on the length L of the sensitive layer, its refractive index n, and the wavelength (given by the wave vector k). Details are given in [43]. Development, limits of measurable refractive index changes, modified arrangements, and comparison to other integrated optics devices have been reviewed recently [146a]. The resulting interferogram is shown in Figure 29.11b. *Lionix* in Twente supplies Mach–Zehnder interferometers commercially and gives some applications [146b].

The first applications to biosensing have been demonstrated [147, 148], and measurements of pesticides in water using immune reactions have been published [149]. Using surface structuring masks, parallelized waveguiding arms can be produced,

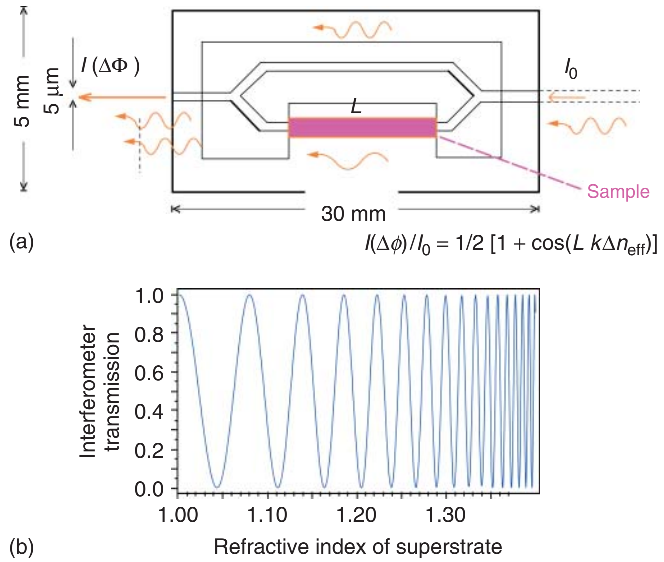

Figure 29.11 Mach–Zehnder direct optical biosensor with two waveguide arms, one covered with a biosensitive layer (a). The phase shift between this arm and the reference one causes an intensity signal at the outlet (left) dependent on refractive index, length L, and amount of interacting sample. This shift is schematically given below in dependence on the superstrate (b). (According to Ref. [15].)

which show good limits of detection combining grating in- and out-coupling with the Mach–Zehnder structure [150]. In principle, these devices are rather difficult to handle. Nevertheless, their high sensitivity makes them interesting for affinity sensing [151, 152]. Integration of microfluidics and using standard complementary metal-oxide semiconductor (CMOS)-compatible processed lab-on-chip systems have been realized to measure DNA [153a]. Modern applications are in the area of health care and point of care testing [153b].

To reduce the limit of detection, magneto-optic modifications have been patented [154] and parallelized. Applying external potential to the sensitive interferometer arm provides a zero phase-shift method, correlating the value of the external field to the analyte concentration. Since zero compensation is more sensitive in principle, better results are achieved [155, 156a]. An all-optic phase modulation system integrated in the Mach–Zehnder interferometer in general improves sensitivity [156b]. However, experimental expenditure increases [157].

29.3.11
Young Interferometer

If the two waveguide arms of the Mach–Zehnder interferometer are not combined, but form a free space arrangement, this device is called a *Young interferometer* [15, 158, 159]. The optical pathways are given in Figure 29.12a. The resulting

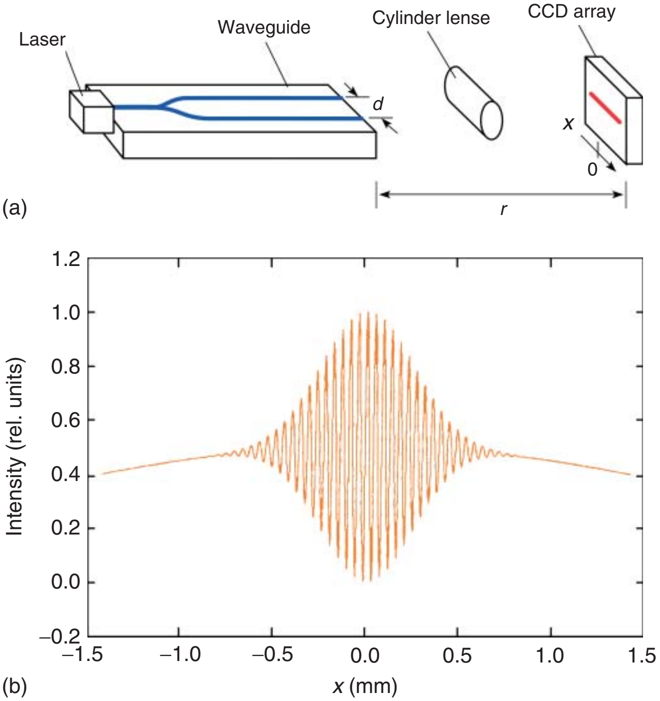

Figure 29.12 Young interferometer with free space optics (a). The resulting interference fringes are given below; this pattern shifts in the *x*-axis with changes in concentration of the interacting material (b). (According to Ref. [15].)

interference fringes of the superimposed partial beams leaving the two arms are given in Figure 29.12b. Such instrumentation was used to monitor an anti-human serum albumin/human serum albumin (α-HSA/HSA) immunoreaction in a microfluidic sensing system [160a]. Viruses can be detected [160b]. The biosensor was compared with others [161]. A dual polarization interferometer working as a Young interferometer has been realized [162].

A rather interesting modification uses two parallel waveguides in a chip in which radiation is coupled in by a grating and coupled out by another grating. This can be considered a free-space Young interferometer [163]. This principle can be seen in instrumentation commercialized by *Farfield* in Crewe (UK) [164] as a dual polarization interferometer (DPI). Polarized light from a laser is coupled-in down stacked waveguides. The evanescent field emanating from the top waveguide interrogates the immobilized molecules. Changes in the resulting optical interference pattern are caused by changes in the structure and/or mass of the immobilized molecules [165]. The *AnaLight®* instrument series provides a variety of instruments for biophysics and surface analysis in many applications [166]. It is used to interrogate DNA immobilization and DNA–small-molecule interactions in real-time [167].

29.3.12
Ring Resonators

It is known from attenuated total reflection spectroscopy used for absorbance sensors that the longer the interaction area, the better the signal-to-noise ratio. For this reason, the evanescent field absorbance sensor (EFAS) was a circular waveguide embedded in a glass substrate [168]. Accordingly, optical micro-ring resonators have gained much research interest in the last decade. Chip-based, stand-alone microsphere-based, and capillary-based opto-fluidic ring sensors are reviewed with a large number of technical modifications and biochemical applications [1].

The first applications to biosensing have been published in [169], modifying an integrated optics ring sensor for protein detection (avidin) at low concentrations (calculated detection limit: 0.1 nM (6.8 $\mu g\,l^{-1}$)). Liquid core optical ring resonators (LCORRs) use a glass capillary as both the fluidics and the ring resonator and show a measurable whispering gallery mode spectral shift of 30 pm/refractive-index-unit (RIU). This calculates a detection limit of approximately 10^{-6} RIU [170], allows quantitative real-time label-free detection of DNA sequences [171], and normally integrates optical ring resonator sensors into the microfluidic delivery system by using glass capillaries with a thin wall [172].

Other authors name similar sensing platforms that integrate the microfluidics and photonic sensing to an opto-fluidic ring resonator (OFRR) sensor. They demonstrate sensitive label-free virus detection [173] and use phage as a receptor for analyte detection [174]. Affinity selection from large libraries of random peptides displayed on phage provides a generic method of discovering receptors for detecting a wide range of analytes with high specificity and sensitivity. For such optical micro-ring resonators, numerical simulations of the distribution of the electromagnetic fields inside the waveguides, the micro-ring, and near the micro-ring surface have been done. Furthermore, all the functionalization reactions and the bio/non-bio interfaces have been studied and modeled by means of spectroscopic ellipsometry [175]. Finally, the design, fabrication, and characterization of an array of optical slot-waveguide ring resonator sensors, integrated with microfluidic sample handling in a compact cartridge, for multiplexed real-time label-free biosensing have been published [176].

29.4
Reflectometric Interference Spectroscopy (RIfS)

29.4.1
Principle

Reflectometric measurements are technically easy to perform and can yield useful information about thin films and their interfaces. The partial reflection of incident light from two interfaces of a thin film with a thickness of about 300–700 nm can function as a Fabry–Perot white light interferometer with low reflectance.

In the scenario depicted in Figure 29.13, the reflected light will show an interference pattern as a function of wavelength, according to

$$R = R_1 + R_2 + 2\sqrt{R_1 R_2}\cos\left(\frac{4\pi nd}{\lambda}\right) \tag{29.21}$$

where R is the reflectance, λ is the wavelength, n is the effective refractive index, and d is the effective physical thickness of the optical layer.

At the beginning, a white light source and a diode array were used to measure the spectral interference pattern according to Figure 29.13 (middle) and binding curves calculated from the spectrum shift on interaction as given in Figure 29.13 (right) [178, 179]. Among various algorithms for the evaluation of the interferograms, a polynomial fit proved to be the best [180]. After approximation of the cosine function in the wave number domain, the shift in extrema is correlated to the change in the product of refractive index and physical thickness according to

$$\Delta = \frac{4\pi}{\lambda} \times n \times d \tag{29.22}$$

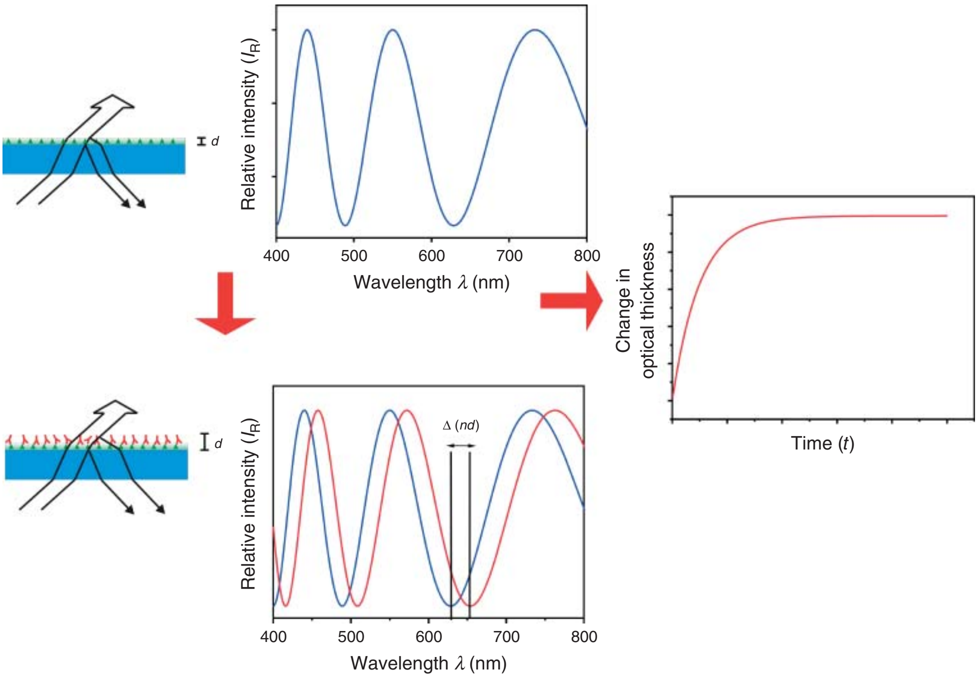

Figure 29.13 The principle of interference reflectometry at a thin film of increasing optical thickness: (left) The thin optical layer with several reflections from increasing optical thicknesses nd, changing physical thickness d by adding biomolecules gives (middle) the shift of the interference spectrum dependent on Δnd (top to bottom); from this shift the binding curve can be calculated (right). (Modified form from Ref. [177].)

This is the principle behind reflectometric interference spectroscopy, or RIfS. Evaluation can be more complex in multilayer systems, but can also be performed by means of Fresnel equations using matrix approaches for multiple reflections at interfaces of thin layer systems [181]. Fortunately, variation in temperature does not affect the signal, since increasing temperature increases the volume (physical thickness) and decreases the refractive index. Both effects nearly compensate each other; therefore, RIfS is only marginally dependent on temperature in contrast to other direct optical techniques based on read-out effects on evanescent fields. Owing to the high sensitivity of the detection, parts per million levels of phase shifts can be measured [182]. Thus, RIfS is a robust, simple, and potential low-cost direct optical detection technique. The principle was compared with other optical techniques and demonstrated limit of detections in the same order of magnitude as others [183, 184]. Also, affinity reactions of low molecular weight molecules such as biotin were detected [185].

29.4.2
Various Realizations

It could be demonstrated that spectral information can be substituted by just a few wavelengths to achieve simple and low-cost realizations. The spectrum was reduced to four selected wavelengths that supplied interpolation points for the parabola fit [186–188], and even a single carefully selected wavelength gives sufficient information [189]. Simulation allows finding the optimum wavelength depending on recognition layer and transducer properties [190]. This approach was transferred to a parallelized set-up improving the former solution, in which a microtiter format had been chosen [191] with a filter wheel sequentially selecting seven wavelengths. Avoiding the large and optically inconvenient microtiter plate format and using an object lens, a quantitative imaging system is achieved with approximately 700 spots cm^{-2} and noise representing less than 10 pm thickness incertainty which is equivalent to 2–5 pg mm^{-2} of biomaterial [192].

Latest developments focus on wavelength-selective detection using a multilayer semiconductor system, where the chip may be disposable in the future and which allows measurements at four wavelengths [193]. Such systems are planned to be used in point of care testing [194a]. A new technological approach together with application has been published using multilayer ‘‘photodiodes’’ to get wavelength-dependent detectivity [194b].

29.4.3
Applications

Starting with antigen/antibody interaction [195], in a next step immuno reactions were quantified [196] and RIfS was applied to directly measure triazine pollution of water [197, 198], opening new aspects in environmental analytics [199]. DNA–ligand interactions also can be quantified [200]. The ligand-induced assembling of the type I interferon receptor on supported lipid bilayers has been examined [201] and the adsorption of proteins on biomaterial surfaces has been quantitatively evaluated [202]. Some kind of RIfS has been used to rapidly detect mecA from methicillin-resistant *S. aureus* [203] and nucleic acid targets on optically coated silicon [204] as well as label-free oligonucleotides [205]. Biochips called *Fabry–Perot interferometer* have been examined [206]. Some additional applications have been reviewed in [207] recently. SPR and RIfS have been compared, giving practical tips for data evaluation and obtaining kinetic constants [208].

Another interesting approach is a Fourier transform version used as LC detector [209] for characterizing antibodies with respect to their affinity constants in affinity chromatography [210]. To qualify the surface modification, affinity constants of LNA (locked nucleic acid) and DNA duplex formation were determined [211] and endocrine receptors were examined [212];cell morphology also can be examined by RIfS [213]. Binding of ubiquitin to short peptide segments of hydrolase was studied in comparison to fluorescence correlation spectroscopy, isothermal calorimetry, and NMR [214].

Hyphenated techniques are frequently used in analytics. The spectroscopic detector can be substituted by RIfS, too. As in SPR, reflectometric interference can be combined with MALDI-TOF measurements by coating the glass type surface with ITO (indium tin oxide) to achieve a matrix for laser desorption; mixtures of the emergency antibiotics vancomycin have been examined [215]. Other applications are combining reflectometry and electrochemistry or applying electric field gradients along the optical chip. Electrophoretic flow conditions can be monitored [216] directly, since no metallic film is involved which would cause a breakdown of any applied electrical potential. Combining electrokinetics and reflectometric interference allows insights into hydrophobic and electrostatic interactions of fibronectins on biofilms and electrostatics of biopolymers [217, 218]. The combination of interferometry with AFM has been reported recently [219, 220]. A combination of infrared spectroscopy with RIfS, which apart from interaction kinetics also provides sample identification, is interesting [221a].

Reflectometry has been recently used to understand the interaction between cadmium and the estrogen receptor α [221b]. Label-free detection in high content screening [222] and the trends in fragment-based screening [223a] have been reported recently. In a very recent publication, reflectometric interference spectroscopy not only could be used to monitor and quantify bio-interaction processes but also to discriminate agonists and antagonists [11]. Further applications deal with label-free detection of C-reactive protein [223b] and the detection of whole cells [223c] and tumor cells [223d]. Auto antibodies directed against the β2-glycoprotein-I (β2GP-I) are known as the best markers for diagnosis of antiphospholipid syndrome (APS) ; however, detection of such antibodies is still a challenge and reflectometry can quantify the interaction process [223e].The use of molecular imprinted polymers allows monitoring in biotechnology [223f]. First applications of a parallelized set-up allowing the determination of kinetic data with up to 700 data points have been published [223g].

Commercialization of reflectometry has started a few years ago, later than SPR and with fewer companies. Reflectometric interference is a stripped-down ellipsometry method [224] that uses polarized radiation and is especially useful in characterizinge biolayers for biosensing [225, 226]. However, the technique is rather complex and not suitable for simple biosensing. Based on this principle, *Maven Biotechnologies* in Pasadena has developed the *LFIRE* [227] (Label-Free Internal Reflection Ellipsometry™), which allows precise real-time measurements of specific interactions between molecular entities in a microarray or well-plate format and combines the principles of ellipsometry and evanescent wave detection. However, the instrumentation thereby loses the advantage of simple RIfS of negligible temperature dependence. A typical application is given in [228] for reverse-phase protein arrays measuring antigen–antibody interaction or glycobiology. *ForteBio* [229] in Menlo Park avoids evanescent problems and utilizes proprietary biolayer interferometry (BLI). Coated fibers dip into the wells of a microtiter plate in this *OCTET* system and the read-out shifts in interference spectra for 16 wells are simultaneously measured to calculate binding curves. For applications, see [230]. Biametrics [231a] intends to bring a family of reflectometric interference instrumentation to the market, covering single-wavelength simple robust devices and quantitative imaging systems. At present, the single-wavelength system is on the market [231c] with its first applications [231b].

A rather special device is the *picoscope,* which in principle is based on correlation of two different interferometer positions [232a]. It can be combined with Fabry–Perot, Mach–Zehnder, or Michelson set-ups, and has also been used as a biosensor.

29.4.4
Ellipsometry

It had been mentioned that ellipsometry uses both polarization states of electromagnetic radiation to get more information on behavior of interaction processes at the recognition layer. Accordingly, some biosensor applications such as characterization and computational 3D reconstruction of flagellar filament protein layer structure [232b] or even gold nanoparticles enhanced ellipsometry have been published [232c].

Imaging ellipsometry has also been applied to monitor biomolecular interaction. A highly sensitive, label-free, real-time detection of the biomarker CA19-9 using microarray biosensors based on total internal reflection imaging ellipsometry (TIRIE) is published, in which anti-CA19-9 is immobilized onto the PEGylated phospholipid membrane [232d]. A special ellipsometry-based optical scanner for high throughput, label-free screening of small molecule compound libraries for protein-ligands in microarrays is discussed [232e].

29.5
Survey on Refractometry and Reflectometry

In recent years, direct optical detection techniques have gained increasing interest. Besides reviews on special methods, some manuscripts have been published that compare the different detection principles [233a]. Another review covers Mach–Zehnder interferometer, Young interferometer, diffraction optics, dual polarization, waveguide microresonators, SPR interferometry, and other reflective interferometry platforms including backscattering interferometry, also giving applications [233b]. A similar review is given focusing on point-of-care diagnostic applications [233c]. Refractometry as well as reflectometry measures the product of refractive index and optical thickness and its changes, respectively. Nevertheless, all the evanescent field techniques preferably determine the changes in refractive index and are dependent on good thermostating, accordingly. The advantage of reflectometry is the good independence on temperature, since changes in refractive index with temperature are widely compensated by changes in volume. Furthermore, reflectometry does not depend on penetration depth of the evanescent field into the observed medium, thus reducing problems of measuring layers thicker than 100 nm and, in addition, independent of layer thickness (evanescent field decays). For this reason, reflectometric techniques have gained interest for some bioapplications – also allowing easier parallelization.

29.6
Circular Dichroism

Circular dichroism (CD) is a form of light absorption spectroscopy that measures the difference in absorbance of right- and left-circularly polarized light (rather than the absorbance of isotropic light) by a sample in solution. CD is related to optical rotary dispersion (ORD), which is a variation of optical rotation as a function of wavelength. CD spectra recorded between 180 and 260 nm enable fast routine determination of secondary structural types in proteins, that is, the α-helix, parallel and antiparallel β-sheet, and β-turn content. Owing to the expanding markets for chiral compounds [233d], the use of CD spectroscopy in bioanalysis is expected to increase. Contemporary CD instrumentation allows levels of accuracy of 97% for the determination of α-helices, 75% for β-sheet, 50% for β-turns, and 89% for the other structure types. The most common application of CD is the study of conformation changes (secondary and tertiary structure). As such, the technique lends itself well to the study of folding and unfolding induced by temperature, pH, and chaotropic ions [234, 235]. Model synthetic peptides have been examined by CD to explore the physical basis of the formation of α-helix and β-sheets [236, 237]. CD is increasingly used to examine tertiary structural features of proteins through aromatic amino acid mutant proteins [238, 239]. The use of CD in membrane and surface adsorption studies has been, unfortunately, limited by differential light scattering and absorption flattening [240].

Vibrational circular dichroism (VCD) was developed as a supplementary technique in the 1970s, and is the IR counterpart of CD [241]. VCD measures the differential absorption of left and right circularly polarized IR light by chiral molecules. Since there are more spectral lines in the IR region than in the UV and each can have a chiral response, a more elaborate stereochemical and structural analysis is possible than on the basis of CD. Researchers have started to use VCD for conformational studies of all classes of chiral molecules, especially carbohydrates [242].

29.7
Other Optical Read-Outs

Even though cantilevers are no optical detectors, they should be briefly mentioned because they frequently use an optical read-out of force-dependent deflection of a cantilever, reflecting a laser source to a different angle [243–245]. Just a few applications are cited [246–249].

For measurements at membranes, nanotubes, or nanowires, mostly electrochemical methods are used [250, 251]. However, optical techniques can yield additional interesting behaviour effects in nanopores [252] or utilizing plasmon resonance scattering of nanocubes that are chemically coupled to a membrane [253].

Interesting approaches are combinations of electrochemical and optical read-outs [254, 255]. In the case of cell-based assays important to drug discovery processes, impedance and SPR measurements are considered in comparison [256].

Surface Plasmon Spectroscopy Methods and Electrochemical Analysis

Akira Baba and Rigoberto Advincula

30.1
Introduction

The surface plasmon resonance (SPR) optical technique is a powerful tool for the characterization and study of ultrathin films, interfaces, and kinetic processes on surfaces, and has been investigated in the applications of SPR sensors and plasmonic devices [1–5]. Many of these applications involve the increase in optical field by surface plasmon excitation at metal–dielectric interfaces. For example, in biosensor applications, this technique is used to investigate the adsorption–desorption of biomolecules onto surfaces and *in situ* time-dependent surface coverage [6].

The combination of SPR with electrochemical (EC) measurements has been demonstrated as a powerful analytical technique for the simultaneous characterization and manipulation of electrode–electrolyte interfaces [7–13]. In EC-SPR measurements, the gold substrate that carries the optical surface mode is simultaneously used as the working electrode in a standard three-electrode EC experiment. One of the advantages in using the EC-SPR technique is that the EC and optical properties are simultaneously obtained on surfaces and ultrathin films at the nanometer scale [14]. This involves the *in situ* monitoring of the film thickness and electrochromic properties during the anion doping–dedoping process of deposited conducting polymers. More recently, we have demonstrated the *in situ* electrochemical-surface plasmon resonance spectroscopy-atomic force microscopy (EC-SPR-AFM) technique for ‘‘real-time’’ dynamic and simultaneous acquisition of the dielectric (optical), surface morphological, and EC data of a depositing conducting polymer thin film at the electrode–electrolyte interface [15]. This enabled the differentiation of cyclic voltammetry (CV) and potentiostatically (chronoamperometrically) deposited films between their dielectric, EC, and morphological properties in real time.

The EC and optical quantitative analyses of π-conjugated polymer ultrathin films on oxidation–reduction and doping–dedoping are of great interest to a number of applications. This includes electrochromic displays [16], battery electrodes [17], sensors, and so forth. Many of these applications make use of the fact that the conductivity or color of the film can be controlled by its redox state [18]. On oxidation

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

(doping), thin polymer films become positively charged, with their conductive state. Several chromic states have been observed at various degrees of doping, but these have never been fully understood. Thus, due to their complex properties, it is very intriguing to obtain more information in a single experiment. As polymer films change their optical, electrical, and morphological properties on various redox states, we need to combine complementary techniques *in situ*. Furthermore, because of their high conductivity and specific redox properties, which are essential for biological communication [19], conducting polymers are sensitive materials for monitoring and manipulating biological interactions. The redox properties of the conducting polymers change during biological interactions, and this change can be detected either as an EC signal or as an optical signal. Electroactive conducting polymers also provide the media for electron transfer to the electrode, enabling the detection of EC signals. Hence, EC-SPR techniques are very powerful tool to monitor these properties [20–23].

In this chapter, recent developments and applications on SPR methods and electroanalysis are overviewed.

30.2
Combined Surface Plasmon Resonance Methods and Electrochemical Measurements

Figure 30.1 shows the attenuated total reflection (ATR) setup used for the excitation of surface plasmons in the Kretschmann configuration combined with an EC cell. When a *p*-polarized laser beam is reflected at the incident angle θ from the base of a prism above the critical angle θ_c, a strong nonradiative electromagnetic

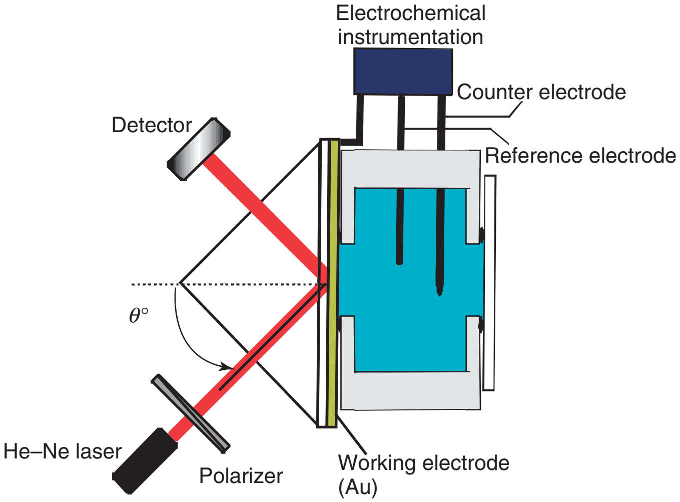

Figure 30.1 A schematic representation of the combined electrochemical-surface plasmon resonance spectroscopy setup.

wave is excited at the resonant angle. This surface plasmon propagates at the metal–electrolyte interface, with the coupling angle being given by the energy- and momentum-matching conditions between photons and surface plasmons. As the energy of the incident light is transferred toward excitation of the surface plasmon, a decrease of the reflectivity in the angular scan is observed. The resonance character of this excitation gives rise to an enhancement of the electric field at the interface by more than an order of magnitude, which is the origin of the remarkable sensitivity enhancements, for example, in scattered light [24], fluorescence [25, 26], or Raman spectroscopies [27, 28] when working with surface plasmon light. If the formation of a thin dielectric coating is observed *in situ*, for example, during the electropolymerization process of conducting polymers at the metal electrode–electrolyte interface, kinetic information can be obtained. This includes film deposition and diffusional transport of mass adjacent to the interface by cycling potentials. The experiment often involves monitoring the reflected intensity at a fixed angle of observation θ_{obs}. The Au–glass substrates used for the excitation of surface plasmons also serve as a working electrode in the EC measurements, with a counter and a reference electrode. For these experiments, the gold film thickness is chosen for optimum excitation of the surface plasmons with both wavelengths (42–45 nm).

30.3
Investigation of Electropolymerization Process of Conducting Polymer Thin Films by EC-SPR

First, the EC-SPR study during the electropolymerization of conducting polymer is shown. Figure 30.2 shows the cyclic voltammograms and SPR reflectivity curve with the first electropolymerization cycle. These were obtained at a concentration of 0.1 M aniline in 0.5 M H_2SO_4 with repeated potential cycling between −0.2 and 1.0 V at a scan rate of $20\,\text{mV}\,\text{s}^{-1}$. An increase in reflectivity with the SPR corresponds to the start of aniline oxidation as seen with the cyclic voltammogram. This was observed prominently in the anodic scan of the first cycle at about 0.8 V and is indicative of the oxidation of the aniline monomer to form polyaniline (PANI). From the SPR curve in the anodic scan of the first cycle, the slope can be divided into two regions, that is, 0.8–0.9 and 0.9–1.0 V. This corresponds to two separate phenomena, namely (i) the oxidation of aniline monomer started at the vicinity of the Au surface at 0.8 V; the SPR curve increased because the growing PANI film has a higher dielectric constant than aniline monomer and (ii) the growing PANI deposits and becomes insoluble to the H_2SO_4 solution at 0.9 V, that is, essentially precipitates out because of increasing chain length (PANI is insoluble to H_2SO_4 solution). In this way, the PANI was deposited onto the Au substrate, at the region where the SPR curve was steeper, that is, between 0.8 and 0.9 V. These phenomena are consistent with previous results using *in situ* electrochemical-quartz crystal microbalance (E-QCM) as reported by Park *et al.* [29]. They observed a time delay in PANI deposition with the oxidation peak of the cyclic

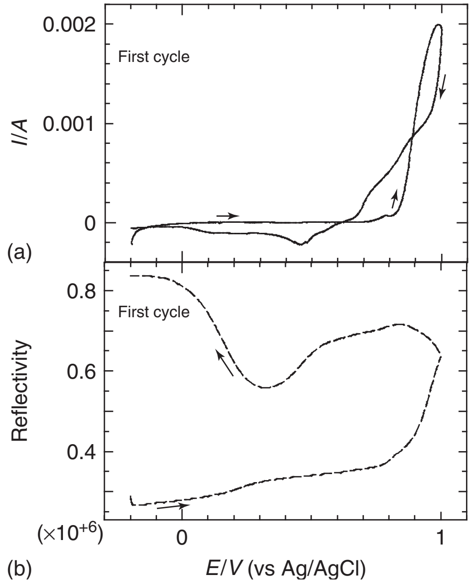

Figure 30.2 (a,b) Simultaneous observation of SPR kinetic curves and cyclic voltammograms during the electropolymerization of 0.1 M aniline in 0.5 M H_2SO_4 solution using repeated potential cycling between −0.2 and 1.0 V at a scan rate of 20 mV s^{-1}; first cycle. (From Ref. [6] with permission.)

voltammogram. For the cathodic scan of the first cycle, the SPR curve continued to increase until 0.88 V, then decrease until 0.52 V, and then subsequently increase again until 0 V. From the cyclic voltammogram, the first region corresponds to the reduction of deposited PANI. The reduction of deposited PANI causes the decrease of the SPR curve due to a change either in the dielectric constant or in film thickness [30]. The reflectivity in the SPR is high after anion dedoping. If the change of the SPR curve in this region is mainly due to the film thickness, the SPR curve should continuously decrease because of film contraction by anion dedoping and/or expulsion of water molecule into the solution. In this case, we believe that the behavior of the SPR curve is mainly due to the increase of the imaginary part of dielectric constant (refractive index). We have observed similar phenomena on our investigations with the layer-by-layer (LbL) PANI–sulfonate polyaniline film by using another surface plasmon technique [12]. This reduction region of the SPR curve consistently decreased during second and fifth redox processes in cathodic scans.

EC-SPR has been applied for *in situ* optical/EC investigations in order to determine the complex dielectric constants of conjugated polymer thin films. In order to be quantitative to all parameters of the films, that is, its thickness and real and imaginary parts of dielectric constant, we used EC-SPR data taken under potentiostatic measurement conditions. In Figure 30.3, the potentiostatic SPR scans are shown for both $\lambda = 632.8$ nm and $\lambda = 1152$ nm. Some very interesting information was obtained from the analysis of these curves. Firstly, it is noticeable

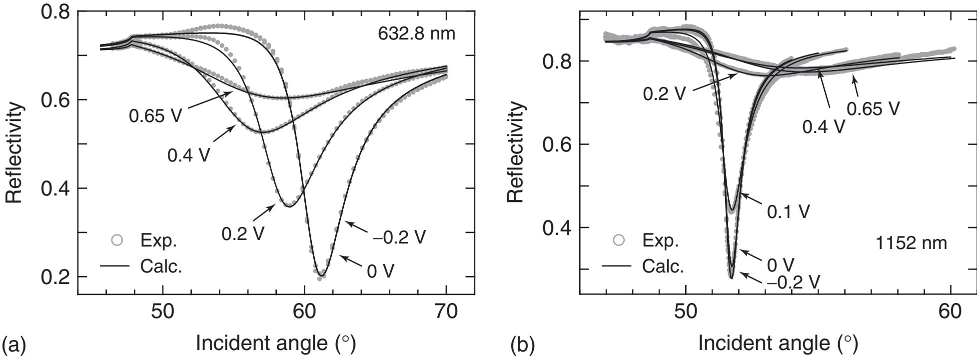

Figure 30.3 (a,b) Experimental angular SPR reflectivity curve (dotted) and calculated curve (solid) under applied potential at 632.8 and 1152 nm, respectively. (From Ref. [8] with permission.)

that the change in the reflectivity curves at around 0.2 V occurs when the PANI "base" film changes, on doping, into the corresponding conducting PANI salt. This process is reversible and many cycles can be performed without any noticeable variation (except for any degradation processes). If the film, in the absence of monomers, is kept at 0.9 V, the behavior of SPR is again likened to that of the insulating state, and subsequent SPR scans at 0.65, 0.4, −0.2, 0.4, and 0.65 V showed no difference. This indicates that in the absence of the aniline monomer, oxidation at potentials higher than 0.65 V leads to an irreversible degradation of the EC response of the PANI film.

As it is difficult to obtain independent information on the thickness and the real and imaginary parts of the dielectric constant from mere SPR measurement, we also used the quartz crystal microbalance (QCM) in a potentiostatic mode of the measurement. As explained earlier, the Sauerbrey equation [31] could be applied to relate frequency shifts to mass changes. The corresponding thickness is roughly estimated on the assumption of a mass density of 1.3 g cm^{-3} [32] for comparison with the EC-SPR results. In contrast to that of the SPR reflectivity curves, which show a large change at 0.2 V, the thickness from the QCM measurement was found to be roughly constant between −0.2 and 0.2 V. The loss of film thickness at 0.9 V was found to be 38% after 3 min. Fitting the experimental SPR reflectivity results with the thickness values obtained from QCM measurement (except the value of 0.9 V) gives the theoretical reflectivity curves that are also shown in Figure 30.3. The calculation was carried out by using Fresnel's equations for a Prism/Cr/Au/PANI/electrolyte solution architecture. Details for the fitting procedure can be found elsewhere [1]. Although the surface plasmons (SP) resonance at $\lambda = 1152$ nm is very broad at high potential, excellent fitting curves were obtained in most cases. The obtained fitting parameters are shown in Figure 30.4. Dramatic changes in both the real and the imaginary parts of the dielectric constants were determined at both wavelengths. The error bars in Figure 30.4 are based on the density fluctuation of the polymer on doping–dedoping, that is, 1.25–1.35. On

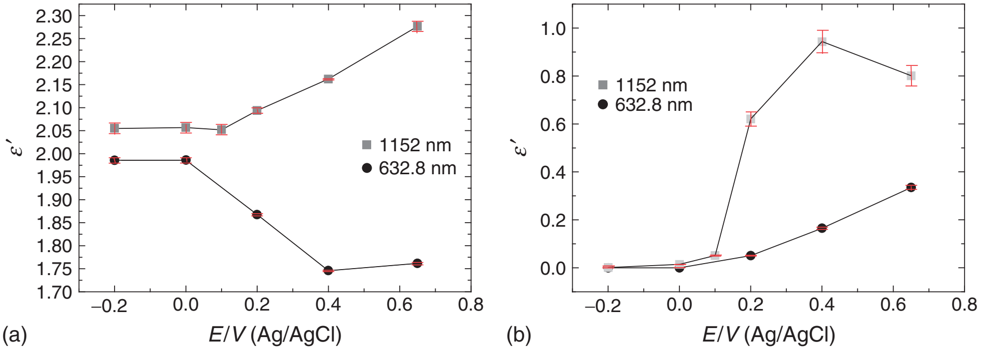

Figure 30.4 (a) Real part (ε') and (b) imaginary part (ε'') of dielectric constants at several potential. (From Ref. [8] with permission.)

the basis of these calculations, the accuracy for the determination of the complex dielectric constant is estimated to be better than ±0.02 for the real part and ±0.10 for the imaginary part of the dielectric constant in this density range, that is, EC-SPR measurements are able to determine the complex dielectric constants of the conducting polymer films in the doped–dedoped state rather independently of the uncertainty in the film density. Thus, the electrochromic phenomena of PANI films can be characterized by this EC-SPR technique with high sensitivity, which may lead to new designs for SPR-based sensors/biosensors based on the electrochromism of thin conducting polymer films.

30.4
Electrochemical SPR-surface plasmon light scattering (SPLS)

The incident light enhanced by surface plasmons and scattered off the substrate–electrode interface also enabled us to investigate the changes in the roughness of the conducting polymer films on the potential cycling. Light scattering due to the roughness of the electrode and/or deposited PANI/surfonate polyaniline (SPANI) LbL film enhanced by surface plasmons was detected by the photomultiplier detector, which was set on the backside of the prism.

Figure 30.5 shows the cyclic voltammogram, SPR, and surface plasmon field enhanced light scattering (SPFELS) data of four bilayers PANI/SPANI in 0.5 M H_2SO_4 solution during potential cycling from −0.2 to 0.9 V at a scan rate of $100\,\mathrm{mV\,s^{-1}}$. The solid line shows the cyclic voltammogram, the dashed line shows the SPR, and the dotted line shows the SPFELS curves. As reported by Orata and Buttry [33], the first redox process (at 0.22 V in the anodic scan and 0.13 V in the cathodic scan) corresponds to anion transport, that is, anion doping and dedoping, from the electrolyte solution to the PANI/SPANI film. The second redox process (~0.8 and 0.75 V, respectively) simply corresponds to the imine nitrogen deprotonation and protonation, that is, protons in the PANI/SPANI film are expelled into the electrolyte solution and inserted into the PANI film, respectively. The anion is also

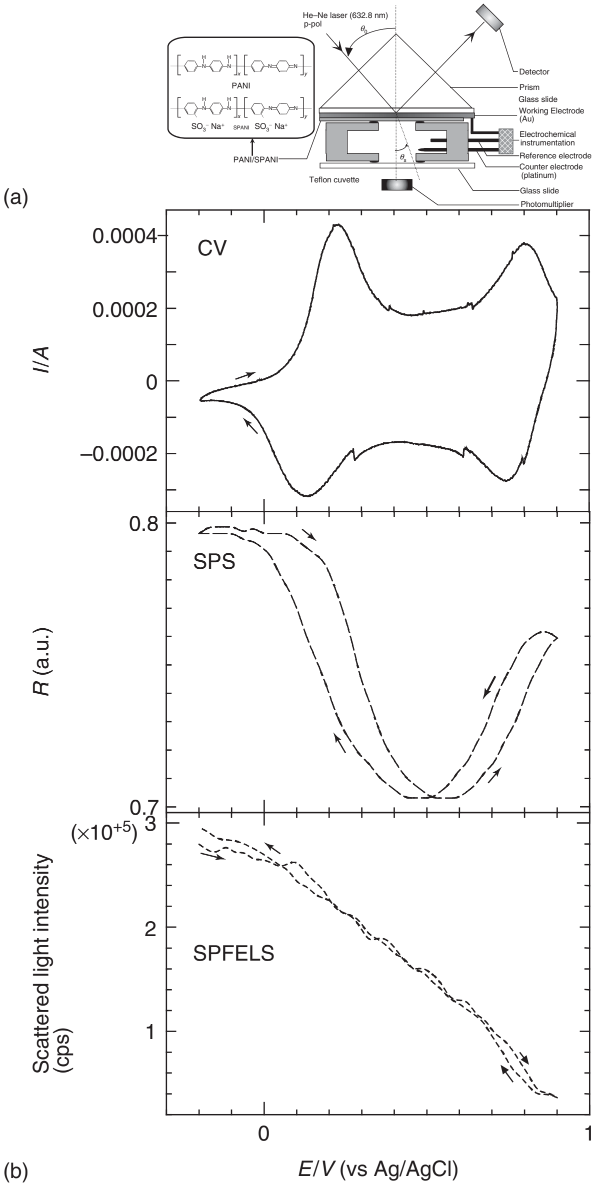

Figure 30.5 (a,b) Simultaneous observation of cyclic voltammogram, SPR curve, and SPFELS curve of four double layers of PANI/SPANI film during the potential cycling in 0.5 M H_2SO_4 solution at a scan rate of 100 mV s^{-1}. (From Ref. [27] with permission.)

inserted during the protonation of PANI/SPANI film and expelled from the film during the deprotonation as a counterion to the iminium cation formation (doping).

The SPR reflectivity decreases during doping by the anion and increases during dedoping of anion for the deposited PANI/SPANI, respectively. Moreover, an increase in the SPR during the deprotonation and a decrease during the protonation can be observed in the anodic and the cathodic scans, respectively. In this experiment, using E-QCM, Orata and Buttry [34] observed an increase in the film mass by the doping and a decrease in the film mass by the dedoping of the ion. This can be associated with changes in the density of the film or in its thickness. However, in our SPR measurements, the SPR reflectivity was observed to decrease by the doping with the ion. Normally, if measured at the low-angle slope of the reflectivity curve, an increase in SPR reflectivity is related to an increasing thickness assuming a constant refractive index. In this case, we believe that the dielectric constant plays a major role in the behavior of observed SPR reflectivity. From the above-mentioned observations, three possible explanations for the change of the SPR curve by anion doping–dedoping process can be considered. This includes the *thickness change*, Δd, of the PANI/SPANI film by anion doping–dedoping and the other two, the dependence of the reflectivity curves for *different dielectric constants*, ε_r and ε_i. If the change in thickness of a PANI/SPANI film is the main component of the SPR curve change, the reflectivity should increase during doping (if measured at angles lower than the resonance) because the insertion of the anion and, simultaneously, of water molecules into the PANI/SPANI film will result in film swelling. This was not observed in our data. Therefore, we believe that the change of the SPR curve in Figure 30.5 is dependent primarily on the change of the dielectric constants, ε_r, and ε_i of the PANI/SPANI film and not of its thickness. This finding then indicates that the dielectric constant of the PANI/SPANI film *decreases* on ion doping and increases on ion dedoping. These observations are consistent with a trade-off between the Δn and the Δd components of the SPR data. We consider this to be consistent with the E-QCM data by Orata and Buttry [34] where ion doping results in an increase in film mass and density (insertion of ions and protonation), thereby decreasing the dielectric constants but not necessarily increasing the optical thickness of the film as monitored by SPR.

30.5
Electrochemical SPR-SPPL

The combination of SPR and surface plasmon-enhanced photoluminescence spectroscopy (SPPL) with electrochemistry was demonstrated for the detection of weak photoluminescence materials such as poly(3,4-ethylenedioxythiophene) (PEDOT) films [35]. In this case, surface plasmons were excited at the metal–dielectric interface, on total internal reflection of polarized light from an He–Ne laser at a wavelength of 594 nm. SPPL from the deposited film was detected by a photomultiplier after passing through a low wavelength cutoff filter ($\lambda = 610$ nm) as schematically shown in the inset of Figure 30.6.

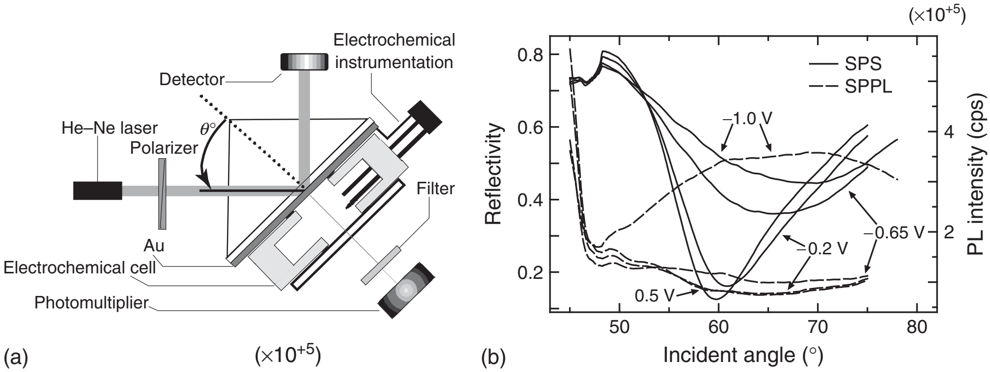

Figure 30.6 (a,b) Angular SPR and SPLS curves of a PEDOT film (solid curve: SPR; dotted curve: SPLS). (From Ref. [36] with permission.)

A most important question in this investigation is whether the photoluminescence can be detected from an ultrathin PEDOT film in the dedoped state. The He–Ne laser of 2.1 eV ($\lambda = 594$ nm), which correspond to the average transition energy from the valence band to the conduction band obtained from UV–vis–near infrared (NIR) spectra, was chosen for the excitation of surface plasmons. The angular measurements were performed under equilibrium conditions with several potentials being held constant. The SPR and SPPL curves of a thin PEDOT film at four different potentials are shown in Figure 30.6. For these measurements, an ultrathin film was prepared intentionally in order to excite the photoluminescence with the evanescent field associated with the surface plasmon mode. The thickness of the film was about 25 nm as deduced from Fresnel fitting curves. From the spectra in Figure 30.6, we can see that the minimum angle of the reflectivity curve increased with increasing negative potential. The minimum angle of the SPR resonance curve for the ultrathin film increases on decreasing the potential from 0.5 to −1 V, which indicates an increase of the real part, ε', of the dielectric constant ($\varepsilon' + i\varepsilon''$) of the PEDOT film. Furthermore, the SPR reflectivity curves significantly broadened at negative potentials. In SPR measurements, curve broadening is either due to an increase of the imaginary part of the dielectric constant, ε'', or to surface roughness. If this broadened curve would be due to surface roughness, the scattered light intensity enhanced by SPR should also increase. As, in our light scattering measurements, an increase of the scattered light intensity was not observed at negative potentials, this result indicates that the electrodeposited thin PEDOT film has a smooth surface, in which the surface roughness does not change with potential. Therefore, the broadening of the SP reflectivity curve is mostly due to an increase in the imaginary part, ε'', of the dielectric constant. This agrees with the observation that the absorption at 2.1 eV increased with negative potentials, that is, on dedoping.

To observe photoluminescence from the conducting polymer film, we needed to use a laser with a higher photon energy than the electronic bandgap energy, that is, in the region that has a strong imaginary part of the dielectric constant. At the same time, the excitation of a surface plasmon is required in order to enhance the electromagnetic field at the Au/PEDOT/electrolyte interface. However, a strong imaginary part of the dielectric constant dampens the excitation of a surface plasmon. An important point in this system is that the surface plasmon is still excited at the dedoped state (−1.0 V), which is only possible because we are dealing with an ultrathin film. Therefore, we can generate an evanescent optical field at the Au/PEDOT/electrolyte interface. The EC-SPPL measurements clearly show the different photoluminescence (PL) intensity properties at different potentials. Indeed, photoluminescence from PEDOT was observed in the dedoped state (−1.0 V) as shown in Figure 30.6. On the other hand, no significant PL intensity was observed at 0.5, −0.2, and −0.65 V. As can be seen, the SPR curve is sharper in the more doped state, which means that the enhanced optical field for the Au/PEDOT/electrolyte system is stronger in the more doped state. However, the enhanced optical field at 2.1 eV is not expected to generate an appreciable $\pi-\pi^*$ transition at 0.5, −0.2, and −0.65 V, and the presence of increased charge carriers might quench the generated exciton. Consequently, no enhancement of luminescence was observed. One possible explanation for the finding that can detect the weak photoluminescence by the EC-SPR/SPPL technique is that the strongly enhanced optical field by the excitation of surface plasmons overcomes the dissipation of the photoluminescence (very low quantum efficiency) in the ultrathin PEDOT film. Another advantage for the use of EC-SPR/SPPL is that we can obtain a strong variation of the photoluminescence by changing the incident angle.

To study the relation between the reflectivity and the photoluminescence, the chronoamperometric measurements using EC-SPR/SPPL were performed. The response of an ultrathin PEDOT film to a sequence of potential steps applied is shown in Figure 30.7. The potential was switched sequentially between the doped and the dedoped states, that is, applied in the following sequence: $0.5 \rightarrow -0.2 \rightarrow 0.5 \rightarrow -0.5 \rightarrow 0.5 \rightarrow -1.0 \rightarrow 0.5$ V. Each potential was applied for 20 s. Characteristic changes were observed in the SPR reflectivity and in the SPPL intensity. The reflectivity increased and decreased when the PEDOT film was dedoped and doped, respectively, whereas the increase of the SPPL signal was observed only when the potential was held at −1.0 V. This observation is quite interesting because it gives direct evidence of the differences between the SPR reflectivity and the SPPL emission. The phenomenon would be very useful in designing optical switching devices because we can obtain three independent signals by this technique. This switching property is in accordance with the result obtained from angular-reflectivity measurements. The reflectivity changed almost immediately if the potential step was applied, and reached a plateau characteristic for each potential applied. On the other hand, the SPPL intensity continued to increase gradually during the applied potential at −1.0 V. The change of the dielectric constant due to the dedoping should be a very fast process: the dielectric constant changed quickly and remained constant. One possible reason for the continued increase of the SPPL intensity is that during the applied potential at −1.0 V, the anion, which quenches the PL intensity in the PEDOT film, moved to the electrolyte solution, so that the PL intensity continued to increase at −1.0 V. Another possible

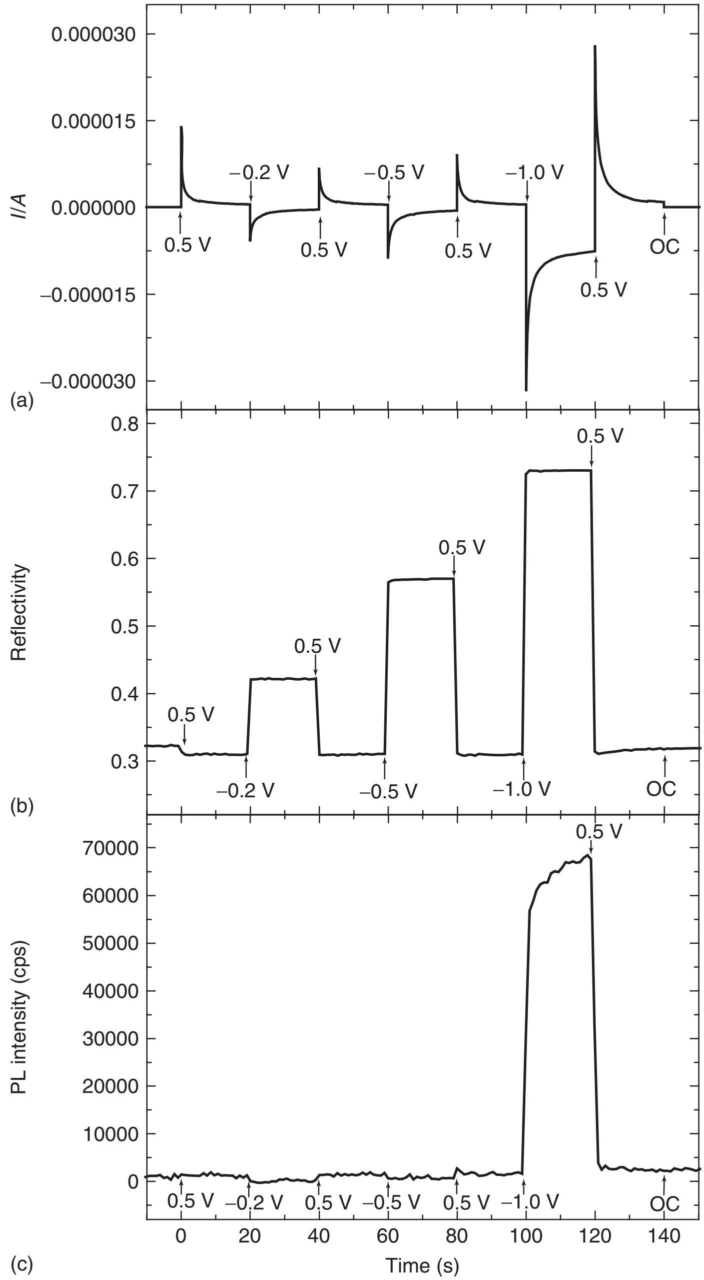

Figure 30.7 (a–c) Chronoamperometric measurements of a PEDOT film switched sequentially between the doped and the dedoped states (0.5 → −0.2 → 0.5 → −0.5 → 0.5 → −1.0 → 0.5 V), respectively. (From Ref. [36] with permission.)

explanation is that the injected charge carriers (leading to recombination and photoemission) might contribute to the enhancement of the light emission process. In fact, a negative current was observed even after 20 s. Even in the dedoped state, an electronic current is expected to exist together with the ionic current [37]. Note that the irradiated area for the excitation of surface plasmons is about 0.010 cm^2, whereas the electrode area is 0.785 cm^2. Therefore, the observed current cannot be mainly assigned to the photocurrent.

30.6
Applications to Biosensors

30.6.1
Glucose Sensing

Electrically conducting and π-conjugated polymers have been shown to be highly sensitive materials for monitoring and mediating enzymatic interactions. This is attributed to the high conductivity and specific EC redox properties of conducting polymers, which can be paired with redox events present in enzymatic reactions [38–40]. For example, the redox property of conducting polymers changes on reduction of the enzyme glucose oxidase (GOx). This change can then be detected either as an EC signal or as an optical signal. On introduction of glucose, GOx is reduced and glucose is converted to gluconic acid (gluconolactone). In the conventional glucose sensors without conducting polymer mediators, the reduced GOx drives the conversion of O_2 to H_2O_2, in the presence of O_2. The H_2O_2 can then undergo oxidation to give H_2O. On the other hand, in the case of with conducting polymer mediators, the oxidation of a reduced chemical species/polymer material can be directly measured by an electrode surface. Thus, electroactive conducting polymers can be considered as ‘‘wiring’’ materials for the EC activation of redox enzymes [41]. Redox enzymes usually have poor direct electrical conductivity contact and communication with metallic electrodes. An electroactive conducting polymer provides the matrix for electron transfer from the enzyme to the electrode, correlated with changes in the EC (I–V) signal. We have endeavored to apply a combined EC-SPR and waveguide approach to enable better differentiation of these factors. Firstly, a water-soluble, positively charged *N*-alkylaminated polypyrrole was synthesized for pairing with the negatively charged GOx. The composite enzyme electrode was fabricated by the assembly of the polypyrrole and the GOx via the LbL electrostatic self-assembly technique [42–44]. As compared to as-deposited LbL film, it was observed that an enhancement in sensitivity for an SPR/amperometric sensor can be achieved by taking advantage of the doping–dedoping effect of these films in a neutral buffer solution condition. As the LbL film can be homogeneously assembled, dips from both SPR and waveguide were obtained when the thick film was fabricated. We have harnessed the EC-SPR technique for demonstrating a glucose biosensor with possible applications for other enzymatic biological optoelectronic differentiation [45].

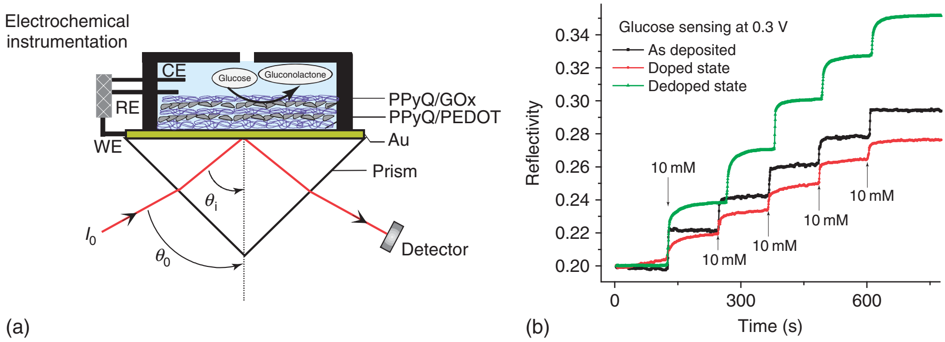

Figure 30.8 (a,b) SPR glucose sensing as a function of concentration (time) at different doping states. (From Ref. [42] with permission.)

As the electrochromic property was obtained in neutral solution, it should be possible to carry out glucose sensing after doping, dedoping, and at the as-deposited states as shown in Figure 30.8. The sensing was carried out in neutral buffer on the addition of 10 mM of glucose every 5 min. As shown in this figure, the change of the optical signal was different by changing the doped–dedoped state before the sensing. This indicates that the doped–dedoped state did not move back even the potential was set at 0.3 V during the sensing experiment. This is probably because the ions are more difficult to move out the LbL films in phosphate buffer solution (PBS) solution. Furthermore, this result indicates that the dedoped state has the highest reflectivity change. This is not counterintuitive as the polypyrrole film is oxidized in the glucose sensing (reduction) event and thus the dedoped state shows the highest change, that is, from a dedoped state to a more doped state. The results obtained also highlights the fact that the change of reflectivity can also be controlled by the doping state of the conducting polymer films. It should be noted that the magnitude of this shift is also a function of the electrochromic behavior of the films and the wavelength of the light source for the ATR experiment.

30.6.2
Detection of Catecholamine

The development of real time and selective detection of catecholamines faces many challenges, despite a high demand for such a technique in the diagnostic field. Catecholamines, such as adrenaline, noradrenaline, and dopamine, are adrenal cortical hormones and neurotransmitters involved in central and peripheral neuroendocrine responses to different types of stress [46, 47]. They are also related to the sympathetic medullar system, which is particularly sensitive to mental and physical stresses [48, 49]. Until now, high-performance liquid chromatography (HPLC) with EC [50–52] or optical [53] detections has been frequently used to detect catecholamines. Although catecholamines can be selectively detected from ascorbic acid and uric acid by the HPLC technique, this method requires a pretreatment process, and the detection measurements take time. Recent research has explored

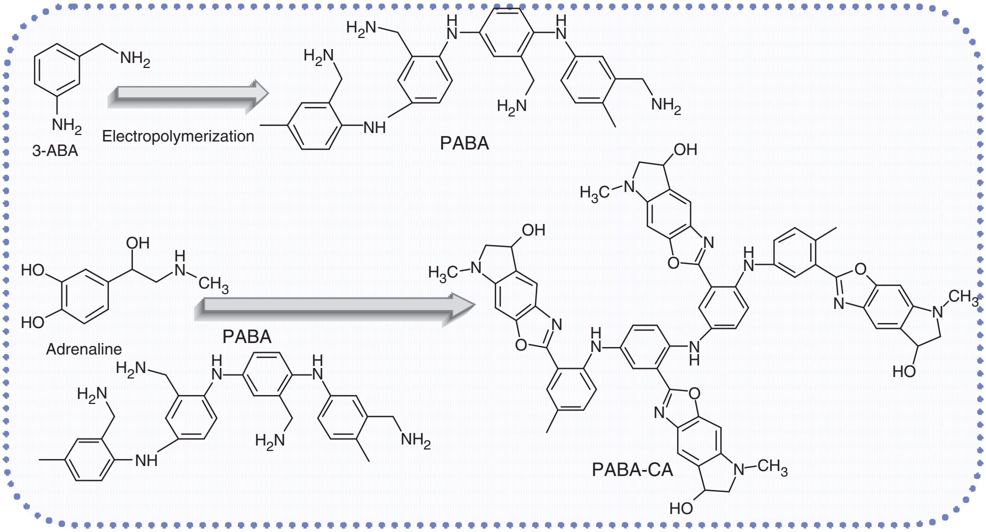

Figure 30.9 Strategy of immobilization of PABA film on electrode and the specific reaction of adrenaline to PABA.

the use of materials such as gold nanoparticles [54, 55], carbon nanotubes [56, 57], and CdSe nanocrystals [58] for the optical detections of catecholamines to obtain lower limit of detection or selectivity [59]. These methods involve distinct adsorption, optical emission, and optical quenching properties. We have reported a real-time detection of optical and EC signals from the specific reaction of adrenaline, which is used as one of the catecholamines, on para-amino benzoic acid (PABA) by EC-SPR. Benzylamines present in the structure of the PANI derivative, PABA, act as specific reaction sites for adrenaline, enabling detection of both optical and EC signals by the surface-sensitive EC-SPR technique, as shown in Figure 30.9 [60]. PABA was electropolymerized from electroactive 3-aminobenzylamine (ABA) monomers. The deposition process was investigated by EC-SPR. Electroactivity of PABA was confirmed from CV in PBS solution, indicating that the signals can be enhanced in the event of specific reactions with adrenaline. The reaction of adrenaline with PABA was studied by UV–vis spectroscopy and X-ray photoelectron spectroscopy (XPS) measurements, and adrenaline was detected within the PABA film by the EC-SPR technique. Signal enhancements were obtained in the case of PABA mediator, while PANI thin film, which was also electropolymerized, showed small enhancement, when the adrenaline was injected into each system. Furthermore, EC-SPR properties exhibited a distinct response for the adrenaline as compared to that for uric acid and ascorbic acid.

The SPR reflectivity and current responses on the detection of adrenaline were obtained at a constant potential of 0.65 V. Figure 30.10a,b shows simultaneous observation of current and SPR reflectivity changes on injection of 100 μM, 1 mM, and 10 mM adrenaline. The current responses exhibited a rapid increase followed by a gradual decrease, corresponding to the transient characteristics of electric double

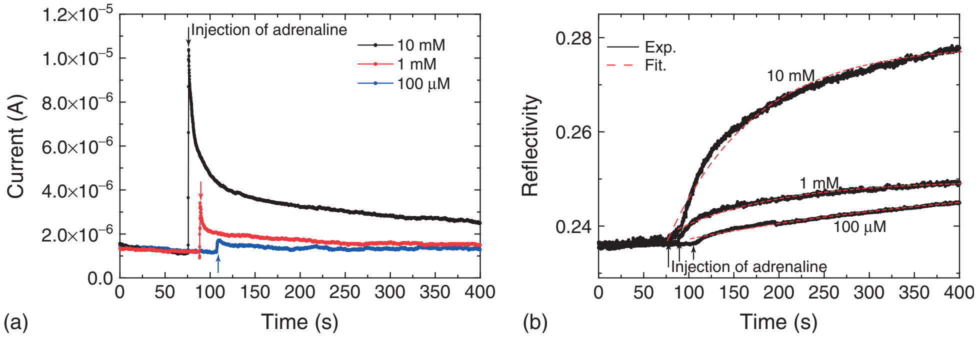

Figure 30.10 Simultaneous observation of (a) current and (b) SPR reflectivity changes on injection of 100 μM, 1 mM, and 10 mM adrenaline. (From Ref. [57] with permission.)

layer reformation at PABA–solution interface and the diffusion of adrenaline. An increase in anodic current was observed as the concentration of adrenaline increased. A gradual increase in the SPR reflectivity, which measures the binding reaction of adrenaline to the PABA film, was observed on injection of adrenaline. As the binding mechanism is based on the chemical reaction between benzylamine and adrenaline, each adsorption SPR reflectivity curve was analyzed using a kinetic model within the Langmuir approach [61, 62]

$$R(t) = (R_{\max} - R_0)\ \left\{1 - \exp\ \left(-k\ c_0\ t\right)\right\} \tag{30.1}$$

where $R_{\max}$ is the reflectivity measured at maximum coverage of the probes at the adrenaline concentration c_0, R_0 is the initial background reflectivity, k is the association rate constant, and $R(t)$ is the time-dependent reflectivity during the adsorption process, which is assumed to be proportional to the number of probe sites occupied by adrenaline at time t. As indicated by the solid lines (Figure 30.10b), the theoretical curves fit well with the experimental kinetic curves for all concentrations. In all cases, the R_2 was higher than 0.97. The k values are 1.0, 8.7, and 27 $\mathrm{M}^{-1}\,\mathrm{s}^{-1}$ for 10 mM, 1 mM, and 100 μM, respectively. The k values derived from the kinetic trace at different concentrations show a decrease with increasing concentration. This might be due to the increasing charge density on the specific reaction of adrenaline with the benzylamine in PABA. This corresponds with XPS and UV–vis results, indicating that the doping state of the PABA film changed after the reaction.

Figure 30.11a,b shows calibrated double-logarithmic plots of the change of the current and reflectivity as a function of concentration. The plot for the current demonstrates that the change in the signal is a linear function of the adrenaline concentration. This result indicates that the current response for the adrenaline detection in this system can be followed within the standard catalytic reaction equation [63, 64]. In the plot of SPR reflectivity change, the relation was also linear to the concentration of adrenaline, while the fitting for SPR kinetic curves shown in Figure 30.5 was carried out within Langmuir adsorption

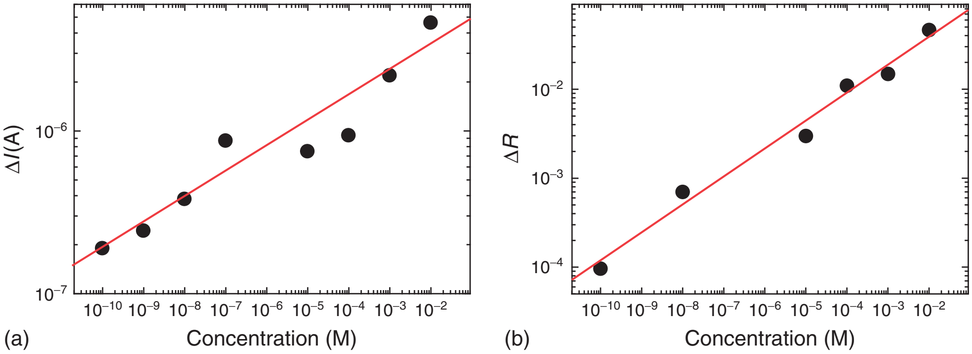

Figure 30.11 Calibrated double-logarithmic plots of the change of (a) the current and (b) reflectivity as a function of concentration. (From Ref. [57] with permission.)

model. This result of log–log plot indicates that the relation corresponds well with extended Langmuir model, that is, Langmuir–Freundlich model further than simple Langmuir model [65–67]. This might be because the PABA film has specific reaction site, benzylamine, not only on the surface but also inside the PABA film. The detection limit in the experiment was determined to be 100 pM from the response with the signal-to-noise ratio of 3 for current response and 10 for SPR reflectivity response.

30.7
Conclusions

In this review, we introduced the combination of SPR methods and EC analysis, which was further combined with a variety of surface-sensitive techniques such as light scattering and photoluminescence for the study of conducting polymer thin films. Their applications to biosensors were also introduced. Besides the combined techniques with EC-SPR shown in this review, other novel combinations such as with scanning EC microscopy [68, 69], microfluidic devices [70], and electrochemically tunable SP-enhanced diffraction gratings [71] have been reported for the study of polymer thin films or sensor applications. In these studies, two surface plasmon excitation methods, that is, prism-coupling method based on Kretschmann configuration and grating-coupling method, were demonstrated.

The introduced method should provide new opportunities both for basic studies and for sensor applications using conducting polymers.

Applications of Fourier Transform Infrared (FTIR) Imaging

Al de Leon, Brylee Tiu, Joey Mangadlao, Katrina Pangilinan, Pengfei Cao, and Rigoberto Advincula

31.1

Introduction

Fourier transform infrared (FTIR) spectroscopy is a common method used to ascertain the molecular identity and composition of a sample. The technique relies on the absorption in the 2–15 μm^{-1} regions of the electromagnetic spectrum resulting to excitation of vibrational, rotational, and bending modes of constituent chemical moieties. The general selection rule for IR spectroscopy is the change in dipole moment during vibration. Although FTIR by itself offers a number of utilities in chemical characterization, coupling it with a microscope allows the elucidation of a chemical structure in a specific spatial region. This technique is called *FTIR microspectroscopy* or simply *FTIR microscopy*. In principle, the combination of spatial specificity and information on chemical makeup allows the construction of an FTIR map or FTIR image (a chemical map) providing information on the distribution of chemical species, morphological assemblies, diffusion profiles, and concentration gradients.

It is important to delineate the difference between FTIR mapping and FTIR imaging. FTIR mapping, also called *point mapping*, is a point-by-point measurement across the sample to obtain spatially resolved information [1]. In detail, an IR spectrum is collected at a particular point, and then the sample is moved to collect the spectrum of another location. The process is repeated within the area of interest. The spectra are then correlated by a computer to a specific and reproducibly obtainable sample position [2]. While a very good signal-to-noise ratio for very small single-point sample areas can be obtained, the method suffers from a number of limitations: firstly, low-spatial resolution at sample areas is restricted to squares $>15 \times 15\,\mu m^2$ [1, 2]. Secondly, diffraction effects and stray light compromise accuracy of the data.

Finally, as the technique is essentially a sequential mapping process, carrying out the analysis takes a long time and requiring very precise X–Y positioning and image reconstruction. In effect, studying dynamic processes with FTIR mapping is extremely challenging.

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

FTIR imaging, on the other hand, was primarily developed to overcome the limitations of FTIR mapping. The use of focal plane array (FPA) detectors in FTIR imaging affords simultaneous collection of spectra at a single experiment thus, a “chemical snapshot” is obtained [1]. FPA detectors consist of a large number of small detectors laid out in a grid pattern. The spectrum, simultaneously acquired by each detector, is represented as a single pixel in the resulting FTIR image. As a given field of view is imaged in a single collection, the sample does not need to be moved and the use of aperture is not required to limit the sample area, and hence, the occurrence of stray light, which compromise spatial distribution, is eliminated [3]. In addition, in FTIR imaging, the collection time is decreased by a factor of n^2, where n is the number of spatial resolution elements in one direction of a square sample area imaged [3]. Koenig *et al.* [3] illustrated that a $500 \times 500\,\mu m$ sample area will take 10 h if it were analyzed by FTIR mapping, while it will only take less than a minute for FTIR imaging with the same image quality and spectral resolution. In addition, the use of mosaicking or assembly of several FTIR images enables sampling over a wider area. Thus, spatially and temporally resolved chemical information can be obtained. In combination with chemometrics or time-resolved studies, it makes a very powerful analytical technique.

Figure 31.1 shows the optical setup for a typical FTIR imaging spectrometer. The heart and soul of the configuration is the FPA detector and the step-scan interferometer. The beam from the interferometer is diverted through the microscope optics and then to the FPA detector. A step-scan interferometer maintains constant

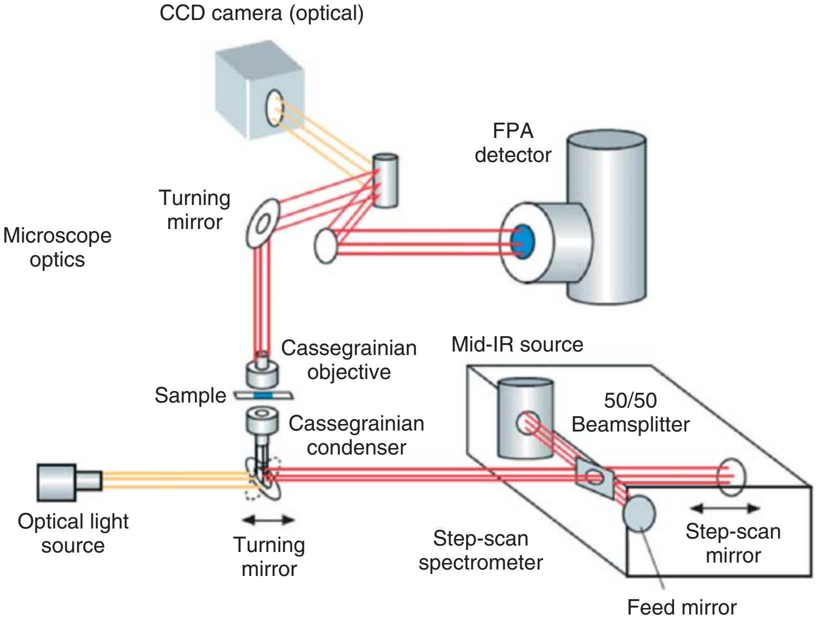

Figure 31.1 Optical setup for a typical FTIR imaging spectrometer. (Copyright from Ref. [1].)

optical retardation for an arbitrarily large time while the FPA coadds collected frames at each optical retardation point in order to improve signal-to-noise ratio. A Cassegraninan condenser and objective are also added to focus the radiation to the plane of the sample [1, 3]. This configuration allows for the imaging of a wide field of view in a single collection.

The speed of image acquisition and improved signal-to-noise ratio in FTIR imaging offer the advantage of real-time monitoring of dynamic phenomena and chemical processes in both biological and nonbiological systems. For example, FTIR imaging is essential in studying both static and dynamic phenomena in polymeric systems. It has been used to investigate single and mixed solvent diffusions in polymer films, polymer blends, polymer–liquid crystal systems, and composites [4–6]. The characterization of structure and morphology, as well as the determination of homogeneity in polymer systems, can also be analyzed by the technique [7, 8]. While much potential has to be exploited in the area of material, FTIR imaging has been widely used in biological arena where it has become useful in the characterization of biological samples, diagnosis, reaction dynamics of pharmaceuticals, and drug delivery [9, 10]. With FTIR imaging, chemical processes can be investigated, and specific molecules inside the cell can be mapped out in real time, because staining and labeling are not required for visualization. More recently, FTIR imaging has also been found useful in forensic science, microfluidics, and biofuels [11–13].

31.2
FTIR Imaging Applied to Polymeric Systems

The chemical nature of single polymer particles and polymer films has been effectively studied using FTIR imaging. While not exhaustive, the applications of the technique of various polymer materials will be described in the following sections.

31.2.1
Polymer Ultrathin Film Characterization

Our group has used FTIR imaging to confirm the successful polymerization of block copolymers from polyelectrolyte atom transfer radical polymerization (ATRP) macroinitiators. The macroinitiators were assembled via layer-by-layer (LbL) deposition onto an aminopropyltrimethoxysilane (APS)-functionalized silicon wafer [14]. Successful polymerization of poly(styrene-*b*-2,2,2-trifluoroethyl methacrylate) (p(St-*b*-TFEMA) was confirmed by comparing the chemical maps before and after polymerization of trifluoromethyl methacrylate (TFEMA) from the polystyrene (pSt) brush, which was polymerized via surface-initiated ATRP. Specifically, FTIR imaging for pSt homopolymer shows no absorbance at 1730 cm^{-1}, which corresponds to carbonyl region. After the polymerization of TFEMA, the carbonyl peak becomes apparent on some regions. The chemical heterogeneity is brought about by the fact that each layer in the LbL film acted as an initiating site. This resulted in varying heights of grafted pSt brush and unequal grafting of the pTFEMA block brushes.

We also utilized FTIR imaging to verify the successful grafting and the spatial distribution of binary mixed brush. Mixed brushes of poly(*N*-isopropylacrylamide) (pNIPAM) and pST were grown from LbL assembly of polyelectrolyte ATRP macroinitiators and 4-4′-azobis(4-cyanovaleric acid) free radical polymerization initiator [7]. IR images focused at 1650 cm^{-1} (–C=O), 2900 cm^{-1} (–CH), and 3300 cm^{-1} –NH) of (pNIPAM) and pNIPAM-pSt mixed brush were compared. The significant decrease in the maximum absorbance in the three regions for the pNIPAM-pST mixed brush relative to that for pNIPAM homopolymer brush confirms the successful grafting of both pSt and pNIPAM. In addition, by looking at the functional distribution, it was concluded that the surface was saturated with pNIPAM. This was also confirmed by ellipsometry studies, which revealed that the brush thickness of pNIPAM and pSt is 159 and 2 nm, respectively, for 20 layers of macroinitiators. This result was expected because with more layers of macroinitiators deposited on the surface, the initiator density increases accordingly, and thicker pNIPAM brush is polymerized. Thick pNIPAM brush limits the availability of the underlying free radical initiator for polymerization of styrene. In addition, the statistical distribution of the pNIPAM-pSt mixed brushes meant that the surface functionalities were randomly configured on the surface.

In another study performed by our group, we used FTIR imaging to estimate the degree of coverage of pNIPAM brush on ATRP-initiator-modified LbL assembly of chitosan and alginate [8]. Image focused at 1650 cm^{-1} (amide I carbonyl backbone stretch) shows that majority of the area is covered by pNIPAM. Comparison with the image focused at 1600 cm^{-1} (carboxylated region), led the author to conclude that about 85% surface was covered by pNIPAM and that its growth was favored on the amine regions derived from chitosan.

31.2.2
Polymer Nanostructures and Surface Patterning

Chemical composition of the patterned surface can also be mapped using FTIR imaging as exemplified by our group [15]. We presented a simple yet versatile route for patterning polymer brushes. This was made possible by using a molecule bearing an electroactive (carbazole) group and a photoactive (benzophenone) group. Two patterning routes available are (i) electrodeposition on patterned indium tin oxide (ITO) surface and then photografting of the spin-coated polystyrene (PS) film (Figure 31.2a,b) and (ii) electrodeposition on ITO and patterned photografting of spin-coated film using a photomask (Figure 31.2c,d).

FTIR imaging was conducted to gain information about the chemical composition of the patterns produced. All images are focused at 3034 cm^{-1}, which corresponds to aromatic –CH stretch of polystyrene. Green areas represent high concentration of pSt, while the blue areas represent either the glass substrate or the electrodeposited benzophenone. These patterns were only visible at this wave number, that is, images focused at different wave numbers (e.g., 1680–1800 cm^{-1}) do

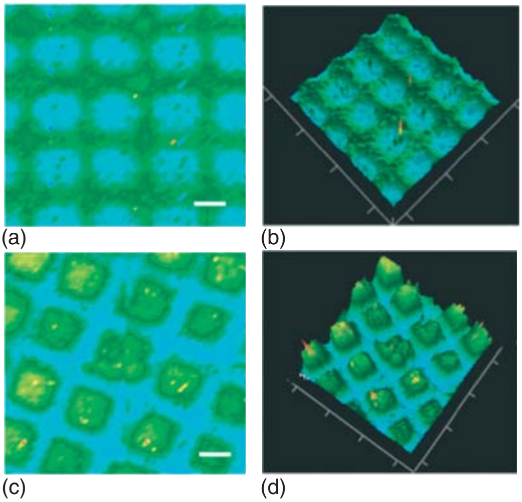

Figure 31.2 2D and 3D IR images for (a,b) electropatterned and (c,d) photopatterned pSt brushes. Scale bar = 30 μm. (Copyright from Ref. [15].)

not show any pattern. On a separate study, we utilized FTIR imaging to chemically characterize binary patterned brush systems initiated by electroactive monomer with chain transfer agent (CTA) moiety and by ATRP-initiator-functionalized silane [16]. CTA-functionalized carbazole was first electrodeposited on a glass substrate coated with patterned ITO, and then pSt brush was grown via surface-initiated reversible addition–fragmentation chain transfer (RAFT) polymerization. pNIPAM was then polymerized on the exposed glass prefunctionalized with ATRP initiator-functionalized silane. By focusing on peaks distinct to the polymer brushes, we obtained a clear image of the patterned surface. Image focused at 3020 cm^{-1}, corresponding to aromatic –CH stretch, reveals that pSt was successfully polymerized on the patterned ITO. On the other hand, image focused at 1650–1700 cm^{-1} (–C=O stretch), 1550–1600 cm^{-1} (amide II peak, –NH bending), or 3100–3400 cm^{-1} (–NH stretch) shows that pNIPAM was polymerized on the region where ITO was etched away.

Characterization of polymer nanostructures is another application of FTIR imaging, more effectively if combined with other characterization techniques. King *et al.* [17] reported the characterization of various polymer nanostructures and heterogeneous patterns of polymer nanostructures by the combination of atomic force microscope (AFM) and FTIR imaging spectroscopy. Hilt *et al.* [18] also demonstrated that FTIR imaging can be used to characterize the real-time photopolymerization of a patterned methacrylate-based hydrogel. The patterns were created by microcontact printing of 1-octadecanethiol on gold, application of monomer solution containing the cross-linker and photoinitiator on the unpatterned areas, and photopolymerization by UV light ($\lambda = 320$–500 nm) irradiation.

31.2.3
Diffusion and Dissolution of Polymer Films

Koenig *et al*. [4] are among the first to employ FTIR imaging to study the physical processes in polymeric systems, such as diffusion and dissolution processes. Their main objective is to spatially resolve the chemical functionalities to monitor the diffusion process involved in polymer–dispersed liquid crystal system. They monitored the diffusion of a low-molecular-weight liquid crystal into a solid polymer film in real time [19], and mapped the multiphase domains. They also studied the diffusion process for both cured and uncured blends of polybutadiene and diallyl phthalate by monitoring the domain compositions, sizes, shapes, and interfaces. In another study, they used FTIR imaging to characterize and calculate the dissolution rate of poly(α-methylstyrene) and poly(styrene-*b*-methyl methacrylate) as a function of solvent and temperature [20, 21].

31.2.4
Phase Separation

Siesler *et al*. [5, 22] demonstrated the applicability of FTIR imaging in phase separation of polymer blends. In their report, they imaged the chemical map of blends with varying compositions of poly(3-hydroxylbutyrate) (PHB) with poly(L-lactic acid) (PLA) [5].

Figure 31.3a shows that the islands of PHB, with a size of 30–40 μm, are embedded in a PLA matrix as confirmed by PLA- and PHB-specific FTIR images. On the other hand, no phase separation can be observed in the visible and FTIR images of 30 : 70 (w/w) blends as shown in Figure 31.3b. Integrated intensities from 1720 to 1700 cm^{-1} and 1770 to 1800 cm^{-1} were used to represent PHB and PLA in the FTIR images, respectively. In another study performed by the same group, they used FTIR imaging coupled with polarized irradiation to understand the orientation mechanism of incompatible and miscible polymer blends on uniaxial elongation [22].

Kazarian *et al*. [23] utilized FTIR imaging to study the CO_2-induced phase separation of pSt/poly(vinyl methyl ether) (PVME) blend, and poly(ethylene oxide) (PEO)/poly(methyl methacrylate) (PMMA) system. Moreover, several groups started to map the chemical composition of polymer spherulite [24, 25]. Recently, Morikawa *et al* [26]. successfully analyzed quantitatively the molecular chain orientation of the PEO spherulite by using the four-polarization method of FTIR imaging.

31.2.5
Polymer Degradation

We were the first to report the study of the photodegradation of PS polymer thin film by using FTIR imaging [27]. In this study, pSt was mixed with [1,12-dodecanediylbis(oxy-4,1-phenylene)][bis[phenylmethanone], a photoinitiator with

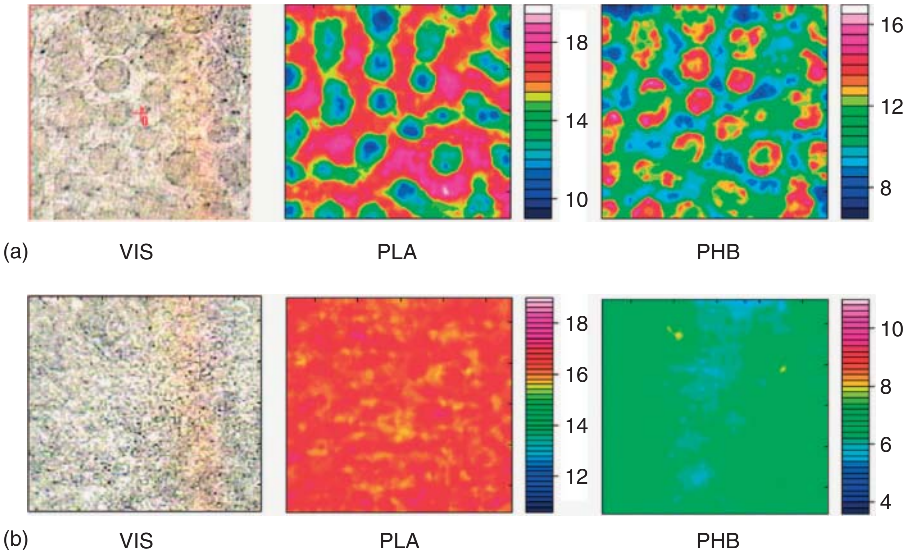

Figure 31.3 Visual image (left), PLA-specific FTIR image (center), and PHB-specific FTIR image (right) of a PHB/PLA (50 : 50% (w/w)) blend (a) and a PHB/PLA (30 : 70 (w/w)) blend (b). (Copyright from Ref. [5].)

two benzophenone moieties, and then spin-casted on silicon wafer. Both photodegradation and cross-linking were studied by irradiating the polymer film in the presence of air. IR images focused at three pertinent wave numbers, specifically 1640 cm^{-1} (–C=O stretch for benzophenone), 1735 cm^{-1} (–C=O stretch for degradation carbonyl), and 3350 cm^{-1} (–OH for hydroperoxide formation), which are shown in Figure 31.4.

It can be seen clearly that as the film was irradiated, the intensity for 1640 cm^{-1} decreases, while the intensities for 1735 and 3350 cm^{-1} increase. In addition, the changes in IR image of the pSt degradation products are more apparent than those for the benzophenone carbonyl. This was explained by considering that degradation of carbonyls and hydroperoxides begin from zero intensity. Furthermore, even after 150 min of irradiation, cross-linking does not proceed to completion. This was expected because not all benzophenone moieties in a film are within reasonable proximity to hydrogen donors.

31.3
Biomedical Applications of FTIR Imaging

31.3.1
Cell Imaging and Diagnosis

FTIR imaging has been applied in the investigation of molecular and metabolic processes due to its ability to probe samples on a molecular level. This imaging

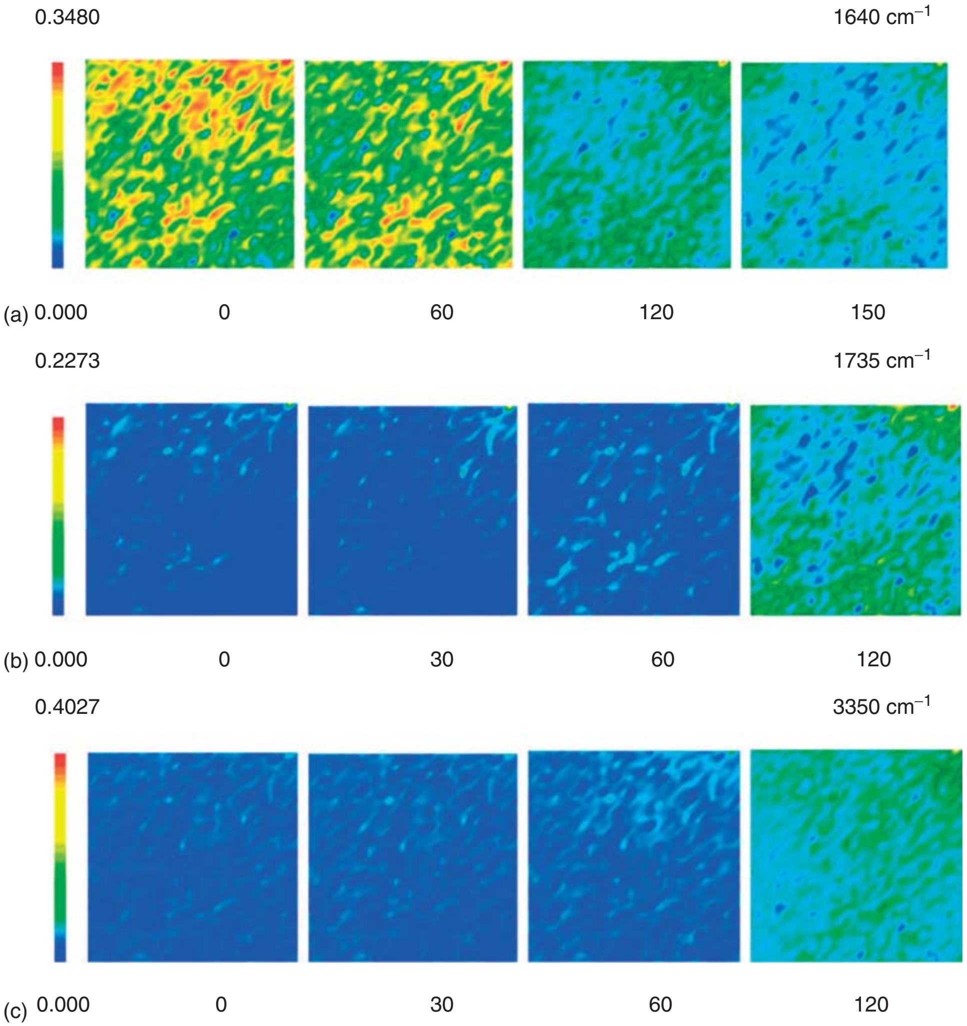

Figure 31.4 (a–c) 2D FTIR images focused at 1640, 1735, and 3350 $\mathrm{cm^{-1}}$ as a function of irradiation time in 30 min increment. Area = 176 × 176 μm^2. (Copyright from Ref. [27].)

technique offers a rapid, high-resolution, and nondestructive molecular analysis that requires neither staining nor labeling, an advantage. Subtle changes in the characteristic infrared signatures of biomolecules such as proteins, lipids, and nucleic acids have been used to characterize tissue specimens for diagnoses (e.g., early development of cancer cells) [28–32].

Cancer is probably one of the most important diseases that are needed to be diagnosed early. Traditionally, cancer is detected after it has already caused significant morphological changes in tissues. Breast cancer is the most common cancer among women, affecting one in eight women in the United States [33].

Mammography is used as a screening tool for the early detection of breast cancer. It works by using small doses of ionization radiation to create images where masses and microcalcifications can be seen. However, mammography by itself is not a very accurate tool and can easily overlook cancer. FTIR imaging, on the other hand, is very sensitive to changes in the structure of biomolecules, and therefore can serve as an effective replacement or complement technique to mammography. As cancer mutations in biomolecules appear before cellular manifestations, early detection with FTIR imaging is possible. This will eventually lead to an increase in patient survival. A recent report has shown that FTIR imaging can differentiate cancerous, benign lesions, calcifications in proliferative lesions, and normal breast tissues [9]. The FTIR imaging of the cancer cell sample was color-coded to show the extent of the disease. Comparison of the spectra for normal and cancer cells showed differences in the position of the peaks and their corresponding intensities. The normal collagen peak at 1203 cm^{-1} shifted to 1207 cm^{-1} for the cancer sample, which is broader and has lower intensity. This suggests changes in the collagen matrix. Another collagen peak for amide III of the cancer sample at 1236 cm^{-1} has lower intensity than for the normal cells. Both spectra have peaks around 1160 cm^{-1}, but only the cancer sample has a small shoulder at 1170 cm^{-1}. The amide I peak at 1600–1730 cm^{-1} for cancer stroma has stronger intensity and is slightly shifted to a lower wave number than for the normal stroma. The shift corresponds to a decrease in the number of random coils and turns in the secondary structure of proteins. Another protein band, the amide II peak at 1544 cm^{-1}, is shifted to a lower wave number. These differences indicate a change in protein conformation in the cancer tissues.

FTIR imaging has also been utilized in the study of other diseases such as leukemia [31, 34], lung cancer [35], ovarian carcinoma [36], and glioma [37]. Glioma is the most common type of brain tumor affecting 66 000 people per year. In a study by Manfait *et al.* [37], relative absorbance percentage fractions of normal and glioma brain tissue components from IR spectra were used to diagnose brain cancer. FTIR maps of healthy and cancer cells were taken based on a cluster analysis. Comparison of the spectra showed that a malignant brain tumor has a lower 1466 cm^{-1}/1396 cm^{-1} ratio corresponding to the amino acid side chain from peptides and proteins than for normal brain tissue. Moreover, the intensity of C=O stretching of the lipids of a malignant brain tumor is lower, consistent with what has been observed before the tumor growth is characterized by a decrease in phospholipid content. These studies show that FTIR imaging can aid in the early detection and quantification of biochemical changes related to cancer. However, it is important to separate the contributions of lipids, proteins, and nucleic acids in the spectra during analysis for proper diagnosis. Another limiting factor in FTIR imaging application in medicine is the brightness available from the blackbody light source, which dictates the resolution and signal-to-noise ratio; therefore, getting an image with a useful signal-to-noise ratio requires long acquisition times and imaging of dynamic living cells proves to be a challenge. To overcome this, Phillips and his colleagues [38] built a pulsed tunable optical parametric generator source that can produce an image at the subcellular level with 100 ps temporal resolution. With this modification, they were able to view cancer cells undergoing mitosis by mapping the characteristic vibrations of amide II band at 1540 cm^{-1} of proteins (Figure 31.5). This makes it possible to acquire *in vitro* IR spectral images of living cells for use in clinical studies.

31.3.2
Pharmaceutical Application

FTIR imaging has been used in evaluating the concentration and distribution of the different components of pharmaceutical formulations for manufacturing [39–41]. It also provides a fast screening tool for evaluating a large number of samples produced by pharmaceutical companies. Samples with controlled diameter are dispensed on attenuated total reflectance (ATR) crystal to form an array (Figure 31.6), and are characterized simultaneously at identical conditions [42].

FTIR imaging can be utilized in differentiating genuine and fake tablets because it is a very sensitive method for detecting trace materials [43–45]. A poor quality drug

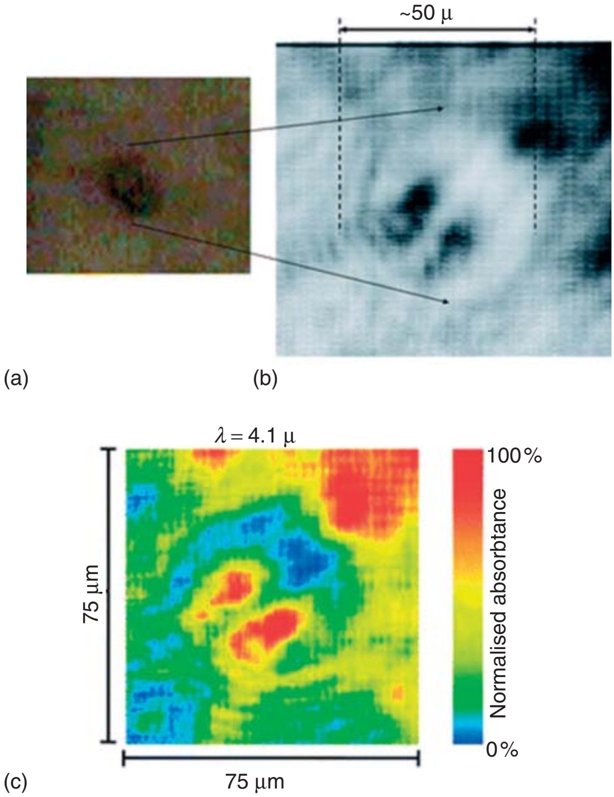

Figure 31.5 (a–c) IR image of a live SK-OV-3 human ovarian cancer cell undergoing mitosis in H_2O-based phosphate buffer solution. (Copyright from Ref. [38].)

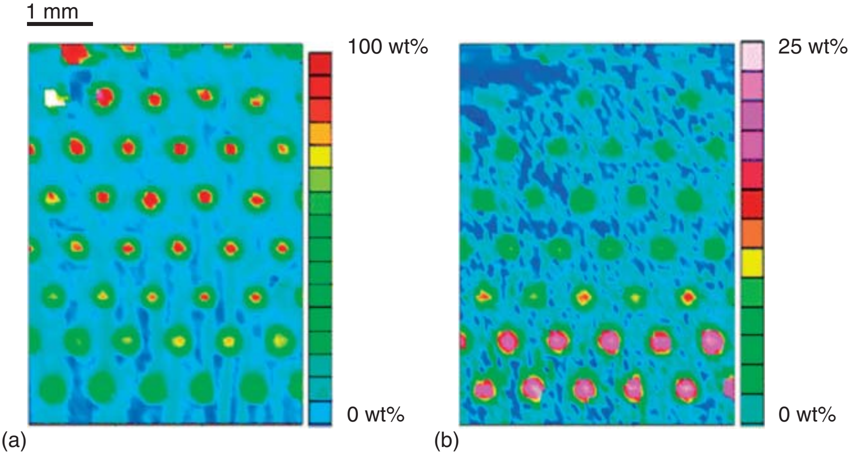

Figure 31.6 Distribution of (a) PEG and (b) ibuprofen in the same sample array. (Copyright from Ref. [42].)

contains inactive ingredients, contaminants, degraded drug, or incorrect dosage, all of which may be harmful to the consumer. Macro-ATR-FTIR imaging of fake tablets can be evaluated against the spectral and image features expected from a pure tablet. Traditional methods such as high-performance liquid chromatography (HPLC), gel permeation chromatography (GPC), and mass spectrometry (MS) are time-consuming, while macro-ATR-FTIR imaging is fast and nondestructive. Thus, this technique can be integrated with standard protocols for forensic investigation of pharmaceutical tablets.

FTIR imaging has also been used to study drug dissolution and drug release by measuring drug concentration as a function of time. The mechanism of drug release (e.g., diffusion of water into the polymer matrix, polymer swelling, polymer dissolution or degradation, or diffusion of drug out of the matrix), along with the chemical structure and morphology of the drug, can be effectively determined by using FTIR imaging. Drug release studies are often performed by imaging the tablet during dissolution. Kazarian *et al.* [10] used a combination of FTIR imaging in its macromode and the ATR–IR approach to study the polymer/drug formulations in contact with water (Figure 31.7).

Ibuprofen, which is slightly soluble in water, was dispersed in poly(ethylene glycol) (PEG), a water-soluble polymer. Figure 31.8 shows FTIR images of ibuprofen/PEG in contact with water. The images at the top row are based on the PEG band integration at 1020–1170 cm^{-1}, and images at the bottom are based on the integration of the C=O absorption band of ibuprofen at 1665–1760 cm^{-1}. Images of PEG show uniform dissolution within 40 min. On the other hand, the images of ibuprofen dissolution show drug accumulation on the surface as evidenced by the increase in intensity of the ibuprofen band (shown in red). The inset in Figure 31.8 shows that the peak of ibuprofen dispersed in and around the polymer. The shift

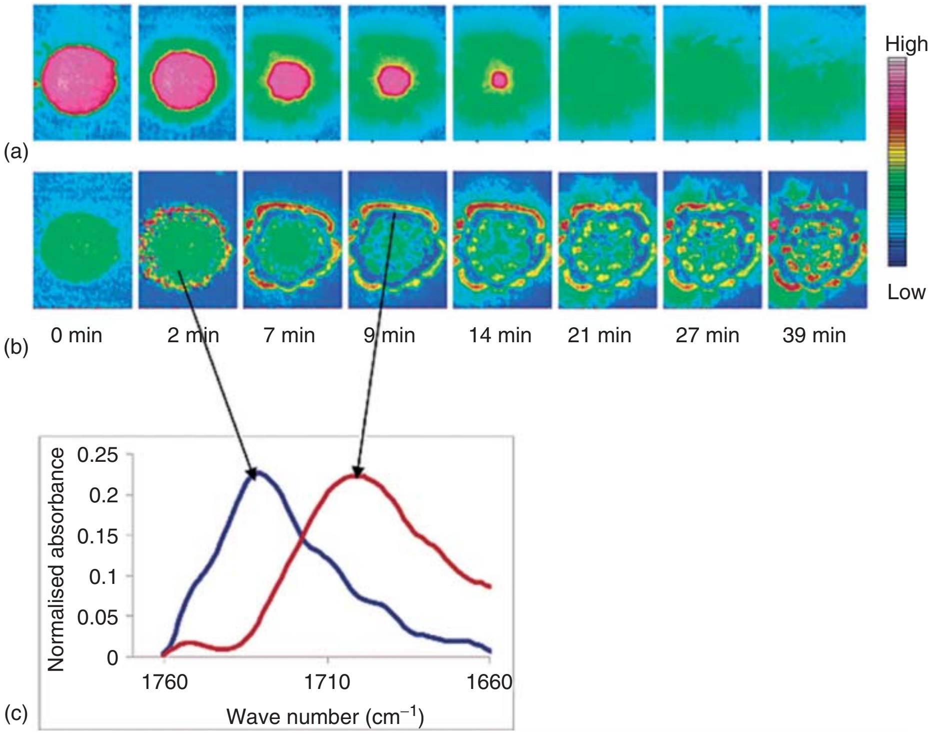

Figure 31.8 (a–c) Macro-ATR-IR images of PEG/ibuprofen formulation show distribution of PEG and ibuprofen as a function of time during contact with water. The inset shows representative IR spectra of ibuprofen to demonstrate the difference between molecularly dispersed (blue) and crystalline drug (red). (Copyright from Ref. [42].)

(blue to red) can be interpreted as crystallization of the drug as it is released in water. When the polymer matrix is dissolved, the initial layer becomes saturated with water-insoluble drug, which leads to its precipitation. In addition, the polymer chains at the interface decreased the rate of dissolution of the drug. As ibuprofen has a carboxylic group, the addition of pH modifiers can affect the dissolution and the rate of release of the drug [46]. The same group studied the drug release of other compounds such as niferidipine [47] and buflomedyl pyridoxal phosphate [48]. Koenig *et al.* [49] investigated the release of testosterone in PEO. From the IR image, the drug release mechanism was identified. It was determined that the homogeneity of the polymer/drug matrix, the drug particle size, the drug concentration, and the molecular weight, morphology, and dissolution of the polymer dictates the rate and uniformity of drug release. The information provided by dissolution studies are the basis for the design and optimization of the formulation for controlled drug delivery.

31.4
Other Applications of FTIR Imaging

31.4.1
Forensic Science

Owing to label-free and noninvasive sample collection and increased chemical information, spectroscopic methods have gained attention in the forensic community for fingermark and trace investigations [11, 46]. As compared to other spectroscopic techniques, the ability of FTIR imaging to analyze a wide sampling area and to identify small amounts of randomly distributed trace materials makes it one of the most promising tools in forensic science. Usually, significant information gained by detecting small particles of prohibited drugs, gunpowder, explosives, and other potential evidences present at localized regions throughout the sample is difficult to record using ‘‘mapping-type’’ spectroscopy methods, but an imaging approach enables fast access to this data in a single measurement [46].

Kazarian *et al.* [47] have demonstrated fingermark analysis via FTIR imaging on samples using two approaches: (i) directly imprinting on the ATR accessory used and (ii) lifting the fingerprint using gelatin adhesive tapes or polydimethylsiloxane (PDMS) films. The instrumentation for both approaches involves an FTIR spectrometer with an FPA detector coupled with a ZnSe crystal accessory in ATR approach. The combined imaging approach was able to provide more information on the composition and the distribution of a wide range of functionalities across the sample. For the first strategy, latent fingerprints were directly laid on the ZnSe ATR accessory under controlled temperatures and relative humidities. Resulting chemical images focused at certain spectral regions clearly show the heterogeneous distribution of lipids and amino acids present in the fingerprint residues. Absorption bands between 3000 and 2800 cm^{-1}, corresponding to antisymmetric and symmetric stretching vibrations for CH_2 groups, respectively, were used to confirm the presence of several types of lipids. Peaks at 1745 cm^{-1} and shoulder at 1712 cm^{-1} reveal the presence of triglycerides and/or phospholipids and fatty acids, respectively. Traces of amino acids and protein substances are identified using the absorption bands at 1654 cm^{-1} (–C=O), 1551 cm^{-1} (–NH in-plane bend), and around 3080–3100 cm^{-1} (weak –NH stretching vibrations corresponding to amide B).

Another approach is to lift and transfer the fingerprints to adhesive tapes or polymer films and subsequently analyzed in the laboratory. This is actually more practical for actual forensic investigations. The same group demonstrated this technique using different types of lifting media such as the BVDA gelatin lifter and the Dycem gel print lifter [48]. The fingers were damped on forehead or nose sebum (to enhance the signals of the samples) before touching a door handle, a mug handle, a curved glass surface, and a computer screen. The lifting material was placed on the fingermarks and was carefully peeled off. Similar to the previous approach, the presence and spatial distribution of lipids and amino acids were analyzed through the absorption bands between 2800 and 3000 cm^{-1} for both the gelatin tip and the Dycem gel lifter. The resulting FTIR images with corresponding IR spectra are shown in Figure 31.9.

Apart from lipid and amino acid analysis, forensic applications of FTIR imaging on fingerprints are expanding to identification of exogenous components such as drug particles [46]. In 2006, a model system of ibuprofen and paracetamol (diameter = 5–30 μm) was carefully lifted by a PDMS film or directly analyzed on a finger surface via FTIR imaging [46]. PDMS works perfectly with the matrix because, unlike the normal adhesive tapes, it does not have absorption bands between 1650 and 1750 cm^{-1} to which the absorption of C=O of ibuprofen is prominent. For paracetamol, the absorbance of the amide II band between 1580 and 1525 cm^{-1} can be used as the chemical marker. Analysis was performed using a (i) ZnSe ATR accessory (macro-ATR) and (ii) IR microscope and a Ge ATR objective (micro-ATR). The first method provided information on the distribution of the drug particles across the sample. However, small drug particles with sizes between 5 and 30 μm were not detected. Imaging resolution was significantly enhanced by incorporating the second method, and thus enabling the analysis of smaller particles. Owing to its success in the characterization and differentiation of the drug particles, the technique was also applied in analyzing small amounts of a street drug diacetylmorphine hydrochloride (heroin) concealed on a binary drug matrix with paracetamol adhered on a PDMS film and/or on the finger. Furthermore, other groups have also worked on the detection of explosive materials, such as hexahydro-1,3,5-trinitro-1,3,5-triazine and the RDX explosive solution (whose IR spectra can be characterized by strong NO_2 deformations and weak –CH stretching modes) [49, 50]. As shown in Figure 31.10a–c, FTIR images of the fingerprints before and after washing of RDX were generated, and results showed that even after washing localized residues can still be detected. This analysis may be used as an evidence for crime investigations to verify previous handling of explosives or other prohibited materials.

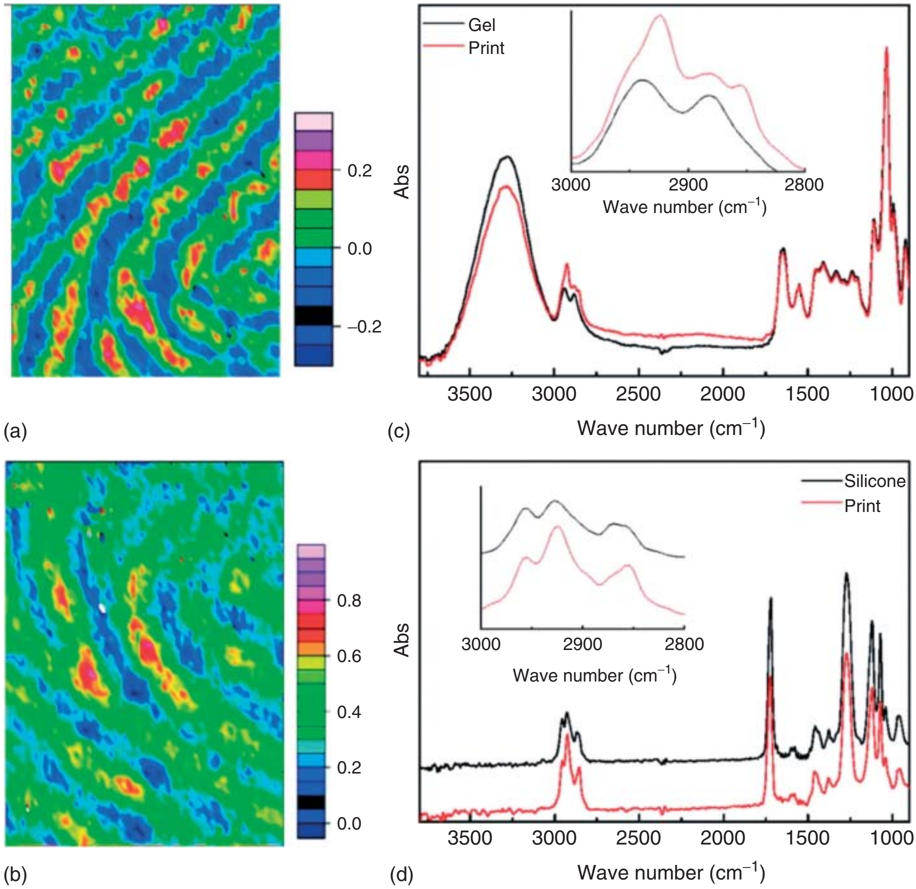

Figure 31.9 Latent fingerprint analysis via ATR-FTIR imaging using a BVDA gelatin tape (a,c) and a Dycem gel lifter (b,d). Measurements were made based on a sample area of $2.5 \times 3.6\,\text{mm}^2$. The integration range selected is between 2830 and 2870 cm^{-1} to highlight the ridges present on the fingerprints. 31.4.2
Microfluidics

In order to optimize traditional process systems, chemical reactions are recently being investigated in microfluidic or microfabricated devices. In these smaller scale systems, concentration gradients of the chemical components are being monitored *in situ* at various points in time and space. Before the development of more advanced techniques, reaction conditions are numerically simulated to determine the concentration gradients throughout the system. However, there is a growing need to develop real-time characterization methods to verify these simulations. Currently, fluorescence imaging is the most widely used technique for microfluidics owing to its sensitivity. However, the use of dyes and other fluorescent additives

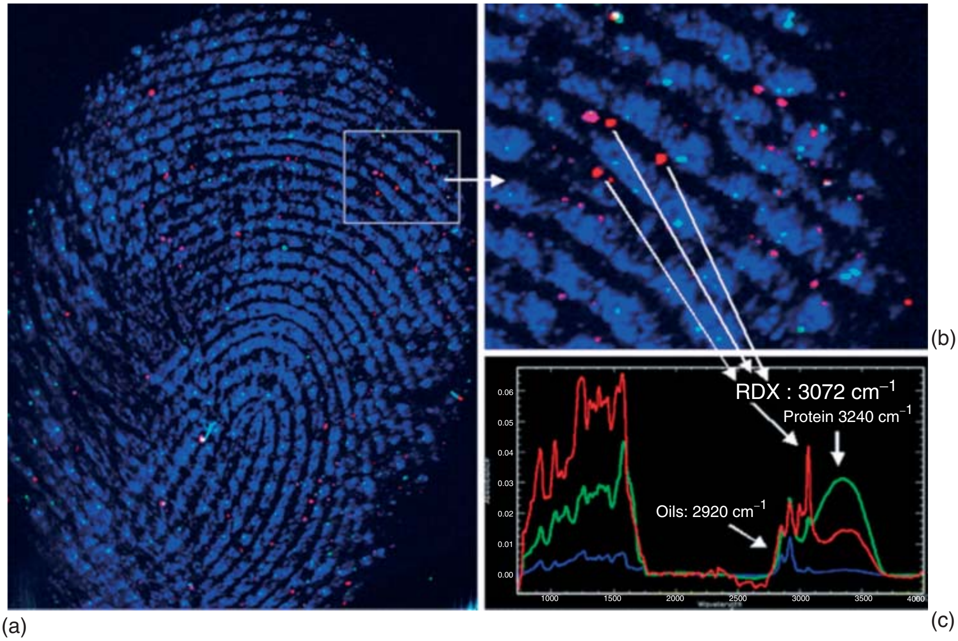

Figure 31.10 FTIR imaging for explosive material detection. These reconstructed images present distributions of oil secretions, proteins, and the RDX solution present across the sample. (a) Fingerprint, (b) Zoomed in region, (c) IR spectra differentiation. (Copyright from Ref. [50])

may cause disturbance and introduce contaminants to the systems. Furthermore, it does not necessarily give exact compositional and functional group information. As a result of which label-free spectroscopic techniques such as FTIR imaging have been gaining attention in these studies. Each pixel in an FTIR image contains spatially resolved infrared spectrum of the chemical components of the system; hence, absorption bands of various functional groups can accurately monitor the movement, emergence, or disappearance of any chemical component in a process system.

In 2009, the mixing behavior of deionized water and PEG in a y-junction PDMS microfluidic device, as depicted in Figure 31.11, was studied by using FTIR imaging [12, 51]. Both liquids were injected at steady state and the system was equilibrated before imaging. The IR images focused at $2800-3000\,\mathrm{cm}^{-1}$ and at $3100-3700\,\mathrm{cm}^{-1}$, for the −CH absorption band of PEG and for the −OH absorption band of water, respectively, were captured. In reference to Figure 31.11, the red colors represent high concentration of the component, while the darker regions correspond to zero concentration. On the basis of the images, it can be concluded that PEG occupies most areas and water slowly diffuses from the left side.

In the same report, FTIR imaging was also used in *in situ* monitoring of the H/D isotope exchange between H_2O and D_2O to produce HDO [12]. As signified by the emergence of two additional peaks at around 1451 and $2500\,\mathrm{cm}^{-1}$, the

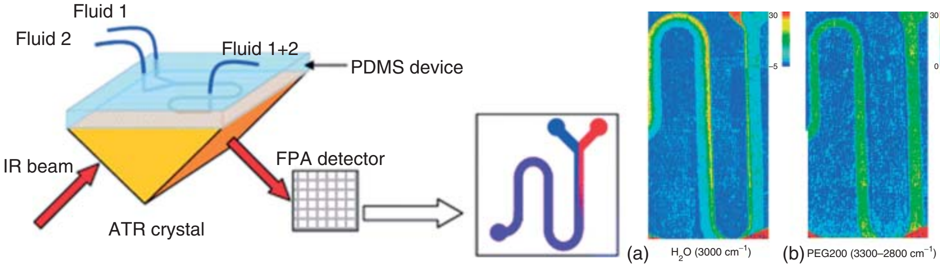

Figure 31.11 (a) A schematic representation of the y-junction PDMS-based microfluidic device integrated in the ATR-FTIR imaging system. (b) The flow patterns as water and PEG 200 is being injected at 75 and 25 μl h^{-1}. (Copyright from Ref. [12].)

formation of HDO occurs at the interface between the H_2O and D_2O streams. IR images not only provide the spatial distribution of the chemical components of the reaction but also present the actual quantitative concentrations of the components at certain points in the flow as correlated by the Beer–Lambert law. Analyzing the intersection of the normalized absorption spectra of the H_2O and D_2O streams at the dotted lines in Figure 31.11 shows that both the reaction kinetics and the equilibration are fast. Although this technique was successful in *in situ* monitoring of a chemical reaction, conventional FTIR imaging is still too slow for producing continuous chemical images of picoliter-sized droplets of various liquid streams. The same group was able to overcome this limitation using a model system of introducing small amounts of water and oil (FC40) that converges in a T-junction microfluidic device and measuring the spectra using a single wavelength measurement and a quantum cascade laser [52]. The resulting FTIR images were produced after a scanning time of 50 ms with a temporal resolution of 120 ms. This can potentially be used for making videos of chemical reactions. Another recent report on the application of FTIR imaging on microfluidics monitored *in situ* the chemical reaction in both laminar and segmented flows in two-phase systems [51].

31.4.3
Single-Particle Characterization

Ro *et al.* [53] studied the artificially generated aerosol particles of micrometer size, such as ascorbic acid and $NaNO_3$ aerosols, by using X-ray microanalysis (electron probe microanalyzer (EPMA)) techniques and FTIR imaging spectroscopy. These techniques provided information on the functional groups, molecular species, and crystal structure of the particles. Employing the same techniques, detailed characterization of mineral particles was also performed on a single-particle level for 24 mineral samples [54], which was later extended to the characterization of an atmospheric aerosol sample collected in Incheon, Korea [55], and aerosols samples collected at King George Island in the Antarctic [56].

31.4.4
Biofuels

In the search for more cost-efficient and environment-friendly energy sources, thermochemical conversion of organic material or biomass through pyrolysis or gasification is continuously being developed as promising substitutes for crude oil. Pyrolysis, which is generally driven by phenomenological changes in chemical and physical properties, is the thermochemical decomposition of organic materials in the absence of oxygen. One of its main uses is to produce a lighter synthetic fuel from crops, agricultural residues, or other biological wastes. Recently, Nimlos *et al.* [13] investigated the changes in the structural and chemical compositions of poplar wood (biomass) after thermal decomposition using FTIR imaging coupled with various multivariate techniques. The FTIR images were analyzed at $1600\,\text{cm}^{-1}$ to monitor the presence of C=C functional groups. Before pyrolysis, the C=C absorption band represents the distribution of lignin; however, the emergence of polyaromatic compounds produced after the pyrolysis causes a broadening of the absorption band centered at $1600\,\text{cm}^{-1}$ ranging from $\sim$1550 to $1650\,\text{cm}^{-1}$. The resulting FTIR images are presented in Figure 31.12, which highlight the increase in empty spaces in the wood and the changes in aromatic C=C absorption band. Apart from lignin, other components of wood such as cellulose and hemicellulose were also analyzed by adding multivariate techniques.

31.5
Conclusion

In summary, FTIR imaging is a very powerful technique for the chemical mapping of surfaces, and for obtaining spatially and temporally resolved chemical information. It also enables the identification of chemical functionalities distributed from a corresponding diffraction-limited optical image, and it distinguishes the presence of overlapping species within the same location. The technique has found utility in studying polymer systems, in biomedical applications, forensic science, and biofuels. More powerful applications can be further developed if we harness the advantages and sampling methods that cannot be carried out by any other microspectroscopic method in a similar resolution or timescale. Furthermore, multivariate methods, chemometrics, and time-resolved spectroscopy enhance its utility in analytical chemistry.

32
Photon Correlation Spectroscopy Coupled with Field-Flow Fractionation for Polymer Analysis

J. Ray Runyon and S. Kim Ratanathanawongs Williams

32.1
Introduction

Photon correlation spectroscopy (PCS), also known as *dynamic light scattering* or *quasielastic light scattering*, is a nondestructive analytical technique that provides an absolute determination of the normal diffusion coefficient (D) of submicrometer-sized analytes in solution. PCS has been used to characterize a wide array of analytes including biomacromolecules, synthetic and natural polymers, and nanoparticles. Information pertaining to the hydrodynamic diameter (d_h) of the sample, macromolecular chain conformation, and analyte interactions can be extracted from the measured D values [1–6]. d_h is calculated from the Stokes–Einstein equation $D = kT/3\pi\eta d_\mathrm{h}$, where k is Boltzmann's constant, T is the temperature in K, and η is the solvent viscosity.

PCS measurements are traditionally performed in batch mode where the sample volume, sample concentration, and timescale of the measurement are well controlled. Batch mode PCS yields average D values of the entire sample and is best suited for the characterization of monodisperse samples. Multimodal samples need to differ in size by two to three times for PCS to register the presence of distinct populations [1, 5, 7–9]. For a polydisperse sample with a continuous distribution of sizes, light scattered by a small number of large-sized analytes will mask the signal from small-sized components because the scattering intensity is proportional to the sixth power of the analyte radius. This sensitivity of PCS to large-sized analytes biases measured D to smaller values. Examination of low-concentration subpopulations within a polydisperse sample by batch mode PCS is difficult, if not impossible, without prior separation [1, 5, 7, 8, 10–13].

Size-based separation techniques including field-flow fractionation (FFF), size-exclusion chromatography (SEC), and hydrodynamic chromatography (HDC) have been coupled with online PCS detection to characterize D and d_h of eluting nanoparticles and macromolecules [5, 6, 12–31]. The separation stage parses the polydisperse sample into the more uniform size fractions required for accurate PCS measurements and makes it possible to obtain a more accurate representation of the analyte sizes.

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

Analytical capabilities beyond diffusion or size measurements are possible when a separation technique such as thermal field-flow fractionation (ThFFF) is coupled with online PCS. ThFFF uses a temperature gradient to fractionate polymers by molecular weight (MW) and composition. The ThFFF separation mechanism relies on the analyte Soret coefficient (S_T), where S_T is a balance between the polymer thermal diffusion (D_T) and D. D_T is a characteristic property of the analyte–solvent pair [32] and has been shown to be independent of homopolymer MW and branching [32, 33] and to be linearly dependent on the mole fraction of one homopolymer component of a copolymer [34–38]. ThFFF separation of mixtures of compositionally different homopolymers has been demonstrated for polystyrene (PS) and poly(methyl methacrylate) and PS and polyisoprene mixtures in tetrahydrofuran (THF), and a PS and poly(*n*-butyl acrylate) (PBA) mixture in methyl ethyl ketone (MEK) [35, 36, 38, 39]. Polymer D_T values can be experimentally measured from ThFFF analyte retention times (Section 32.3) provided D values are accurately known from an external source such as SEC or batch mode PCS. The integration of online PCS with ThFFF would allow D to be measured as a function of retention time. This would enable the subsequent calculation of D_T and the simultaneous characterization of both the size and composition distributions of heterogeneous polymers and/or polymer mixtures.

The majority of reported studies involving online PCS have focused on hydrophilic analytes [5, 6, 12, 13, 17–25, 28–31, 40]. Very few have addressed synthetic polymers [14–16, 26, 27], and none has investigated ThFFF coupled with online PCS. The characterization of synthetic polymers with online PCS detection is demanding because of the weak scattering intensity of these analytes in common organic mobile phases. This problem is exacerbated for dilute samples, polymer–solvent combinations with low specific refractive indices (d_n/d_c), and low-MW polymers. The separation process can dilute sample by 15–100 times. Band broadening during the separation leads to further dilution. High concentrations of analyte can be injected to increase the eluting sample concentration, but at the expense of decreased resolution of the separation, column overloading, or complete column plugging (in the cases of SEC and HDC). The sensitivity of PCS to large-sized analytes has lead to the previous conclusion that online PCS is best used with relatively high-MW samples (>300 kDa) with higher d_n/d_c values [15, 16, 26].

PCS detectors often have preset scattering angles usually between 90° and 110°. Low-MW polymers (isotropic scatters where $d_h < 1/10$th the wavelength of incident light) are best measured at small angles to increase the timescale of data collection [3, 4, 16, 27, 41]. The D values for PS with MWs as low as 12 kDa and poly(hexylisocyanate) with MWs below 100 kDa were measured at scattering angles $<32^\circ$ [16, 27]. However, there was a large standard deviation in the measured data as a result of low-analyte concentration and small d_n/d_c values. For high-MW polymers (anisotropic scatters), small scattering angles yield the true translational diffusion while large scattering angles provide information about the intermolecular motion of the polymer [3, 6, 16, 25]. No systematic trends of angular dependence on D have been reported for online PCS of 200 nm PS latex particles but were observed in batch mode measurements of 13 million Da PS [17, 40].

Additionally, when using online PCS as a detector, the time interval for data collection is dictated by the flow rate used to achieve the separation. The separation flow rate has been shown to have an insignificant effect on measured D values for aqueous analytes [5, 21, 29], but this has yet to be confirmed for organosoluble polymers in common organic solvents. Liu *et al.* [26] measured batch mode D values for polydimethylsiloxane (PDMS) in 1,2,4-trichlorobenzene over different data collection times ranging from 10 to 600 s and concluded that accurate D values can be obtained in as little as 10 s (with an associated increase in the standard deviation).

This chapter focuses on the usage of online PCS as a detection method for liquid-phase separations. The specific objectives are to (i) establish guidelines for coupling online PCS with a flow-based separation technique utilized for polymer characterization and (ii) apply these guidelines in the characterization of synthetic organosoluble polymers fractionated by ThFFF and proteins and protein aggregates fractionated by flow field-flow fractionation (FlFFF). The coupling of online PCS with FFF provides a powerful new approach to polymer characterization rich with potential applications.

32.2
Photon Correlation Spectroscopy

PCS measures the timescale of fluctuations in the detected intensity of scattered light from analytes undergoing Brownian motion in a liquid. It differs from static light scattering in that the latter measures a time-averaged scattering intensity. In PCS, a plot of intensity (I) versus time (t) shows I fluctuating about an average value due to the phase changes of scattered light reaching the detector. The D values can be extracted from this fluctuation through the use of an autocorrelation function [1, 3, 4, 16, 41].

The intensity normalized autocorrelation function ($g_2(\tau)$) is defined in Eq. (32.1) [1, 41]

$$\frac{\langle I(t)I(t+\tau)\rangle}{\langle I\rangle^2} = 1 + bg_2(\tau) \tag{32.1}$$

where $I(t)$ is the intensity at time t, $I(t+\tau)$ is the intensity shifted by a delay time of τ, and b is an optical coherence factor that ranges from 0 to 1. Initially, at $\tau \to 0$, $I(t)$ equals $I(t+\tau)$ and $<I(t)I(t+\tau)>$ equals $<I^2>$ (where $<I^2>$ is the average of the squared scattering intensity). At long delay times ($\tau \to \infty$), the solutes greatly change their position in solution relative to one another and $I(t)$ and $I(t+\tau)$ become less correlated and $<I(t)I(t+\tau)>$ equals $<I>^2$ (where $<I>^2$ is the square of the average scattering intensity). The rate of decay of the autocorrelation function from $<I^2>$ to $<I>^2$ holds the information on the diffusion of the analyte. It is assumed that the long time average of the scattered intensity is equal to the ensemble average or the average over all possible positions and shapes of the analyte in solution.

Averaging over the total duration of the experiment yields Eq. (32.2) [1, 41]

$$g_2(\tau) = \frac{\lim}{t \to \infty} \frac{1}{\Omega} \int_0^{\infty} I(t) I(t+\tau) \mathrm{d}\tau \tag{32.2}$$

where Ω is the experiment duration. $g_2(\tau)$ is converted to the electric field normalized autocorrelation function ($g_1(\tau)$) by Eq. (32.3) [1, 41].

$$g_2(\tau) = \langle I \rangle^2 \lfloor 1 + b |g_1(\tau)|^2 \rfloor \tag{32.3}$$

When $g_1(\tau)$ is plotted against the log of the delay time (τ), the decay of the autocorrelation function can be represented as a function of the analyte diffusion coefficient by Eq. (32.4) [1, 41]

$$|g_1(\tau)| = \mathrm{e}^{(-\Gamma\tau)} \tag{32.4}$$

where Γ is the decay rate. Γ is related to the analyte diffusion through Eq. (32.5) [1, 41]

$$\Gamma = Dq^2 \tag{32.5}$$

where q is the scattering vector shown in Eq. (32.6) [1, 41].

$$q = \frac{4\pi n_0}{\lambda_0} \sin \frac{\Theta}{2} \tag{32.6}$$

where n_0 is the refractive index of the solvent, λ_0 is the wavelength of the incident light, and θ is the scattering angle normal to the path of the incident light. This derivation holds true for D values at infinite dilution (D_0), where analytes can be considered point masses that move independently of one another. The earlier discussion assumes a monodisperse sample and precisely controlled analyte concentrations and data collection times (conditions met by batch mode PCS).

In online PCS, data collection times are determined by the flow rate used to achieve the separation. In addition, the sample concentration at the detector is continuously changing due to band broadening and dilution of the analyte during the separation stage. Thus, investigation of the contribution of variables such as analyte concentration, flow rate, and scattering angle to the accuracy of measured online D values, along with understanding of the magnitude of the error associated with each variable, is important in establishing guidelines for accurate online PCS detection.

32.3
Field-Flow Fractionation

FFF is a family of techniques designed to separate and measure the physicochemical properties of complex macromolecular, colloidal, and particulate materials [35, 42, 43]. In an FFF experiment, a sample in solution is injected into a high-aspect ratio, thin ribbonlike channel devoid of packing material. Under laminar flow conditions, the carrier liquid has a characteristic parabolic flow velocity profile with the highest flow velocity at the center of the channel and decreasing flow velocities toward the channel walls. The analyte is subjected to an external field applied perpendicular to the sample flow as shown in Figure 32.1a. Different fields can be applied, that is, a cross flow of fluid, a temperature gradient, centrifugal force, an electrical potential, and so on, to probe different physicochemical properties of the analyte such as hydrodynamic size, composition, density, surface chemistry, and semiconductive properties [35]. The separation mechanism and open parallel plate channel impart important characteristics on FFF such as low shear rates (ideal for investigating fragile samples), low sample loss, tunable selectivity, and speed. FFF is applicable to diverse samples spanning a broad MW/size range (10^3–10^9 Da; ~2 nm–100 μm). Descriptions of FFF theory, the separation mechanism, channel designs, applied fields, and targeted sample physicochemical properties can be

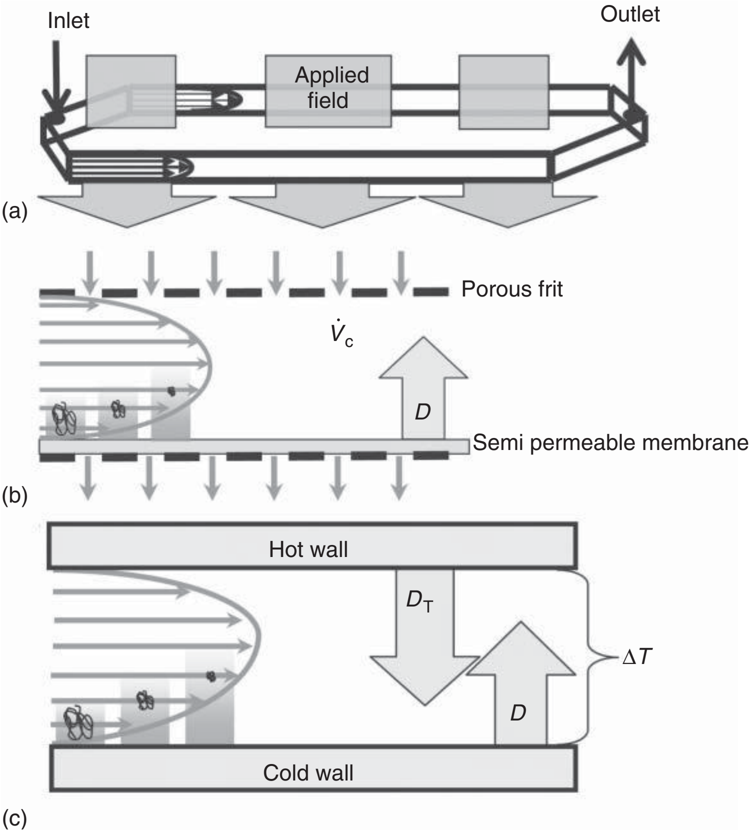

Figure 32.1 (a) FFF channel showing parabolic flow profile of carrier liquid and direction of applied field. (b) Longitudinal cross section of a symmetric FlFFF channel showing semipermeable wall and the two opposing transport processes denoted as the cross flow rate ($\dot{V}_c$) and the analyte D. (c) Longitudinal cross section of a ThFFF channel showing D_T and D. The gray-shaded rectangles on the left-hand side of (b) and (c) represent the exponential concentration profiles for three polymers.

found in previous publications and the reader is directed to Refs. [34, 35, 42–44] for more detailed discussions.

ThFFF utilizes a temperature gradient on the order of 10^4 K cm^{-1} as the applied field and is predominately utilized to fractionate organosoluble samples. FlFFF utilizes a cross flow of fluid as the applied field and has been mainly used to characterize water-based samples. Under the influence of the applied field, the injected analyte plug is compressed into slower velocity carrier liquid flow streams near one channel wall termed the *accumulation wall*. The accumulation wall is a semipermeable membrane in FlFFF and the cold wall in ThFFF as shown in Figure 32.1b,c. An exponential analyte concentration profile develops across the channel thickness with the highest concentration at the accumulation wall. This concentration gradient results in diffusion of the analyte away from the accumulation wall. Under steady-state conditions, the field- and the concentration-induced mass transport processes are balanced and the net flux of the analyte is zero. Retention is a result of the analyte residing in slower than average flow velocities within the channel. Separation occurs because of the differential distribution of analyte species across the parabolic flow velocity profile of the carrier liquid. In the normal mode of separation, small-sized analytes with larger D values will diffuse into fast-moving carrier liquid flow streams and be retained less. Hence, the expected order of elution is from small to large sizes, that is, low to high MW (Figure 32.1b,c) [34, 35, 44]. This statement holds true for ThFFF if the polymers are the same composition.

Equation (32.7) is the general retention equation for FFF [44]

$$R = \frac{t^0}{t_\mathrm{r}} = \frac{V^0}{V_\mathrm{r}} = 6\lambda\left[\coth\left(\frac{1}{2\lambda} - 2\lambda\right)\right] \tag{32.7}$$

where R is the retention ratio, t^0 and t_r are the retention times of nonretained and retained analytes, V^0 and V_r are the void and retention volumes, and λ is the retention parameter. The λ is a dimensionless parameter that represents the degree of zone compactness of the analytes relative to the channel thickness. It is also a measure of the extent of the interaction between the applied field and the sample components [34, 44]. Equation (32.7) is valid for FlFFF but must be adjusted for ThFFF to account for nonidealities in the carrier liquid parabolic flow profile that arise from changes in carrier liquid viscosity and thermal conductivity due to the applied temperature gradient. (The velocity profile is skewed toward the hot wall with the maximum velocity located above the midplane of the channel.) This adjustment is shown in Eq. (32.8), where ν is a velocity distortion factor and is equal to 0 when the parabolic profile is regained [44, 45]. Values for ν for several commonly used organic carrier liquids can be found in Ref. [45]

$$R = \frac{t^0}{t_\mathrm{r}} = \frac{V^0}{V_\mathrm{r}} = 6\lambda\left[\nu + (1 - 6\lambda\nu)\left[\coth\left(\frac{1}{2\lambda} - 2\lambda\right)\right]\right] \tag{32.8}$$

Let us assume λ as a different form for each FFF technique because of the different applied field. Equation (32.9) describes λ for FlFFF, where $\dot{V}_\mathrm{c}$ is the volumetric cross flow rate and w is the channel thickness [44]

$$\lambda_{\text{FlFFF}} = \frac{DV^0}{\dot{V}_c w^2} \tag{32.9}$$

Equation (32.9) shows that FlFFF is a size-based separation technique because the analyte physicochemical parameter that governs analyte retention is D. Changes in the hydrodynamic size of the analyte will result in a corresponding change in retention time.

Equation (32.10) describes λ for ThFFF, where D_T is the analyte thermal diffusion coefficient and ΔT is the temperature drop across the channel thickness [44]

$$\lambda_{\text{ThFFF}} = \frac{D}{D_T \Delta T} \tag{32.10}$$

Equation (32.10) shows that the Soret coefficient (D_T/D) is the physicochemical parameter that governs analyte retention in ThFFF. A change in the polymer size or composition will result in changes in D or D_T and be reflected in the analyte retention time.

This study coupling FFF with online PCS for polymer analysis was conducted in two parts. In the first part, the contribution of analyte concentration, MW, carrier liquid flow rate, and the scattering angle to the accuracy and precision of measured online D values was investigated. This was accomplished by introducing a large volume of sample directly into the PCS instrument (no FFF separation). These experiments enabled measurements of D at controlled and steady analyte concentrations in the presence of flow. These results were then used to establish guidelines for the second part of this study, which incorporated FFF with online PCS. This second set of experiments was complex because the concentration varied across each sample peak as it eluted from the FFF channel. The objective is to examine the accuracy and precision of D measurements and hence determine a best approach to processing the collected data. Online D values measured in the second part of the study are referred to as either *ThFFF/PCS* or *FlFFF/PCS D* values.

32.4
Materials and Methods

Table 32.1 lists the polymer and protein standards used in both parts of this work.

32.4.1
Direct Sample Introduction into the PCS Instrument

The polymer standards listed in Table 32.1 were prepared in uninhibited THF (Mallinckrodt Chemicals, Phillipsburg, NJ, USA). Five milliliters of each solution was filtered through a 0.2 μm polytetrafluoroethylene (PTFE) 13 mm syringe filter (Millipore, Billrica, MA, USA) before batch mode PCS measurements. Bovine serum albumin (BSA), bovine thyroglobulin (BTG), fibrinogen, and myoglobin protein solutions were prepared in 50 mM phosphate buffer saline (PBS) adjusted

Table 32.1 Polymer and protein standards.

Standard	MW (kDa)[a]	PDI[b]	Suppliers[c]
Polystyrene (PS20)	20.4	1.06	PCC
Polystyrene (PS52)	52	1.02	Waters
Polystyrene (PS90)	90	1.04	PCC
Polystyrene (PS254)	254	1.17	PE
Polystyrene (PS411)	411	1.1	Mann
Polystyrene (PS575)	575	1.06	PCC
Polystyrene (PS1800)	1800	<1.20	PCC
Polystyrene (PS250BR)	250	2.5	APSC

to pH 7.0. NaN_3 was added (0.02% w/w) to prevent bacterial growth. Five milliliters of each protein solution was filtered through a 0.1 μm Durapore (Millipore) inorganic membrane before batch mode PCS measurements.

Experiments were conducted by injecting each filtered sample directly into the PCS detector using a Valco injector (VICI Valco Instruments Co. Inc., Houston, TX, USA) equipped with a 500 μl sample loop. The large volume sample loop resulted in the formation of a plateau with a steady analyte concentration. Online *D* values were measured within this plateau region for PS and proteins in THF and 50 mM PBS solutions, respectively.

32.4.2
FFF Coupled with Online PCS for Polymer Analysis

ThFFF/PCS *D* values were measured for four different polymer samples and mixtures all prepared in MEK (Mallinckrodt Chemicals). The samples investigated were (i) a mixture 23.8, 411, and 1800 kDa PS standards with a polydispersity index (PDI) <1.2; (ii) a mixture of 390 kDa PS and 263 kDa PBA standards; (iii) a mixture of 242 kDa poly(2-ethylhexyl acrylate) (P2EHA242), 171 kDa poly(methyl acrylate) (PMA171), and PBA263 standards; and (iv) a 250 kDa broad MW PS standard with a PDI of 2.5. FlFFF/PCS *D* values were measured for BSA and BTG. Triplicate measurements were made for each sample.

32.4.3
Instrumentation

PCS measurements were made with a Wyatt quasielastic light scattering (QELS) that consisted of a fiberoptic cable connected to a DAWN-EOS multiangle light scattering (MALS) detector (Wyatt Technologies, Santa Barbara, California). The MALS is equipped with a 30 mW laser with a wavelength of 690 nm. The MALS detector can be used in either batch mode or online configurations. In batch mode, a 20 ml scintillation vial containing at least 5 ml of filtered sample solution is placed in the MALS detector. In the online configuration, a flow cell constructed from optical glass is placed in the MALS detector and sample eluting the FFF channel is pumped through this flow cell. The QELS fiberoptic cable can be moved to 1 of 18 different positions in the MALS detector allowing scattering data to be collected at different angles in both batch and online modes. The default manufacturer configuration connected the fiberoptic cable to position 13 on the MALS instrument (108° normal to the incident light). PCS angle-dependent studies were performed by placing the fiberoptic cable at positions 4, 8, 11, 13, and 16 (38°, 64°, 90°, 108°, and 134°) of MALS detector. All scattering data was collected using ASTRA V software (v. 5.1.8). A Waters 510 high-performance liquid chromatography (HPLC) pump (Milford, MA, USA) was used to maintain the desired carrier liquid flow rate.

A ThFFF system (Model TF2000; Postnova Analytics, Salt Lake City, Utah) was utilized for synthetic polymer separations. MEK was utilized as the carrier liquid because it yielded good sample retention. A symmetrical FlFFF system (Model F-1000; Postnova Analytics) equipped with a 5 kDa MW cutoff regenerated cellulose membrane was utilized for protein separations. Fifty millimolar of PBS at pH 7.0 (with 0.02% NaN_3 added to prevent bacterial growth) was used as the carrier liquid. Each FFF system was coupled with the Wyatt MALS and PCS detectors plus a Wyatt Optilab DSP differential refractive index (dRI) detector. Waters 510 and 590 HPLC pumps were used to set and maintain the desired carrier liquid flow rates.

32.5
Results and Discussion

32.5.1
Contribution of Individual Variables to the Accuracy of *D* Values Measured in Flowing Streams

The effect of sample concentration, carrier liquid flow rate, scattering angle, and analyte MW on the accuracy and precision of online *D* values measured from the introduction of the sample directly into the PCS instrument (without FFF) are discussed individually later. Measured online *D* values were compared against experimental and literature batch mode *D* values.

32.5.1.1 **Effect of Sample Concentration**

Solution concentrations were maintained below the overlap concentration, c^*, to ensure insignificant polymer chain overlap and entanglement as this could lead to errors in measured D values because of the presence of large aggregated species in solution [3, 16]. c^* was calculated using the equation $c^* = \mathrm{MW}/N_A \rho R_g{}^3$, where R_g is the radius of gyration, ρ is the polymer density, and N_A is Avogadro's number. For PS1800, the c^* value was calculated to be 6.7 mg ml^{-1}.

Figure 32.2a shows the effect of analyte concentration and flow rates on the measured D values for PS in THF. For the purpose of comparison, the D value for each flow rate was extrapolated to infinite dilution (D_0); therefore, the polymer chains can be considered point masses that move independently of one another. The measured online and batch mode D_0 values are within 5% of previously reported batch mode D_0 values, which were measured across a large concentration range from 1.0 to 20.0 mg ml^{-1} [46]. The lower end of the concentration range in Figure 32.2a is representative of analyte concentrations eluting from an FFF channel or SEC column and the upper end is typical of injected concentrations.

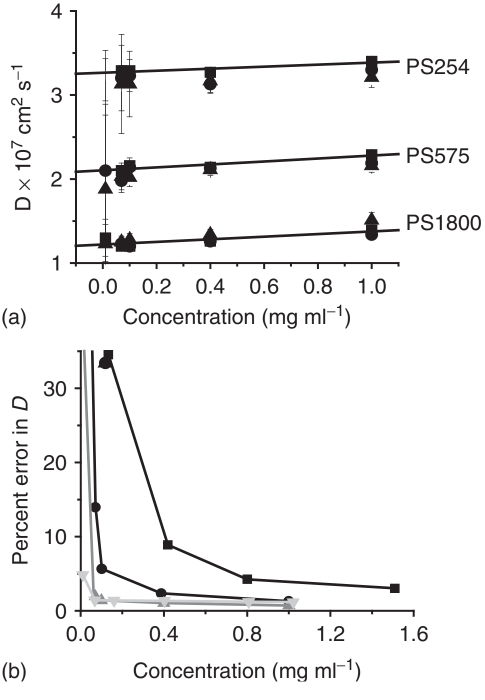

Figure 32.2 (a) Effect of analyte concentration on measured D values (at different flow rates) for PS standards prepared in THF (■, batch mode; ●, 0.1 ml min^{-1}; and ▲, 1.0 ml min^{-1}). The solid black lines are linear regression lines for batch mode values. (b) Measurement error for batch mode measurements (■, black line – PS20; ●, dark gray line – PS52; ▲, gray line – PS254; and ▼, light gray line – PS1800). Scattering angle: 108° for (a) and (b). The samples were introduced directly into the PCS detector.

The observed increase in D with increasing concentration agrees with previously reported trends [3, 8, 46, 47]. The observed slopes ranged from 0.2 to 0.4, which is in agreement with literature values of 0.007–0.3 ml mg^{-1} [46]. No systematic increase in the slope is observed with increasing MW. This is attributed to the low-concentration range at which the measurements were made.

The percentage error in D as a function of solution concentration is plotted in Figure 32.2b. For concentrations below 0.1 mg ml^{-1} (typical analyte concentrations eluting from an SEC column or FFF channel), the error in the measurement increases significantly even for high MWs. An error of <10% in D is observed for PS MWs as low as 52 kDa when concentrations >0.1 mg ml^{-1} were used.

Figure 32.3a,b shows analogous data for BSA, BTG, fibrinogen, and myoglobin protein standards. A similar pattern of increasing D values with increasing analyte concentrations and a concentration threshold of 0.1 mg ml^{-1} were observed.

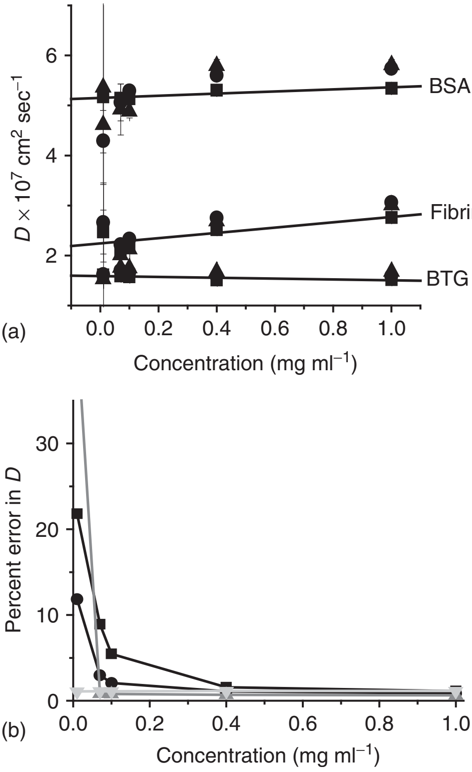

Figure 32.3 (a) Effect of analyte concentration on measured D values (at different flow rates) for protein standards prepared in 50 mM PBS (■, batch mode; ●, 0.1 ml min^{-1}; and ▲, 1.0 ml min^{-1}). The solid black lines are linear regression lines for batch mode values. (b) D measurement error for batch mode measurements (■, black line – myoglobin; ●, dark gray line – BSA; ▲, gray line – fibrinogen; and ▼, light gray line – BTG). Scattering angle: 108° for (a) and (b). The samples were introduced directly into the PCS detector.

The precision of online D measurements is better for low-MW proteins compared to analogous PS standards. For example, myoglobin had an error of 1.6% at a concentration of 0.4 mg ml^{-1} compared to PS20, which had an error of 8.9% at the same concentration. This is a result of the compact globular configuration of the proteins in PBS and the lower background scattering intensity of water compared to THF.

The PS and protein results demonstrate the importance of concentration on the accuracy of measured D values. An analyte concentration of at least 0.1 mg ml^{-1} is desirable to measure online D values within 2–4% of D_0. This is within experimental measurement error.

32.5.1.2 **Effect of Separation Flow Rate**

Figure 32.2 and Figure 32.3 show that flow rates <1.0 ml min^{-1} had a 2–6% impact on D_0 compared to batch mode measurements. Figure 32.4a,b shows the results of a more detailed systematic study of the effect of carrier liquid flow rate on the measured D values for PS and protein standards prepared at concentrations of

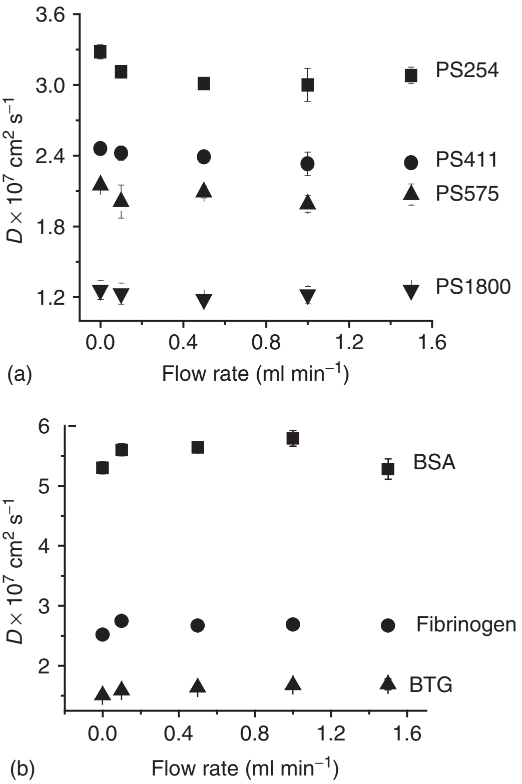

Figure 32.4 Effect of flow rate on measured D values for (a) PS standards in THF (0.1 mg ml^{-1}) and (b) protein standards in 50 mM PBS (0.1 mg ml^{-1}). The samples were introduced directly into the PCS detector.

$0.1\,\mathrm{mg\,ml^{-1}}$ in THF and 50 mM PBS, respectively. It is observed that flow rates in the typical ranges used for SEC and FFF separations do not have a significant effect on the measured D values. This conclusion is in agreement with data previously reported for BSA at concentrations of $5.0\,\mathrm{mg\,ml^{-1}}$ measured at flow rates ranging from 1 to $10\,\mathrm{ml\,min^{-1}}$ and for gold nanoparticles and PS sulfonate polyelectrolytes fractionated using FlFFF and flow rates up to $2\,\mathrm{ml\,min^{-1}}$ [5, 21, 29]. The scatter in the data in Figure 32.4a,b is observed to increase with decreasing MW of the analyte. This is likely a result of analyte concentration rather than changes in flow rate as discussed earlier.

Table 32.2 compares D_0 values for PS in THF and proteins in 50 mM PBS under different flow conditions and with literature values. Good agreement is observed between PS and fibrinogen online and literature D values [2, 44, 46]. The measured D values for unfractionated BSA and BTG are lower than reported literature values for protein monomers because of contributions from dimers or higher order aggregates [48–51]. It is concluded that the flow rates typically used for separation ($<2.0\,\mathrm{ml\,min^{-1}}$) have a small effect on the accuracy of D values obtained by online PCS.

32.5.1.3 **Effect of Scattering Angle**

Figure 32.5 shows the relationship between the scattering angle at which data is acquired and the measured D value for PS575 and PS1800 in batch mode and at $0.1\,\mathrm{ml\,min^{-1}}$. The data is plotted as D/D_{38} versus the scattering angle of the measurement to enhance the observed angular dependence of the measured D values. D is the value obtained at the scattering angle indicated on the x-axis and D_{38} is the value measured at 38°. Batch mode and online PCS data are in agreement and no significant angular dependence (deviation <5%) was observed for PS575. However, a systematic angular dependence is observed for PS1800 with measured

Table 32.2 Online PCS: comparison of D_0 values for polymers in THF and proteins in PBS under different flow rates.

[b] Percentage change from batch mode measurements.

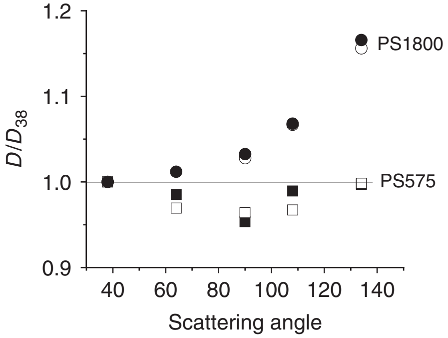

Figure 32.5 Effect of scattering angle on measured D values for PS575 (squares) and PS1800 (circles) prepared in THF ($0.1\ \mathrm{mg\,ml^{-1}}$) and measured in batch mode (solid symbols) and at $0.1\ \mathrm{ml\,min^{-1}}$ (open symbols). The horizontal line indicates no angular dependence. D measurement taken at the scattering angle indicated on the x-axis. D_{38} is the D value at a scattering angel of 38°.The samples were introduced directly into the PCS detector.

D values increasing up to 20% as the measurement angle increased from 38° to 134°. The observed increase in D values for higher MWs can be attributed to internal motions of the macromolecule [3, 6, 16, 25, 40].

This data shows that the measurement angle must be considered. Additional considerations arise from Eq. (32.5), which shows that the decay rate is linearly dependent on the square of the scattering vector q and the timescale of the decay can be increased by collecting data at smaller angles. For example, the time for the diffusion process viewed at 15° is 29 times longer than for the same process measured at 90°. Moreover, the amount of light scattered into the detector is proportional to the scattering volume and ~3.9 times as much light is collected at 15° compared to 90° [4]. Data collection at small angles is advantageous for low-MW polymers with extremely fast decay rates because data collection time and scattering intensity are effectively increased (compared to the standard 90° settings). For high-MW samples that exceed isotropic scattering dimensions ($d_h > 1/10$ the wavelength of the incident light) low-angle data collection yields the true center-of-mass diffusion. This is because contributions of internal motions of the polymer chain to D are eliminated in the limit of $q \rightarrow 0$ [3, 4, 6, 16, 25, 40, 41]. Therefore, small scattering angles should be used for online PCS to be applicable to the widest possible range of polymer MWs.

32.5.1.4 Effect of Sample Molecular Weight

Diffusion coefficient and MW are related through the well-known equation $D = A(\mathrm{MW})^{-b}$, where A and b are the intercept and slope of a plot of log D versus log MW. Log–log plots can be used to determine polymer MW from measured D values, assess the polymer configuration in solution (i.e., globular, random coil, or rodlike), and evaluate the thermodynamic goodness of a solvent for a polymer [3]. Deviation from the expected linearity of a log–log plot for linear polymers could indicate angular dependence of the scattering intensity or changes in the

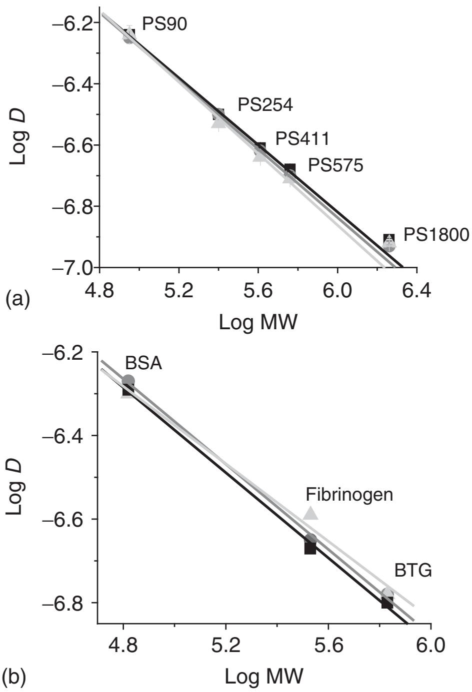

Figure 32.6 Effect of analyte MW on measured *D* values for (a) PS in THF and (b) protein standards in 50 mM PBS. The lines are linear regression lines for data collected under different flow conditions. (For both (a) and (b): ■, black line – batch mode; ●, gray line – 0.1 ml min^{-1}; and ▲, light gray line – 1.0 ml min^{-1}.) The samples were introduced directly into the PCS detector.

configuration of the polymer. Figure 32.6a shows the log–log plot for PS standards in THF. Literature reports of *b* values for PS in THF obtained from batch mode experiments range from 0.55 to 0.58 [32, 46, 47]. The experimental *b* values obtained in batch mode and for flow rates up to 1.0 ml min^{-1} also fell in a similar range. Experimental *A* values that ranged from 2.9 to 4.5×10^{-4} (for batch mode to 1.0 ml min^{-1}) were also in good agreement with literature [44, 46, 47]. The PS1800 standard was consistently observed to lie above the linear regression for each flow condition. This systematic overestimation of *D* for PS1800 is due to a combination of the angular dependence of the scattering intensity and inaccuracy in the nominal MW. The MW of PS1800 was measured to be $((1.42 \pm 0.23) \times 10^6$ Da).

Figure 32.6b shows that the diffusion behavior of proteins as a function of MW also follows the $D = A(\mathrm{MW})^{-b}$ relationship. The linear regression for batch and online *D* values yielded *b* values of ~0.50. The slope of this regression line is expected to be 0.33 for globular proteins such as BSA and BTG. Table 32.2 shows that the measured *D* value for BTG of $1.59 \times 10^{-7}\ \mathrm{cm^2\,s^{-1}}$ is significantly lower than the literature value of $\sim 2.6 \times 10^{-7}\ \mathrm{cm^2\,s^{-1}}$ for a BTG monomer due to the presence of aggregates. In addition, the *D* values for BSA are in better agreement with the values for dimer proteins. The measured *D* for fibrinogen agreed with literature values [2, 44].

It is concluded that the relationship between analyte *D* values and MW is similar for batch and online mode PCS measurements of unfractionated samples. However, the contribution of high-MW species, dimers, and/or higher order aggregates to measured *D* values resulted in unexpected *b* values because of the high sensitivity of PCS to large-sized analytes.

32.5.1.5 **Summary**

Accurate and precise online *D* values can be measured with PCS by utilizing low-scattering angles to increase the measurement timescale and analyte scattering intensity, and by maintaining an analyte concentration $>0.1\ \mathrm{mg\,ml^{-1}}$. Typical flow rates used to achieve FFF or SEC polymer separation have an insignificant effect on measured online *D* values.

32.5.2
Factors Affecting the Accuracy of *D* Values Measured by FFF-PCS

The previous sections demonstrated the contribution of individual variables such as analyte concentration and MW, carrier liquid flow rate, and scattering angle on the accuracy and precision of online *D* values. The two most critical variables were the analyte concentration (should be $\geq 0.1\ \mathrm{mg\,ml^{-1}}$) and the scattering angle (low angles will minimize the angular dependence of the scattering). These conditions will maximize analyte signal and provide more accurate and precise online *D* values by increasing the data collection time and sample scattering intensity. The results to this point have been obtained by direct injection of the sample solutions into the PCS detector.

Part 2 of this study demonstrates the application of ThFFF/PCS to lipophilic macromolecules (PS and polyacrylate standards) in organic solvent and FlFFF/PCS to proteins (BSA and BTG) in aqueous solution. These applications are preceded by a discussion about the criteria used to select retention time intervals for the online determination of *D* and further refinement of FFF/PCS instrument configuration. The four samples characterized by ThFFF/PCS were selected to demonstrate different capabilities of this combined technique. Sample 1, which is a mixture of PS homopolymers, demonstrates the capability of ThFFF/PCS to fractionate a polymer mixture based on size differences of the analytes and accurately measure *D* for each eluting component. Samples 2 and 3 demonstrate the ability of ThFFF/PCS to fractionate polymer mixtures based on differences in component chemistry. Sample 3 represents a challenging mixture of three different polyacrylates. Sample 4 demonstrates the capability to characterize high-PDI polymers.

32.5.2.1 **Selection of Retention Time Intervals**

The studies in the previous sections demonstrate the relative importance of analyte concentration, scattering angle, flow rate, and analyte MW on the accuracy of online *D* measurements. While it is important to examine the effect of each parameter individually and identify the major contributor(s) to potential inaccuracies in *D* measurements, it is also important to note that their effects are interdependent. For example, high-MW PS exhibits higher scattering intensities and thus the threshold concentration for accurate *D* measurement is lower than that for a lower MW PS. This becomes significant when coupling a separation stage with online PCS as the eluting sample peak varies in concentration and possibly composition. The scattering intensity of the eluting sample is a culmination of analyte properties and experimental conditions and hence can be related to percentage errors in *D*. A signal-to-noise (S/N) ratio >2.5 is used to guide the selection of the retention time interval over which *D* values are averaged for each component separated by FFF. This ratio corresponds with errors <10% in measured FFF/PCS *D* values as shown in Figure 32.7, which plots the percentage error in ThFFF/PCS *D* measurement versus S/N for PS in THF. This curve should be independent of the chosen solvent.

32.5.2.2 **Carrier Liquid Temperature**

ThFFF utilizes large temperature gradients to achieve polymer separations, which can cause elevated carrier liquid temperatures. Furthermore, the temperature gradient is often programmed to decrease from high to low ΔT values to reduce analysis times. This may result in a constantly changing carrier liquid temperature as it passes through the PCS detector. The temperature sensitivity of *D* and d_h necessitates that the carrier liquid temperature remains constant in the PCS instrument so that accurate values are measured. The temperature of the carrier liquid passing through the MALS detector was found to remain constant between 25 and 26 °C when either constant ΔT or programmed decay ΔT conditions were used. ThFFF/PCS *D* values for PS254 in THF using different constant ΔTs of 30, 50, 70, and 90 °C were measured to be 3.34 ± 0.12, 3.45 ± 0.14, 3.50 ± 0.14, and $3.42 \pm 0.14\,\text{cm}^2\,\text{s}^{-1}$, respectively. These results show that the carrier liquid temperature does not systematically contribute to measure online *D* values for the ThFFF/PCS setup used in this study. However, this potential effect should be evaluated for each individual ThFFF channel. If needed, the carrier liquid temperature

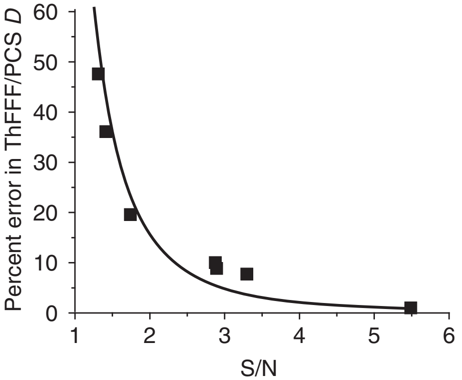

Figure 32.7 Percentage error in ThFFF/PCS *D* versus S/N for PS in THF.

can be accurately maintained at a desired constant temperature by using a column heater/exchanger in between the ThFFF outlet and the detector inlet [52].

32.5.2.3 Optimum Instrument Configuration

The results shown in Figures 32.2 and 32.3 were obtained by injecting a sufficiently large sample plug directly into the PCS detector so that a constant concentration is maintained throughout the D measurement. This situation is quite different when the PCS detector is connected to a separation instrument such as FFF. First, each separated sample component elutes as a peak that varies in concentration over time. Second, achieving an analyte concentration of 0.1 mg ml^{-1} at the detector is challenging because of significant dilution (15–100×) during the separation stage. Injecting higher concentration samples may cause channel overloading, which in turn leads to peak broadening, fronting/tailing, shifted retention times, and loss of resolution. Another alternative to optimizing the concentration of the eluting sample components is to minimize band broadening, particularly, those associated with the instrumental setup [44]. One facile instrumentation modification is to use a smaller volume sample loop. The contribution of sample injection volume to band broadening is represented by Eq. (32.11), where $\sigma_{\text{inj}}{}^2$ is the sample injection variance and Δt_{inj} is the time needed for the sample to flush out of the sample loop

$$\sigma_{\text{inj}}^2 = \frac{\Delta t_{\text{inj}}^2}{12} \tag{32.11}$$

Reducing the injected sample volume by 50-fold from 20 to 0.4 µl theoretically results in a 50-fold decrease in the sample injection volume contribution to the band broadening. To maintain the sample-injected amount, the sample concentration would need to increase 50×. However, in practice, the upper limit of sample concentration that can be injected using a 0.4 µl sample loop is determined by the viscosity of the polymer sample solution. Figure 32.8 compares fractograms obtained for PS411 in MEK using 0.4 and 20 µl sample loops. A higher signal intensity is measured when using the smaller volume sample loop with a higher concentration sample. The D value obtained using the 20 µl sample

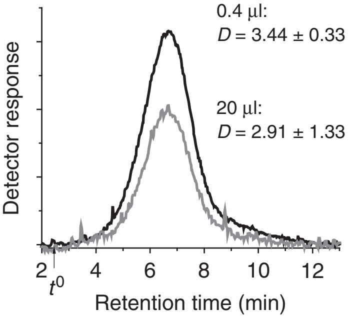

Figure 32.8 Comparison of ThFFF fractograms for PS411 in MEK obtained using a 0.4 µl (black trace) sample loop and a 20 µl (gray trace) sample loop. The D values are indicated for each peak ($\times 10^7$ cm^2 s^{-1}).

loop was $(2.91 \pm 1.33) \times 10^{-7}\,\mathrm{cm}^2\,\mathrm{s}^{-1}$. The D value measured using the 0.4 µl sample loop was $3.44 \pm 0.11 \times 10^{-7}\,\mathrm{cm}^2\,\mathrm{s}^{-1}$, which is in agreement with the value of $3.43 \times 10^{-7}\,\mathrm{cm}^2\,\mathrm{s}^{-1}$ obtained from batch mode measurements. These results demonstrate the advantage of injecting small volumes of high concentration analyte solutions.

Low angles for PCS data collection and the injection of concentrated low-volume samples were used in the ThFFF/PCS analysis of a mixture of three low PDI PS standards in MEK (shown in Figure 32.9). Three components can be easily identified and the elution order is as expected from low to high MWs. The shaded regions indicate the retention time ranges over which the S/N was >2.5 and ThFFF/PCS D values were averaged. The separation seen in Figure 32.9 was performed under both the manufacturer's instrument configuration (20 µl sample loop and 108° scattering angle) and the optimized instrument configuration (0.4 µl sample loop and 38° scattering angle). Triplicate measurements of ThFFF/PCS D values for each PS component in the separated mixture are compared in Table 32.3. Using the optimized configuration, the error in the measurement is reduced by almost 50% and an accurate value for D is obtained for the high MW sample, which was not obtained using the manufacturer's instrument configuration (recall 1800 in Figure 32.6a).

Figure 32.10 compares the ThFFF/PCS average D values listed in Table 32.3 to nominal batch mode values in a log–log plot. The linear regressions between the optimized instrument configuration and batch mode data are in excellent agreement and the slopes of these lines are also shown in Figure 32.10. The linear regression for the manufacturer's instrument configuration and the batch mode data deviates particularly for the high MW standard. It is not possible to discern whether this increase in D is due to contributions from internal motions of the

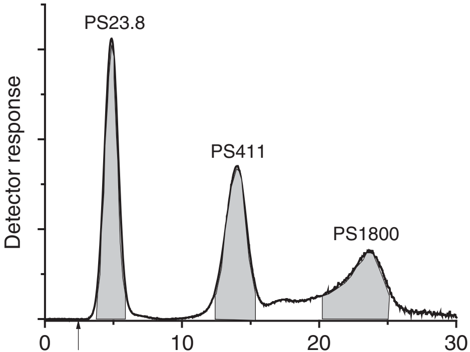

Figure 32.9 ThFFF separation of a three component mixture of low-PDI PS standards in MEK. Shaded regions mark the time interval over which the S/N was >2.5. ThFFF conditions: carrier liquid, MEK; ΔT, programmed exponential temperature decay (exponent of 2); initial ΔT, 80 °C for 5 min; flow rate, 0.4 ml min^{-1}; injection volume, 0.4 µl; scattering angle, 38°; and sample concentrations: PS23.8, 80 mg ml^{-1}; PS411, 4.0 mg ml^{-1}; and PS1800, 1.4 mg ml^{-1}.

Table 32.3 Comparison of ThFFF/PCS *D* values measured from the peaks of separated standards in MEK using different instrument configurations.

	$D \times 10^7$ cm^2 s^{-1}	
Sample	**Manufacturer configuration**[a]	**Optimized configuration**[b]
PS23.8	17.30 ± 1.35	16.93 ± 0.76
PS411	3.61 ± 0.34	3.48 ± 0.20
PS1800	2.53 ± N/A[c]	1.55 ± 0.11

[a] 20 μl Sample loop, 108° scattering angle, MEK, PS23.8, 411 and 1800–1810, and 0.5 and 0.17 mg ml^{-1}, respectively.

[b] 0.4 μl Sample loop, 38° scattering angle, MEK, PS23.8, 411 and 1800–1880, and 4.0 and 1.4 mg ml^{-1}, respectively.

[c] Only one of three injections yielded data.

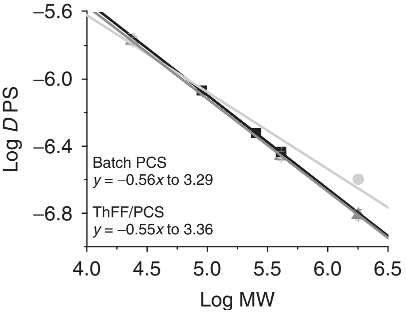

Figure 32.10 Comparison of ThFFF/PCS *D* values measured in MEK using the optimized instrument configuration (▲, gray line) and the manufacturer's instrument configuration (●, light gray line) with nominal batch mode values (■, black line).

polymer or because of poor precision, because *D* for only one of the three replicate injections was successfully measured.

Figure 32.11 demonstrates that ThFFF/PCS *D* values can be measured for weakly scattering polymers such as PBA and PMA when using the 0.4 μl sample loop and a scattering angle of 38°. Excellent agreement is observed between batch mode and online *D* values.

32.5.3
ThFFF/PCS Characterization of Synthetic Polymers

The optimum experimental conditions identified earlier were employed for ThFFF/PCS characterization of synthetic homopolymer mixtures and polydisperse samples. *D* and D_T values are simultaneously obtained at each slice of a fractionated sample eluting from the ThFFF channel, in addition, to average *D* and D_T values for the entire sample. This allows both the size and the composition distributions

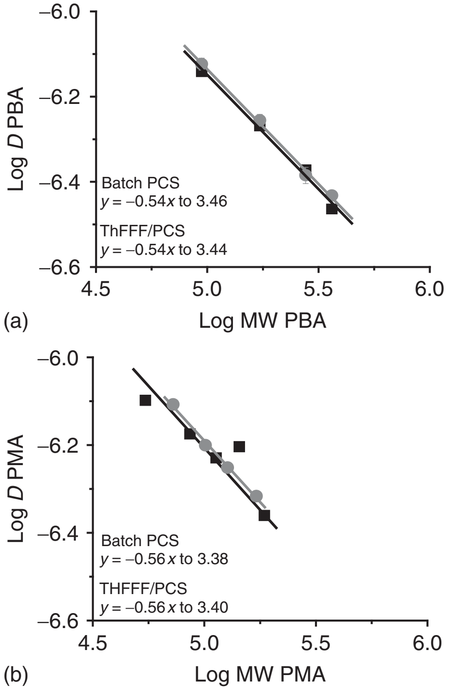

Figure 32.11 Comparison between batch mode (gray line) and ThFFF/PCS *D* (black line) values measured in MEK using the optimized instrument configuration for (a) PBA and (b) PMA homopolymers.

of homopolymers with broad MWs, heterogeneous polymers or polymer mixtures to be characterized.

Figure 32.12 shows a near baseline separation of a mixture of PBA and PS linear homopolymer standards. The average ThFFF/PCS D and D_T values for each component of the mixture were calculated from the time intervals ($S/N > 2.5$) indicated by the shaded regions. The similar D values for both homopolymers indicate that they have similar hydrodynamic diameters and that the separation is based on different homopolymer chemistries, which is reflected by their different D_T values. As expected, a longer retention time is observed for the analyte with the larger D_T value. The average D_T values for PBA263 and PS390 in MEK were calculated to be $(1.00 \pm 0.04) \times 10^{-7}$ cm^2 K^{-1} s^{-1} and $(1.69 \pm 0.03) \times 10^{-7}$ cm^2 K^{-1} s^{-1}, respectively. This is the first reported D_T value for PBA in MEK while the D_T value for PS in MEK agrees well with the range of $(1.39–1.9) \times 10^{-7}$ cm^2 K^{-1} s^{-1} reported in literature [32, 53].

ThFFF/PCS fractionation of a broad MW PS standard with a weight average MW of 250 kDa and a PDI of 2.5 (250BR) is shown in Figure 32.13a. Sample elution was also monitored by MALS-dRI detectors. The sample is well retained and the peak is broader than those seen in Figure 32.9 for low PDI PS standards. In this case, the additional complication is that the MALS and dRI traces in

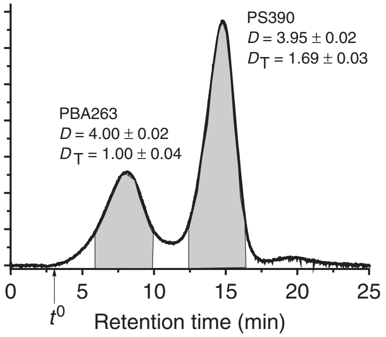

Figure 32.12 Composition-based ThFFF separation of a mixture of PS and PBA homopolymer standards with similar *D* values but different D_T values. Shaded regions mark the time interval over which the S/N was >2.5. ThFFF conditions: carrier liquid, MEK; flow rate, 0.4 ml min^{-1}; ΔT, 70 °C constant; injection volume, 0.4 µl; scattering angle, 38°; and sample concentrations: PS390, 4.0 mg ml^{-1} and PBA263, 20 mg ml^{-1}.

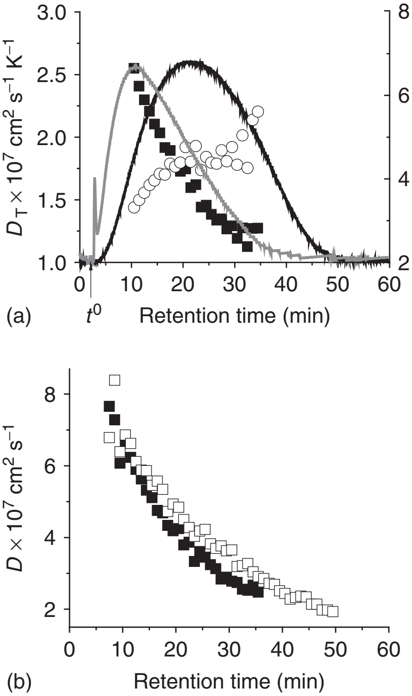

Figure 32.13 (a) ThFFF separation of a broad MW PS standard (MW: 250 kDa, PDI: 2.5) prepared at 50 mg ml^{-1}. MALS (black trace) and dRI (gray trace) fractograms are overlaid with *D* (■) and D_T (○) values taken at 1 min intervals across the peak. (b) Comparison of online *D* values taken at 1 min time intervals across the ThFFF fractogram of PS250BR injected at concentrations of 50 (■) and 100 mg ml^{-1} (□). ThFFF conditions: carrier liquid, MEK; flow rate, 0.4 ml min^{-1}; ΔT, 100 °C; injection volume, 0.4 µl; and scattering angle, 38°.

Figure 32.13a have different peak maximum retention times. Consequently, two average D_T values for PS250BR can be calculated using each peak maximum t_r. The question that arises is which average D_T value is most accurate. Average D_T values of $(0.98 \pm 0.02) \times 10^{-7}$ cm^2 K^{-1} s^{-1} (dRI) and $(1.83 \pm 0.07) \times 10^{-7}$ cm^2 K^{-1} s^{-1} (MALS) were calculated to be 40% lower and 10% higher, respectively, compared to the expected D_T value of $(1.67 \pm 0.14) \times 10^{-7}$ cm^2 K^{-1} s^{-1} for PS in MEK. The peak maximum of the MALS trace yields the more accurate average D_T value for polydisperse samples. The lower than expected D_T calculated from the dRI trace can be attributed to the shift of the peak maximum to shorter retention times because of a large amount of low-MW species. The higher than expected D_T calculated from the MALS trace may be a result of either a detector bias toward high-MW species due to their increased scattering intensity or to sample overloading.

Figure 32.13a shows D and D_T taken at 1 min time interval across the fractogram. D is observed to decrease across the peak width as expected with increasing retention times. D_T initially increases, then plateaus at 20 min, and increases again at 30 min. D_T should be constant across the elution peak because homopolymer D_T has been shown to be independent of MW and branching for polymers with MWs >10 kDa [32, 33, 54]. The deviation of D_T at short and long retention times can be attributed to inaccuracies in ThFFF/PCS D measurements because of low-sample concentrations (≤ 0.02 mg ml^{-1}) eluting the ThFFF channel. This concentration is 5× below the desired threshold of 0.1 mg ml^{-1} and results in larger errors in D measurements. D_T values within the plateau region between 20 and 30 min (which corresponds with MALS peak maximum) are observed to be $\sim 1.75 \times 10^{-7}$ cm^2 K^{-1} s^{-1}. This is in good agreement with literature values for PS in MEK and demonstrates that retention times near the MALS peak maximum can be used to calculate D_T values. Figure 32.13 b shows the effect of doubling the injected sample amount on measured ThFFF/PCS D values. Before 15 min, the measured D values for each concentration agree. Beyond 15 min, the D values increased by up to 30% for the more concentrated sample. This translates into an increase of D_T by the same amount. This current limitation of ThFFF/PCS to measure a constant D_T value across a sample elution peak warrants further investigation.

Analysis of mixtures composed of chemically similar polymers is difficult from both the separation and the characterization perspectives. Pressure-sensitive adhesives represent this class of sample as they are often formulated from mixtures of polyacrylate homopolymers. ThFFF/PCS can be used to accomplish separation and characterization in a single step because of ThFFF's composition- and size-based separation mechanisms. A partial separation of a mixture of P2EHA242, PBA263, and PMA171 is shown in Figure 32.14. D slightly decreases while D_T significantly increases across the fractogram. This indicates that the three components have similar hydrodynamic sizes and that the separation was driven by differences in their chemistry. Qualitative identification of each component was achieved by comparing the D_T value measured at peak maximum retention time with that measured from individual homopolymer injections. D_T from individual injections were measured to be 0.83 ± 0.13, 1.01 ± 0.06, and $1.88 \pm 0.26 \times 10^{-7}$ cm^2 K^{-1} s^{-1} for P2EHA, PBA, and PMA homopolymers, respectively. The observed elution order

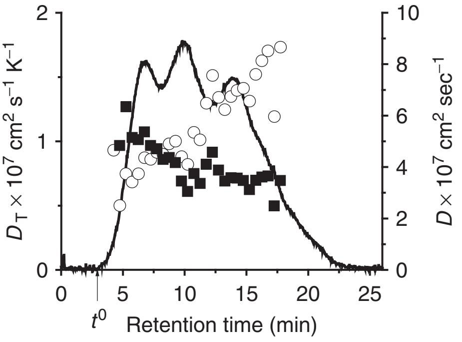

Figure 32.14 ThFFF/PCS characterization of a mixture of P2EHA242, PBA263, and PMA171 homopolymers. D (■) and D_T (○) taken at 30 s time slices overlay the MALS fractogram. ThFFF conditions: carrier liquid, MEK; flow rate, 0.4 ml min^{-1}; ΔT, 80 °C constant; injection volume, 0.4 μl; scattering angle, 38°; and sample concentrations: 22–40 mg ml^{-1}.

of P2EHA242, PBA263, and PMA171 follows the order of increasing D_T values as expected. Figure 32.12 and Figure 32.14 demonstrate ThFFF/PCS's potential for characterizing multiple component polymer mixtures.

32.5.4
FlFFF/PCS of Proteins

The established operational guidelines for online PCS are equally applicable to hydrophobic analytes such as proteins and protein aggregates. The fractograms for BSA and BTG are shown in Figure 32.15, which demonstrate FlFFF's ability to separate monomers from aggregates. The shaded regions signify the time interval where the S/N was >2.5 and measured D values have errors below 10%. Excellent agreement is observed between FlFFF/PCS D and literature values for both protein monomers (Table 32.3). The D for the aggregate peak in the BTG fractogram

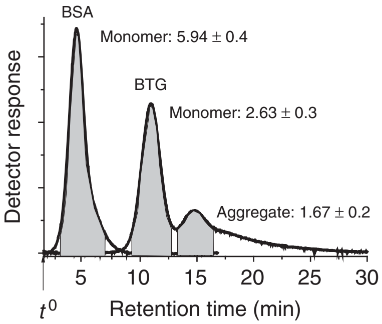

Figure 32.15 Overlay of BSA (gray trace) and BTG (black trace) FlFFF fractograms. FlFFF/PCS D values ($\times 10^7$ cm^2 s^{-1}). Shaded regions mark the time interval over which the S/N was >2.5. FlFFF/PCS conditions: $\dot{V}_c$, 2.85 ml min^{-1}; $\dot{V}$, 1.25 ml min^{-1}; and sample concentrations: BSA, 11.0 mg ml^{-1} and BTG, 2.0 mg ml^{-1}.

was measured to be $1.67 \times 10^{-7}\,\mathrm{cm^2\,s^{-1}}$ which, as expected, is lower than that for monomer. The plot of log D versus log MW of the protein monomers yielded a slope of 0.34 between the BSA and BTG monomers, which agrees with the literature value of 0.33 for globular proteins [51]. This is in contrast to the 0.54 slope observed in Figure 32.6b, which was obtained without any sample separation. The batch mode D values for the rod-shaped fibrinogen fall well below the linear regression for globular proteins as expected [51]. These results demonstrate that a separation stage is important to obtain accurate D values of broadly distributed or multimodal samples.

32.6
Conclusions

The effects of analyte concentration, flow rate, scattering angle, and MW on the accuracy of D measurements from online PCS were evaluated by comparison with values obtained in batch mode. Analyte concentrations $>0.1\,\mathrm{mg\,ml^{-1}}$ at the detector and measurement at small scattering angles are desired for accurate online D determinations. While the absolute numbers reported in this study are instrument specific, the general observations are expected to be applicable across different instruments.

An S/N ratio of >2.5 was established as the threshold for maintaining errors in D below 10%. This criterion was applied when obtaining average D results for ThFFF/PCS of polymers in organic solvent and FlFFF/PCS of proteins in aqueous solution. Excellent agreement was obtained between FFF/PCS and batch mode D values. The use of an optimized instrument configuration was crucial to successful ThFFF/PCS determinations of D and D_T. The combination of a separation stage with online PCS has enabled the successful characterization of subpopulations present in mixtures or high-polydispersity samples, which would otherwise remain hidden in traditional batch mode measurements. The guidelines presented for online PCS are shown to be valid for both lipophilic and hydrophilic analytes, and are expected to be applicable to other separation techniques.

Surface Plasmon Resonance Spectroscopy and Molecularly Imprinted Polymer (MIP) Sensors

Allan Cyago and Rigoberto Advincula

33.1
Introduction

In the advent of new concerns over environmental pollution, diminishing sustainable clean water supplies, and contamination of food products, the need for novel analytical methods has prompted research on sensors with low-cost preparation and highly efficient capabilities. Chemical sensors and biosensors have gained a major role in the development of innovative techniques for the measurement and detection of biologically (pharmaceuticals and biomolecules) and environmentally (contaminants and pollutants) important substances. The focus of sensor preparation and research usually emphasizes on two fundamental parts, which are essential in the improvement of overall sensor device performance; first, the signal generation process or how the ''sensor response'' is made based on specific molecular interactions between the target molecule and the ''recognition site'' and second, on the signal transduction method employed, which directly affects the analytical figures of merit of the complete sensor.

Chemical sensors employ detection based on signal obtained from covalent or noncovalent types of interaction, such as metal–ligand complexation, van der Waals force, and electrochemical redox transport of electrons. On the other hand, biosensors use specific covalent and noncovalent types of interaction, but facilitated by biomolecules serving as recognition sites embedded on the sensor platform. Most biomolecules used in biosensors act via enzyme–substrate interaction, antigen–antibody bonding (immunosensors), or membrane-based proteins as ion-transport sensors. These natural receptors offer exceptional sensitivity and selectivity when coupled with a suitable detection method, but they require special handling conditions and are less stable chemically and mechanically, often more expensive. The success of the analytical method also depends strongly on the signal transduction process, especially techniques with high resolution and signal-to-noise ratio, which allows the detection of target molecules at trace concentrations. Common examples include various electrochemical methods [1], mass-sensitive techniques such as quartz crystal microbalance (QCM) [2], and also surface-based techniques such as atomic force microscopy (AFM) [3]. An important

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

consideration in sensor design is the ability to incorporate the sensing platform directly to the transducer surface, which allows for more sensitivity as the signal generated is directly transported to the digital output device used. This effectively lowers the signal-to-noise ratio generated for the device and leads to higher calibration sensitivity and lower limits of detection (LODs).

An important class of signal transduction techniques that is capable of direct integration with the recognition element is the surface plasmon resonance (SPR) technique. This technique involves measurement of changes in property of reflected light from the surface of a thin film noble metal, such as gold or silver, as a result of the evanescent excitation of surface plasmon waves propagating on the metal–dielectric surface. Initially, SPR has been extensively studied for biosensors applications owing to high sensitivity and specificity, and as proof many instruments have since been commercialized successfully [4]. However, the drawbacks inherent to the use of biomolecules in sensor applications, such as short lifetime and loss of sensitivity due to deactivation have led to the research and discovery of novel and stable chemical-sensing platforms.

Molecular imprinting as a method of preparing recognition sites has now become a leading research field in the study of sensors. The technique has the ability to mimic the action of biomolecules, while having exceptional mechanical and chemical stabilities in otherwise harsh conditions. Molecular imprinting has become a widely preferred technique due to its effectiveness, low-cost preparation, and directness of approach. Molecular imprinting technique has been widely studied over the last decade [5] (Figure 33.1), with the number of publications increasing dramatically over the last few years. This has lead to a wide variety of applications, some of which have already been commercialized. In general, the technique is based on entrapment of molecules and other particles of interest in a predetermined scaffold,

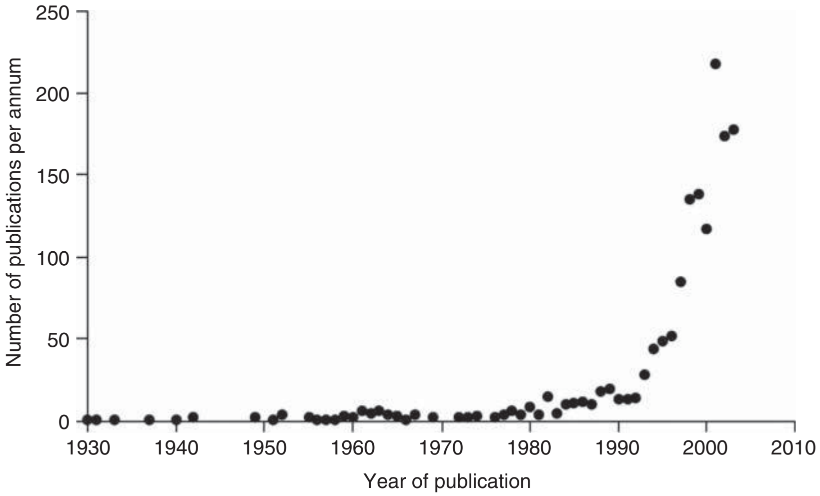

Figure 33.1 The number of publications within the field of molecular imprinting science and technology per annum for the period 1931–2003. (Taken from Ref. [5].)

after which a suitable washing step is performed to remove most of the originally entrapped material. The washing process leaves behind a cavity – the recognition site – that is sensitive toward the original or other similarly structured molecules. Another term for this model is the ''lock-and-key'' model, which is also used to refer to enzymes. For most of the molecular imprinting techniques currently applied in sensors, organic-based scaffolds, particularly polymers, are commonly used, and the number of original papers on ''molecularly imprinted polymers'' or MIPs have dramatically increased over the past decades [5, 6]. As the different methods of polymerization have now been well reported, this knowledge has been extensively applied in the preparation of MIPs, resulting in the formation of tunable recognition elements that have specific properties, for example, enhanced selectivity, enzymelike catalysis, and enantioselectivity. With a suitable signal transduction method, MIP-based sensors can achieve higher sensitivity, accuracy, and selectivity compared to similarly designed biosensors, making them more commercially viable and able to meet the demands of low-cost sensing. Flow injection process, microfluidics, and other miniaturization techniques should enable the MIP sensor setup to be portable and thus allow onsite monitoring of environmental pollutants and contaminants that may be considerably difficult for humans to handle. As a signal transduction technique, SPR allows the detection of molecules of interest down to picomolar levels. With MIPs as recognition element, it can achieve even more sensitive detection at ultratrace levels. One major advantage of combining MIP with SPR is the ability to prepare the imprinted polymers directly on the SPR substrate, thus lessening the time needed for sensor preparation and allowing enhanced sensitivity as the recognition event happens within the range of the evanescent field for plasmon absorption to occur. Research on MIP-SPR (Figure 33.2) sensors have increased steadily over the last few years, with efforts focused on more simple

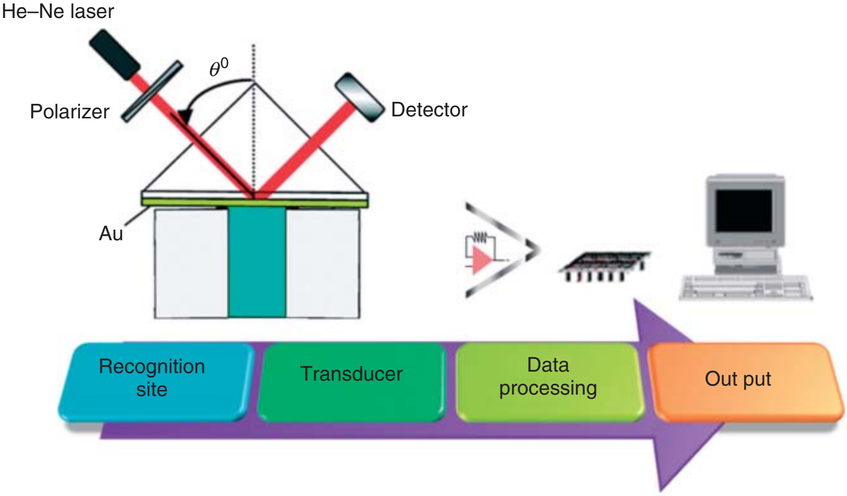

Figure 33.2 MIP-SPR setup.

methods of preparing the MIP-gold sensor chip and use of simple and more sensitive SPR setups. This review describes the research made on MIP sensors with SPR as a detection process, based on previous works and the current models that utilized novel preparation techniques and improvements on instrumentation setup.

33.2
Molecularly Imprinted Polymers

33.2.1
MIP Technique

Molecular imprinting on polymer scaffolds is a facile and versatile way of preparing artificial receptors. As different polymerization techniques had been discovered, it has become a widely used method in making the selective recognition element for sensors. MIP synthesis (Figure 33.3) starts with the introduction of monomers in solution together with the template – the molecule to be imprinted – based on a "prepolymer" condition. This allows the templates to interact more with the monomers and be dispersed evenly in solution. During polymerization, the template is entrapped along with the growing polymer chains, a process that essentially determines the number of active recognition sites. A subsequent washing step is performed to remove the bound template, leaving behind cavities with shape and size complementary to the original template. When the washed polymer is placed in a solution of same template or similarly structured molecules, selective adsorption takes place as the particles bind to the cavities, and with an appropriate transducer the accompanying change in properties of the polymer can be converted into a quantifiable signal. Such changes may be observed in terms of polymer porosity, dielectric/refractive index property, surface energy, mass variations, or conductivity (electrochemically conducting polymers (ECPs)). Vinyl-based free-radical polymerization is a very common route in preparing MIPs [5, 6], but other techniques have also been adopted, most notably electropolymerization with electroactive monomers, and polycondensations. Several

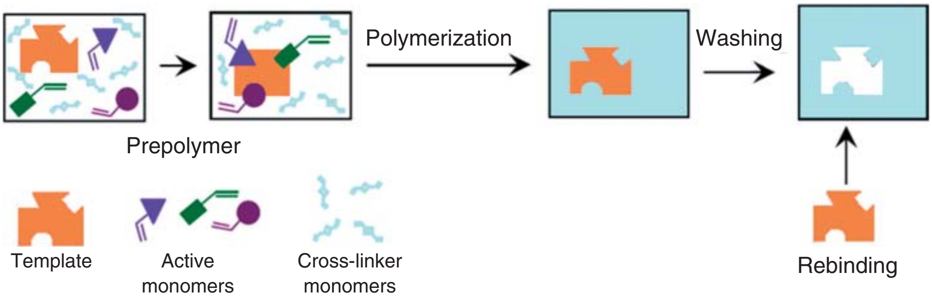

Figure 33.3 Diagram of MIP preparation.

methods have also been performed to introduce functionality in the MIP recognition sites. The noncovalent approach uses monomers with specific functional groups that enhance the ligand–template complex during the prepolymer step. This is, particularly, useful in preparing MIPs with special properties, such as enantioselectivity [7], catalysis [8], and transport capability [9]. In the covalent approach, the target molecule is attached covalently to one of the monomer components in the MIP. In a reported covalent MIP approach, a sialic acid template was covalently attached to the active monomer *p*-vinylbenzeneboronic acid ester. After preparation of the MIP, the system was shown to have greater binding affinity toward GM1 ganglioside, which contains a sialic acid moiety in its structure [10].

33.2.2
Methods of Preparing MIPs: from Bulk Imprinting to Surface Imprinting Techniques

The earliest reports on MIP synthesis were based on solution polymerization systems involving functionalized vinyl-based monomers, cross-linkers, and initiator mixed initially in a prepolymer solution condition. To prepare an MIP-sensing film, this prepolymer solution can be casted on the surface of a substrate followed by thermal or photocured, resulting in a ''grafted to'' polymer film. Another way is by initially grinding the resulting polymerized solid MIP (monolith) to make fine particles before dispersing with a suitable solvent, which is then casted on the transducer surface. These methods of preparation are proved to be simple and straightforward, and readily available for various modifications with additives. However, MIPs films prepared from this method suffer from a host of problems observed due to binding site heterogeneity and incompatibilities among the polymer, template, and porogen (solvent) [5, 11]. The application of molecular imprinting on large templates also poses difficulty in terms of regenerating the binding sites – as the polymer network encloses on the templates, they become more hindered and thus become more impeded from being washed off from the binding site cavities. The reverse also applies during the rebinding step, where target molecules are impeded from accessing the sites due to slow mass transfer [11]. These effects could be addressed by using an optimum monomer:cross-linker:template ratio to ensure homogeneous binding sites formation with good final polymer porosity. To enhance access of binding sites during washing and rebinding, polymerization methods such as suspension and emulsion polymerizations can be employed to make polymer spheres with defined particle size. With smaller polymer particle size, the surface area:volume ratio increases, thus allows enhanced washing/rebinding of templates. However, binding site heterogeneity is still an issue as the monomer–template complex envisioned in the prepolymer condition does not always result in an actual active binding site. This may be a result of several processes, including dissociation of monomer–template aggregates, leaching of template during polymerization process, random coiling processes giving clustered templates bound in the polymer, as well as binding site collapse after the washing step [12]. Attempts to minimize binding site heterogeneity in artificial sensor films prepared on transducer surfaces have led to the discovery of a class of imprinting processes that can be aptly called *surface molecular imprinting* technology. For MIP-SPR sensors, other than the ''grafting-to'' approach described earlier, two other methods are reported, namely surface-initiated polymerization (SIP) or ''grafting-from'' approach and electrochemical polymerization (electropolymerization). SIP as a surface molecular imprinting technique requires the initiator to be initially immobilized on a surface before polymerization takes place [13]. In electropolymerization, the conducting substrate serves as initiator-formation site by providing the current or potential necessary to cause radical-ion formation among the monomers [14]. In general, for any surface imprinting method, the resulting imprint cavities formed after polymerization are within the vicinity of the substrate surface, that is, thin to ultrathin film configuration, which allows ease of template removal and access during rebinding. Moreover, the polymerization mechanism of the growing thin film could ensure greater homogeneity among the imprint cavities, which should enhance the rebinding capability of the final imprinted polymer [14, 15]. These properties make surface molecular imprinting a more reliable route for preparing imprints of a variety of small and large templates [14–16]. Surface molecular imprinting finds great use in preparing recognition elements as thin films directly on the surface of transducers, showing improved qualities over conventional biosensor techniques [17]. *In situ* monitoring is particularly beneficial during the growth process of surface-grafted imprinted polymers, as it allows control over the final polymer properties, such as thickness and viscoelasticity [18]–which should help regulate the final MIP-sensor performance. With a suitable sensitive signal transduction technique, sensors with various configurations can now be prepared via surface molecular imprinting approach, which have found great use in many commercialized applications.

33.3
Surface Plasmon Resonance Spectroscopy as Signal Transduction Method

SPR spectroscopy is a special type of surface-sensitive optical signal transduction technique that has become a popular method for sensing due to its inherent high sensitivity and simple setup. Originally developed as a characterization method for thin films and processes occurring at metal–dielectric interfaces, SPR has been extended ever since for applications that involve chemical and physical changes occurring directly on the surface of the metal substrates, that is, interactions of immobilized biomolecules. The number of original research articles on SPR-based biosensors has increased dramatically over the last decade, with emphasis on sensing of important biomolecules such as DNA, RNA, proteins, pharmaceuticals, and other drugs [4, 19]. As antibody–antigen interactions are highly specific, affinity biosensors with SPR as signal transduction mode allow real-time investigation of biomolecular interactions without the use of labeled molecules, that is, label-free methods [20]. Since then, SPR has been extended to other sensor formats, shown to exhibit high robustness and have capability of being resolved to sensitivities of up to picomolar levels, depending on the setup configuration used as well as the recognition elements employed. The demand for onsite testing has also increased, and SPR-based sensors can serve this purpose and be developed for the detection of even trace levels of environmental pollutants and contaminants found in harsh conditions. As a substitute for natural receptors, MIPs have been prepared on the surface of SPR substrates, and with increasing innovative methods for surface imprinting, MIP-SPR sensors have been demonstrated to achieve the level of sensitivity observed in SPR biosensors. As SPR spectroscopy has now become an important signal transduction method, it is important to be familiar on SPR phenomenon and theory, which is vital for understanding important considerations for optimum sensitivity during analytical chemistry measurement. Several review journals [19, 21] have been specifically dedicated to this purpose, and so, only a brief discussion is included in this work, focusing mainly on concepts related to sensors development and control of conditions.

33.3.1
Basic SPR Theory

At a metal–dielectric interface, the resulting Coulombic and attractive forces among the surface-bound ‘‘sea of electrons’’ result in charge density oscillations known as *surface plasma oscillations*. The energy conditions (hence eigenvalues) for these oscillating electrons can be mathematically determined using quantum mechanical solutions, with a quantum of these oscillations being collectively referred to as a *surface plasmon*. The surface plasmon is considered an evanescent electromagnetic wave propagating along the metal–dielectric interface, as the longitudinal or plane-polarized electric field decays exponentially both in metal and toward the dielectric (Figure 33.4). Solving the Maxwell’s equation for metal–dielectric kind of refractive index distribution gives the propagation constant of surface plasmons, which shows dependence on the dielectric constants of the metal layer and dielectric medium. Metals such as gold and silver satisfy the conditions of the equation at optical wavelengths and are most commonly used in SPR applications. For an incoming light wave to couple with a surface plasmon, the wave vector of light parallel to the metal–dielectric interface should have energy and momentum, which matches the propagation constant of the surface plasmon. As a result, surface plasmons cannot be excited directly by light incident onto a smooth metal surface, but can be achieved with the use of a coupler. Most SPR sensors employ couplers in the form of a prism, waveguide, or grating device, which operate under the conditions of attenuated total reflection or diffraction. The most common configuration used for prism coupling is the Kretschmann configuration (Figure 33.5), wherein the prism is held in contact with a thin metal film (~50 nm) that faces the lower dielectric medium (air or sensing media). Incident photons approaching from the side of the prism are totally reflected at the prism–metal interface. At a particular incident angle θ, these photons can then excite a surface plasmon wave located at the outer boundary of the metal, via evanescent tunneling through the thin metal layer. By plotting the reflected light as a function of incident angle

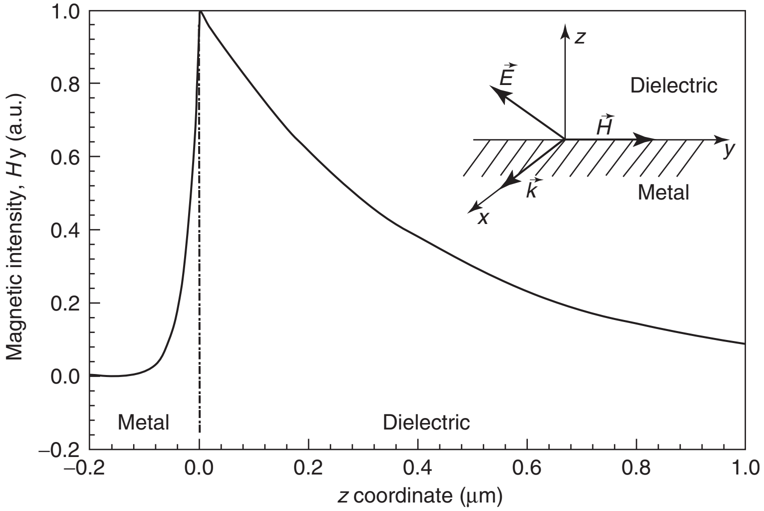

Figure 33.4 Spatial distribution of the magnetic intensity for a surface plasmon at the interface between gold and a dielectric ($n_d = 1.328$) in the direction perpendicular to the interface, $\lambda = 850$ nm. (Adapted from Ref. [21].)

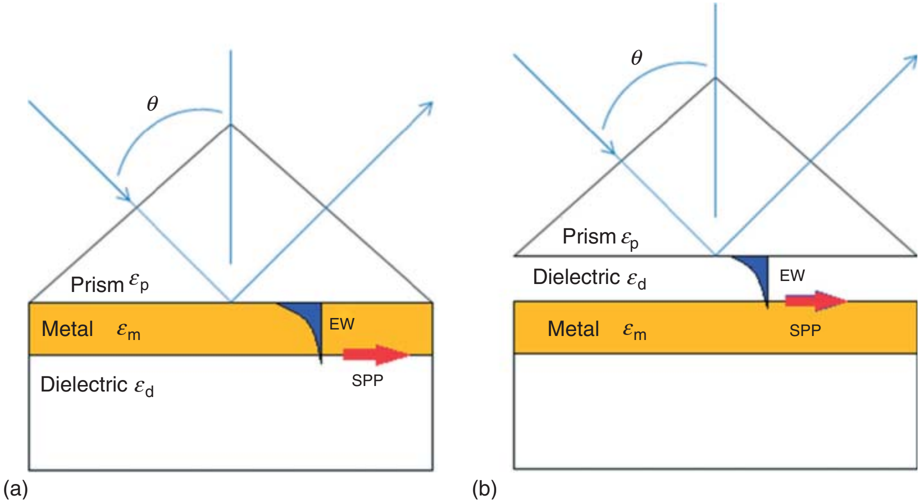

Figure 33.5 Kretschmann (a) and Otto (b) configurations of prism-based couplers showing evanescent wave (EW) and corresponding surface plasmon polariton (SPP) propagation.

(angular scanning or interrogation technique), a dip in the curve is observed, that is, minimum in reflectance owing to loss of reflected light, which corresponds to optical light energy being transferred to the surface plasmon wave (resulting in a surface plasmon polariton). SPR is exhibited at this point, which is then monitored to probe events occurring in the metal–dielectric surface. In particular, processes that result in changes of the optical properties of the dielectric adjacent to the metal layer can cause a shift in the incident angle θ required for optimum surface plasmon polariton formation. Other than the shift in incident angle for resonance to occur, parameters such as reflectance intensity, wavelength of incident light [22], polarization, and phase [23] may be measured and quantified to correlate with the changes occurring at the metal–dielectric interface. Another configuration that allows measurement of SPR based on prism couplers is the Otto configuration (Figure 33.5); however, the Kretschmann configuration has been widely used even in commercialized instruments and is discussed in detail later in the chapter.

33.3.2

Performance Characterization of SPR-Based Sensors

A typical SPR sensogram shows a plot of reflectivity change or shift in incident angle (at plasmon coupling condition) versus time as changes in refractive index takes place at a thin film (hence recognition element) found between the metal layer and the dielectric medium. Fresnel equations can be used to correlate the incident angle at which reflectivity is at minimum to the changes in refractive index based on three-layered system consisting of the prism, metal layer, and dielectric medium. This also allows calculation of the real and imaginary components of the dielectric constants for the film found on the surface of the metal, which may give further information on its properties. The refractive index of the thin film may change depending on particular interactions that occur, such as adsorption of particles on the metal surface, transport of material over the film, or changes in thickness. Sensitivity of an SPR sensor is therefore dependent on its ability to determine changes in the monitored SPR parameter with respect to the corresponding change in refractive index of the recognition element located at the metal–dielectric medium interface. In general, for SPR sensors based on angular interrogation, a positive shift in resonance angle indicates an increase in refractive index, and sensitivity is high if the corresponding resonance angle shift is large per change of refractive index (reported as degrees per refractive index units or deg RIU^{-1}). For wavelength-reflectance intensity domain type of SPR measurements, silver metal is a good choice for substrate, and sensitivity is increased when higher wavelength is used [24]. The sensitivity of SPR sensors using reflectivity prism couplers is shown to be higher than most SPR devices that use grating couplers [21, 24]. The thickness of surface-imprinted polymer films prepared as recognition elements on the surface of SPR substrates has been shown to affect the sensitivity of an SPR sensor device that uses the Kretschmann configuration; however, this can still be studied using waveguided modes during sensing [25]. In general, for MIP-SPR sensors based on the Kretschmann setup, thinner films result in better sensitivity during sensing [26]. SPR resolution is also another important property addressed in SPR-based sensors, which can be defined as the minimum change in measured parameter that can be detected by the sensing device. This depends strongly on the accuracy of measuring the sensor response elicited by changes in property of the corresponding recognition site. The resolution achieved by SPR devices is essentially limited by its own instrument noise level, which can come from sources similar to those observed in spectrophotometric devices, such as influences of temperature, light source, and photodetector used [27]. For angular scanning mode SPR method, the accuracy is directly affected by the width of the resonance curve, which is related to the thickness of the metal film substrate used. Narrower SPR curves often result in more accurate resonant angle response corresponding to refractive index changes at the sensor recognition site. Noise can also be generated from the signal response of the recognition element toward a blank medium (sensing solvent), which is quantitatively determined as part of the LOD measured for a particular SPR-sensing experiment. *LOD* is quantitatively defined as the concentration of analyte that produces sensor signal relative to three standard deviations of signal measured for a blank sample. The use of MIPs as recognition sites for SPR-based sensing has been demonstrated to enhance signal resolution using polymers that can generate localized dielectric changes during the specific recognition processes. This localized dielectric change is essentially translated into refractive index changes in the film, which affect the evanescent surface plasmon waves. Enhanced sensing of refractive index changes in the polymer can also be done by coupling the surface plasmon wave with localized surface plasmon resonance (LSPR) of metallic nanoparticles (NPs) embedded in the polymer film. These MIP-NP composites have been shown to amplify the signal generated by the local dielectric changes (refractive index changes) caused by molecules interacting with the recognition sites, leading to exceptionally high-sensor performance parameters [28]. Finally, resolution and sensitivity for a particular SPR sensor device are best determined on collective effects of the instrument configuration and the degree of optimization implemented, which collectively dictates the analytical figures of merit for a measurement process.

33.3.3
Configurations of SPR Instruments

A typical SPR instrument consists of a light source, coupler-sample stage, and optical detector (Figure 33.6). Prism-based SPR devices allow more flexibility in terms of measuring variations in refractive index as analyte interacts with metal substrate. High-quality optics employed in the SPR system can limit optical noise, which can lead to enhanced resolution measurements. Most MIP-SPR sensors that have been reported employ prism-based coupling on Kretschmann configuration for enhanced sensing. The prism is made from high-refractive index material, such as BK7 ($n = 1.52$) and LaSFN9 ($n = 1.85$), which allows total internal reflection of the incoming light to occur. A thin Au or Ag metal layer ($\sim$50 nm) is deposited onto a separate glass substrate that matches the material of the prism used. To ensure

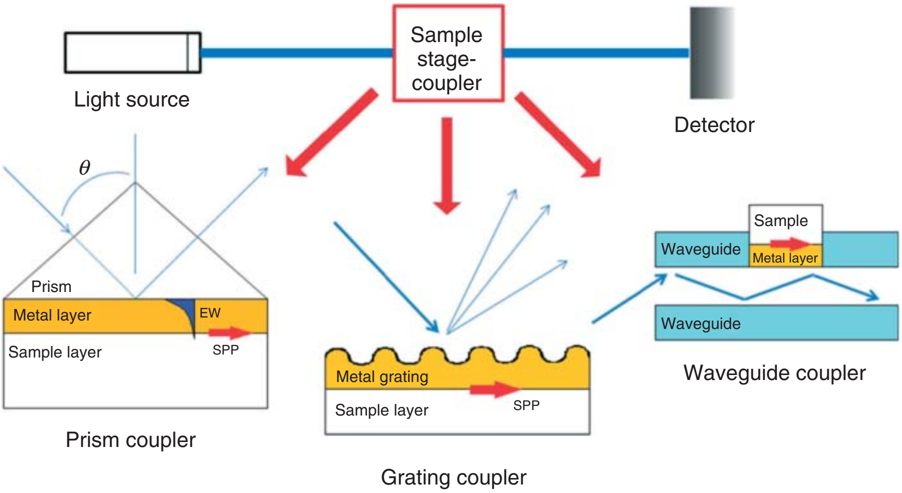

Figure 33.6 General SPR instrumentation diagram showing prism, grating, and waveguide types of couplers.

strong adhesion, an under layer coating of another material is initially deposited, usually Cr metal (~5 nm) or aluminum oxide. The prism and glass with metal film layer are clamped together (a liquid, usually an oil with refractive index matching the glass substrate is placed in between to form a continuous phase) to form a three-layered system consisting of the glass, metal surface, and dielectric (air, transparent medium such as water, or sensing material). Simultaneous angular scanning and reflectivity measurement are achieved by placing the prism-sample holder setup in a two-stage goniometer, with a laser as monochromatic light source and a CCD or PMT as detector. This instrument arrangement allows for dual domain analysis, as both angle and reflectance intensity are simultaneously measured, with resolution of up to 1×10^{-3} deg RUI^{-1} [29]. Excitation of the surface plasmon wave, hence SPR, is observed at the point of minimum reflectivity for a particular angle of incidence. Wavelength domain analysis or measurement via wavelength of incident light wave in resonance with the surface plasmon wave has also been demonstrated, with reported resolution of $6.9–8.0 \times 10^4$ nm RUI^{-1} for Jena-SPR device [22], and 1×10^5 nm RUI^{-1} using a parallel channel optics architecture [27]. Prism-based SPR sensors with a CCD array type of detector for angular scanning have been extensively commercialized by several companies, such as BIAcore and Autolab ESPRIT, which can attain a minimum resolution values in the range of 1.0×10^{-7} to 2.0×10^{-5} deg RIU^{-1} [30]. However, these instruments can only be used for measuring SPR within a short range of angle, and therefore have limited use for high-refractive index MIP films. The Kretschmann-ATR configuration is also attractive for the development of multichannel-sensing devices by adding several flow injection components, as well as microfluidic techniques on the prism-sample holder compartment. Miniaturization is also possible by integrating the light source, detector, and optical system for excitation and analysis of surface plasmon wave into a single component. A miniaturized device previously developed by Texas Instruments [31] relies on the detection of SPR angular position using a divergent light beam that passes through a polarizer and linear diode array detector. The sensor allows a resolution of 5×10^{-6} RIU, which shows that the Kretschmann-ATR SPR configuration can be adapted into a suitable format for the development of mobile, compact, and cost-effective sensing devices with potential for field applications.

Excitation of surface plasmon waves can also be achieved with the use of grating couplers. Periodic distortions on metal–dielectric interface will cause an incident optical wave to be diffracted and form reflected beams from the surface at different angles. If the component momentum and energy of the diffracted light is equal to the propagation constant for the surface plasmon, coupling occurs, which results in SPR. Most grating couplers used in SPR devices have specially designed patterns that result in optimum diffraction conditions for surface plasmon wave coupling to occur. An advantage on the use of grating couplers is the low-cost fabrication with the use of plastic and other materials useful for disposable sensors [32]. However, the mathematics involved in grating-based SPR is known to be more complex than planar prism-based systems [21], which make modeling and analysis of sensor data difficult. Grating-based MIP-SPR sensors have been demonstrated, using intensity, wavelength, and angular domain analysis for the detection of important substances [33].

Optical waveguiding is another method to excite surface plasmons in SPR sensors. The coupling process is essentially similar to the Kretschmann-ATR prism couplers, in that total internal reflection provides the energy and momentum necessary to excite the surface plasmon. As a light wave passes along the waveguide (fiber optic or slab slide), it enters a region with a thin metal overlayer that evanescently penetrates through the metal layer. If the surface plasmon wave and the waveguided light are phase-matched, SPR occurs at the outer interface of the metal. The sensitivity of most waveguide-based SPR devices is approximately similar to that of corresponding Kretschmann-ATR configurations. However, most SPR-waveguide sensor designs require more constraints compared to bulk prism-based SPR-sensing devices, which limit their use in MIP-SPR sensors [34].

33.4
MIP-SPR Sensors

Although SPR-based biosensor applications have been studied in the early 1980s, it is only in the late 1990s that MIPs were first successfully employed as a recognition element in combination with SPR. Sensitivity is a major issue encountered with the use of MIP-SPR sensor, particularly as the refractive index changes induced by target molecule–recognition site interaction may not be sensitive enough to be detected by the evanescent field, especially with small molecules. Consequently, detection can only be achieved at relatively high concentration levels. However, with advances in polymerization techniques, surface imprinting has now been applied to prepare polymer films capable of generating sensitive refractive index changes that can be detected by surface plasmon waves. Currently, MIP-SPR sensors have the advantage of being label-free sensing techniques and the majority requires only low-cost materials (commonly available monomers and initiators) in preparing the recognition films. A number of recently reported MIP-SPR sensors also show robustness in terms of longer response lifetime and even miniaturization (sources herein). This section discusses about MIP-SPR sensors published so far in research journals, and describes briefly specific categories, namely MIP recognition element and its properties, SPR instrumentation involved, and final sensor performance parameters obtained.

33.4.1
Sensor Film Preparation Methods for MIP-SPR Sensors

33.4.1.1 MIP Films Prepared via Solvent Casting

The successful integration of MIP as recognition site into an SPR setup was first reported by Lai and co-workers [35] in 1998. The bulk MIP was prepared from the polymerization of methacrylic acid (MAA) monomer, ethylene glycol dimethacrylate (EGDMA) cross-linker, and 2,2′-azobis(2-methylpropionitrile) (AIBN) as initiator, with theophylline, xanthine, and caffeine as imprint/analyte molecules. After polymerization, the solid MIP was ground into fine particles and dispersed in acetonitrile-acetic acid solvent. The sensing film was prepared by the drop cast method of dissolved MIP over a silver substrate. Using two different detectors in the prism-based SPR setup – photothermal deflection spectroscopy (for sensitivity enhancement) and photodiode array detection (for faster characterization), no cross-sensitivity was observed for theophylline-imprinted films toward structural analogs. An LOD of $0.4\,\mathrm{mg\,ml^{-1}}$ theophylline was reported, which is relatively high compared to other MIP-SPR methods prepared for theophylline. Morphological characteristics of the MIP film could have an effect on the sensor performance, although this was not discussed in the chapter. Kugimiya and Takeuchi [10] prepared an MIP thin film by placing a prepolymer solution composed of methacrylate monomers and sialic acid-modified *p*-vinylbenzeneboronic acid ester as active monomer in between a thiol-modified Au substrate and cover glass. This was then illumined by UV light to photoinitiate the polymerization process. The resulting MIP was shown to have imprints capable of detecting GM1 ganglioside, with minimum detected concentration of $0.1\,\mathrm{mg\,ml^{-1}}$. However, the reported MIP did not show response toward sialic and galacturonic acids, which are small molecules, indicating that the refractive index changes in the polymer induced by these molecules could not be detected by the surface plasmon wave (prism-based). Li and coworkers [36] prepared an enantioselective MIP-SPR toward imprinted L-phenylalanine ethyl ester (L-PHET), with a methacrylate-based MIP film prepared via spin coating on a gold substrate. Significant selective response to L-PHET over enantiomer D-PHET was observed at $1.0\,\mathrm{g\,l^{-1}}$ sensing solution concentration. Substantial improvement of MIP-SPR sensor properties prepared with spin-casted films was shown by Taniwaki *et al*. [37] by using an oligopeptide additive into the polysulfone-based MIP film. The oligopeptide serves as a highly specific recognition element for the template molecule 9-ethyladenine due to strong H-bonding. This significantly increased the MIP-SPR sensitivity toward adenosine molecule using prism-based optics, with increased apparent affinity constant (1.30×10^4 to $1.60 \times 10^4\ \text{mol}^{-1}\ \text{l}$) relative to decreasing imprinting ratio (1.0–0.25, respectively). Similarly, Roche and coworkers [38] prepared an MIP for dextromethorphan based on with poly(toluene diisocyanate-*co*-β-cyclodextrin) system. β-Cyclodextrins are known to form inclusion complexes with target organic molecules having complementary size with lypophilic inner cavity. With a waveguide-type of SPR setup (wavelength-intensity domain), a linear calibration range was obtained from 0.035 μM to 6.00 mM and an LOD of 0.35 μM was achieved for sensing dextromethorphan in aqueous buffer. Another specialized MIP-SPR sensor application was demonstrated by Raitman *et al*. [39] for studying noninvasive enzymatic reactions. The MIP film was prepared by casting a solution of NADH-imprinted acrylamide–acrylamidophenylboronic acid copolymer on the surface of gold substrate employed for prism-based Kretschmann-ATR SPR. The MIP-SPR displayed highly sensitive response toward the original template NADH at the concentration range of 1×10^{-6} to 1×10^{-3} M and showed significant selectivity in the presence of other similar cofactors. In addition, the NADH-imprinted films could be used to track the biocatalyzed oxidation of lactate to pyruvate, in the presence of NAD^+ and lactate dehydrogenase. This MIP-SPR setup represents a less destructive way in the detection of NADH compared to electrochemical detection, which often results in irreversible oxidation of the NADH molecule. The size of the polymer particles dispersed in the precasting solvent can affect the performance of the overall sensor. As described earlier, smaller polymer particle size results in higher surface area:volume ratio, which can effectively enhance washing–rebinding of templates. Lavine and coworkers [40] reported an MIP-SPR sensor for theophylline based on poly*N*-(*N*-propyl)acrylamide (polyNNPA) nanobeads synthesized via suspension polymerization. The sensing surface was prepared by spin coating an Au SPR substrate (Kretschmann configuration) with methanol-dispersed imprinted polyNNPA nanobeads. With angular and reflectivity domain analysis, they showed that the polyNNPA beads respond specifically toward theophylline, with decrease in angular incidence due to decreasing refractive index as theophylline swells the beads. Even at low level of cross-linking (20% as reported), the MIP-SPR sensor achieved an LOD of 200 ppb for theophylline, which is significantly better compared to the initial MIP-SPR sensor setup by Lai. MIP-SPR sensors with sensing films prepared from casted prepolymer solutions have also been shown to detect target molecules in nonaqueous media. Wei and Wei [41] prepared an MIP for testosterone using methacrylate monomers and benzophenone initiator. The sensing film was prepared via polymerization directly on the surface of the Au substrate. This was achieved by sandwiching the prepolymer mixture in between an alkane-thiol-modified Au-LaSFN9 substrate and a specialized microflow cell. After photoinitiation and curing, the resulting MIP film was about 50 nm in thickness. Subsequent washing and rebinding tests gave calibration sensitivity in the range of 10^{-12} to 10^{-8} M measured in acetonitrile. The authors suggest that the method is more simple and straightforward in preparing grafted MIP films compared to methods that use surface-attached polymer systems. A similar procedure was followed by Hao *et al.* [42] (same corresponding author) in preparing an MIP film for sensing morphine. With the use of an SPR device with Kretschmann-ATR configuration, the resulting linear calibration range was determined at 10^{-9} to 10^{-6} M in acetonitrile. The sensor was also tested for repeated injections of morphine and subsequent washing, which showed that it has good reproducibility at three cycles. In a proof-of-concept report, Matsui and coworkers [43] were able to prepare an MIP-NP composite film composed of poly(MAA-*co*-EDGMA)-thiolcarboxylic acid-modified Au nanoparticles (AuNPs) for nonaqueous sensing of atrazine herbicide. The use of Au NPs (4.28 ± 0.98 nm) was expected to enhance the electromagnetic field via coupling effects between gold NPs (LSPR) and a gold substrate (SPR) on the MIP-SPR sensor chip when the NPs are immobilized in close proximity to the substrate surface [28, 43]. Polymer-NP composite films were prepared by casting the prepolymer solution in between an SPR chip (mercaptan-modified) and glass substrate (thiol-modified), and subsequent thermal polymerization and curing. A thickness of about 251 ± 14 nm was obtained for the MIP film, which is considerably thicker than most films employed in MIP-SPR sensors. Their results show high sensitivity toward atrazine template, with an LOD value of about 1 pM in acetonitrile solvent, and also high selectivity against other similarly structured agrochemicals (prism-based Kretschmann-ATR configuration). Overall, the MIP polymer-AuNP composite-SPR sensor system is expected to be useful for other environmentally important molecules, and as low detection limits are obtainable, it can be applied for direct sample testing with limited use of solvent-consuming preconcentration steps.

The method of preparing MIP films by thermal or photocuring of solvent casted prepolymer solutions can be aptly called as a *grafting-to* approach as the resulting polymer films are physically attached on the surface of the sensor substrate. ‘‘Grafting-onto’’ techniques are also reported for film preparation of MIP-SPR sensors, wherein the monomers used are covalently linked on the surface. Nishimura *et al.* [44] prepared an MIP film by immobilizing MAA monomers on aminothiol-modified Au surface via ethyl(dimethylaminopropyl) carbodiimide/N-Hydroxysuccinimide (EDC/NHS) coupling, and then subsequent polymerization in the presence of template. The MIP-SPR sensor system showed good selectivity toward tetracaine original template. Another reported grafting-into approach using disulfide-linked monomers is that of Matsunaga and coworkers [45]. Self-assembled monolayer bearing vinyl groups on the Au-SPR sensor chips was prepared using *N*,*N*′-bis(acryloyl)cystamine. The prepolymerization mixture composed lysozyme (template), acrylic acid, 2-methacryloylethyl phosphorylcholine, and *N*,*N*′-methylenebisacrylamide were dissolved in aqueous buffer with varying amounts of NaCl. Their results indicated that presence of salt in the prepolymerization mixtures gives higher selectivity and decrease of nonspecific binding, which essentially demonstrates a way to enhance the selectivity on protein imprinting.

33.4.1.2 Grafted Initiators on Substrate: Surface-Initiated Polymerization Approach

SIP or ''grafting-from'' approach is a class of techniques employed in surface imprinting technology that is based on immobilization of initiator on the surface of sensor substrate. SIP differs from photo- or thermal-grafted polymerization described in the previous chapter as it allows more control on the properties of the resulting polymer (brush density, degree of functionalization, surface uniformity, etc.). The SIP approach as an MIP film preparation technique has been reported only a few times in several journals for MIP-SPR sensor applications (as compared to electropolymerization and grafting-to approaches), possibly due to the additional initiator immobilization step, which adds time and cost during preparation. Nevertheless, SIP techniques give more reliable MIP films compared to most solvent casted methods, in terms of morphological control and possible binding site homogeneity. Initiator immobilization is commonly done by self-assembly monolayers (SAMs) of thiol- or mercaptan-based molecules, followed by appropriate coupling reaction. With the use of a specific form of initiator, we can also perform living-radical polymerizations via atom-transfer radical approach (ATRP) [46] or reversible addition-fragmentation chain transfer approach (RAFT) [47] in preparing an MIP film. Although these methods have already been performed on substrates for MIP with other forms of signal transduction [47, 48], several authors have reported ATRP-based MIP film method on the surface of Au-SPR substrates.

Lotierzo and coworkers [49] first reported a surface-imprinted film prepared via free-radical SIP approach for the detection of domoic acid (DA). Cyanovaleric acid photoinitiator was first immobilized on a mercaptoethylamine SAM-modified Au substrate by carbodiimide coupling, followed by free-radical polymerization of pre-MIP mixture composed of 2-(diethylamino)ethyl methacrylate, *N*,*N*-methylenebisacrylamide, and template DA. Surface morphological analysis by AFM and contact angle measurement revealed a thickness of 40 nm for the grafted MIP layer and root-mean-square roughness (RMS) of 13 nm. The MIP performance characteristics were compared with a DA-antibody immunosensing scheme for the same SPR device (BIAcore 3000), and results showed that MIP had approximately three times higher detection limit compared to that of monoclonal antibody (5.0 vs $1.8\,g\,l^{-1}$ of DA, respectively). Although the calibration sensitivity of the MIP film was lower in value (half of observed) as compared to the monoclonal antibody, the detection range of the MIP sensor was considerably higher ($5-100\,g\,l^{-1}$), proving that there is significantly higher distribution of MIP binding sites present. The MIP film also appeared to be robust enough to withstand harsh treatment and multiple regeneration cycles. A similar method of preparing MIP films through SAM-immobilized free-radical SIP route was recently reported by Wei *et al.* [50] for MIP-SPR sensing of aqueous acephate (Figure 33.7). The ultrathin acephate-imprinted film was prepared on the surface of Au SPR sensor chip from dilute prepolymer solution of acephate, MAA, and trimethylolpropane trimethacrylate (TRIM) and finally photopolymerized via surface 4-aminobenzoic acid hydrazide (ABAH)-initiated radical polymerization. Their polymerization process was done at 4 °C, which the authors claim would ensure efficient noncovalent interaction between MAA and acephate in order to increase the imprinting efficiency. By using

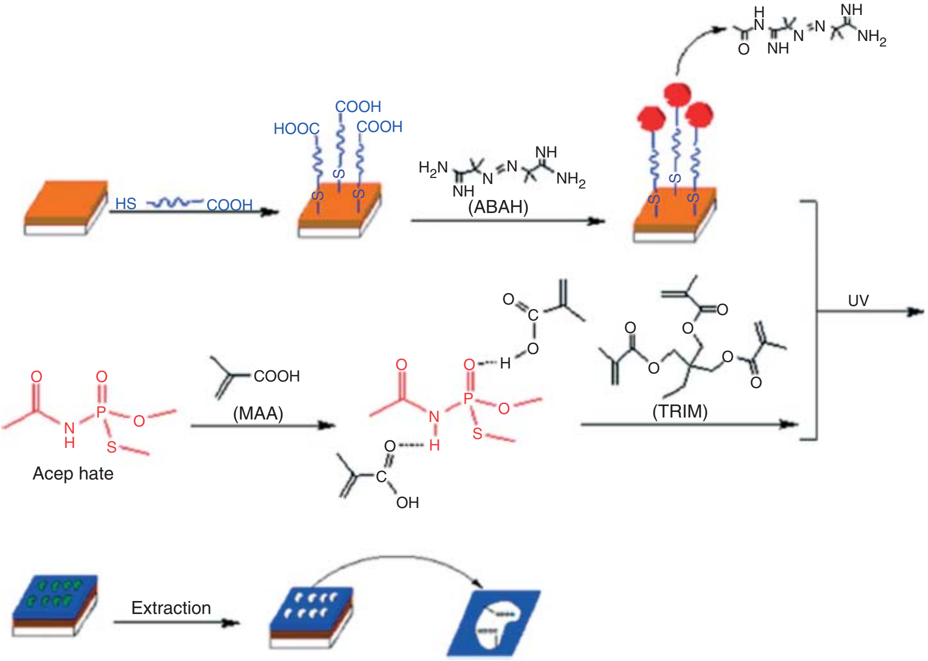

Figure 33.7 Schematic illustration of the formation of MIP ultrathin film by a surface-bound photoradical initiator. (Adapted from Ref. [50].)

a Fourier transform surface plasmon resonance (FT-SPR) (wavelength-reflectivity domain analysis), the group reported an affinity constant of $7.7 \times 10^{12}\ \mathrm{M}^{-1}$ for the acephate-MIP film system and linear response of $0.5–8.0 \times 10^{-12}$ M for acephate detection. The group also performed recovery analysis using their MIP film for sensing acephate in spiked real samples (apple and cole) and obtained percentage recovery values of up to 98%, proving the system can be used as an alternative sensitive technique for acephate measurement.

ATRP as an SIP-based film preparation method is known to produce high-polymer segment densities that shield the underlying substrate, and can form highly uniform polymer surfaces with controllable layer thicknesses at the nanoscale level. These properties therefore make ATRP suitable and advantageous in MIP film preparation in tandem with SPR detection method. An ATRP-based MIP film with SPR detection was reported by Li and Husson [51] for sensing dansylated cysteine (DDC) and dansylated lysine amino acids (DDK). SPR Au surfaces (BIAcore AB) with SAMs of mercaptoundecanoic acid-(4-chloromethyl)benzoyl chloride served as initiator-modified surface. ATRP was performed using Cu(I)-tris-(2-(dimethylamino)ethyl)amine as catalyst with *p*-vinylpyridine functional monomer and EDGMA cross-linker. Surface morphological characterization revealed MIP film thickness of about 7 nm and RMS of ~1.6 nm, indicating smoother and more uniform film distribution on the Au substrate. The kinetics of DDC rebinding toward DDC-MIP films was analyzed using SPR kinetic data, and their results show that dual-site Langmuir binding model more accurately describes the template molecule rebinding process, which can be attributed to heterogeneity of binding sites formed in the polymer film. Equilibrium binding studies also showed that the Langmuir–Freundlich (LF) model was found fit to model the adsorption behavior over the entire concentration region up to saturation, which supports the claim of having binding site heterogeneity. Cross-reactivity was observed between similar template compounds, but MIPs still showed selective binding, and selectivity was also shown to vary with pH values. The application of ATRP-prepared MIP-SPR sensor is expected to be extended over analysis of other nonfluorinated templates. A recent ATRP-based MIP film preparation scheme was described by Zhao *et al.* [52] for the FT-SPR sensing of ametryn herbicide. First, the initiator 2-bromo-2-methylpropionyl bromide was covalently coupled to an aminothiol SAM prepared on the Au SPR chip. Then, a prepolymer mixture containing MAA, EDGMA, and ametryn (13 : 15 : 1 mmol ratio) together with Cu(I)-tetra-azacyclotetradecane catalyst was placed on top of the modified Au chip to allow MIP film formation. The FT-SPR system allows SPR detection via reflectivity and wave number domain analysis. With an estimated film thickness of 75 nm, the MIP-SPR sensor was shown to have linear response toward ametryn in the range of 1.0×10^{-7} to 1.0×10^{-5} M, and an association constant of $1.09 \times 10^{4}\ \mathrm{M}^{-1}$ employing Langmuir isotherm. This system shows promising application of ATRP-based MIP-SPR sensor for the detection of herbicides and other environmental contaminants. A novel and way of activating the sensor surface with initiators for surface-initiated MIP preparation was described recently by Dong *et al.* [53]. Initiator AIBN was mixed with polyvinylchloride to form PVC-AIBN paste, which was spread on the Au SPR disk (Autolab ESPRIT). MAA and cross-linker EDGMA, together with malachite green (MG) as template, were polymerized on the surface of the paste-modified Au SPR disk, which gave approximately 40 nm MIP film sensitive to MG. The performance of the sensing film was compared to a similar film prepared from an SAM-initiator-modified Au SPR disk. Their results indicate that MIP film prepared from paste-initiator approach has more sensitivity toward MG at high-sensing concentration, while both MIP-paste and MIP-SAM systems showed almost similar response at low-sensing concentrations.

33.4.1.3 **Electropolymerization of Monomers for MIP Film Preparation**

Electropolymerization of monomers is now one of the most preferred approaches in preparing MIPs attached to transducer surfaces, owing to its high versatility and controllability in making thin films. Electrochemically synthesized polymers were only recently employed in sensing applications, but have been thoroughly investigated for their electronic properties, that is, conductivities and capacitances that can be modulated for use in electronic device applications. Electropolymerized molecularly imprinted polymers (E-MIPs) were studied for sensor applications early in the 1990s, primarily using electrochemical-based signal transduction methods, but it has only been recently employed as a sensing platform in tandem with SPR detection schemes [14, 15]. E-MIP in tandem with SPR offers several advantages over other signal transduction methods: (i) simultaneous electrochemical and

SPR *in situ* monitoring of E-MIP growth is achieved, allowing more control over film properties; (ii) dual-sensing capability is possible as the SPR signal can also be monitored along with changes in electronic properties of the E-MIP film; and (iii) simple instrumentation design as the Au substrate is compatible to both electrochemical signaling and surface plasmon wave generation at optimum thickness. Although E-MIP can also be tandem with other techniques, for example, electrochemical QCM as mass-sensitive technique [18], the inherent sensitivity of surface plasmon wave coupling with refractive index changes of the polymer matrix makes E-MIP-SPR still more advantageous for many sensing applications.

Yu and Lai [54] first reported the use of electropolymerized molecularly imprinted polymer polypyrrole films (MIPPy) for ochratoxin A (OTA) target molecule prepared on a Spreeta^{TM} Au-covered sensor surface. Growth of MIPPy film done by potentiostatic electropolymerization at +0.85 V with 1 : 20 OTA : pyrrole mole ratio in 1 : 9 ethanol:H_2O solvent. This was monitored *in situ* by SPR angle shifts as polypyrrole deposits on the surface of the Au substrate. Subsequent washing was successfully performed via pulsed elusion technique, which resulted in MIPPy films sensitive to OTA. The SPR angle increased when binding of OTA molecules occurred, and the linear calibration range was determined from 0.05 to 0.5 ppm and an LOD value of 0.01 ppm ($\sim 2.5 \times 10^{-8}$ M) OTA. The results demonstrated a novel combination of SPR device with E-MIP technique, with advantages in terms of short preparation time, low consumption of print molecules, and real-time sensing (flow injection setup added). However, the E-MIP-SPR sensor showed significant response when real samples (wine and wheat) were tested, which indicates that nonspecific interactions occur between other components coming from the real sample and MIPPy film. Choi *et al.* [55, 56] also prepared an E-MIP based on polypyrrole for imprinting mycotoxins zearalenone and deoxynivalenol with SPR detection setup (prism-based Kretschmann configuration). Electropolymerization of MIPPy together with the target templates were performed via potentiostatic process at 0.9 V and a current density of $5\,\mathrm{mC\,cm^{-2}}$ in acetonitrile solvent. The resulting E-MIP systems showed large calibration range of $0.3-3000\,\mathrm{ng\,ml^{-1}}$ for MIPPy-zearalenone and $0.1-100\,\mathrm{ng\,ml^{-1}}$ for MIPPy-deoxynivalenol. These results indicate that pyrrole is a good monomer for preparing low-cost E-MIP films with SPR detection, and can achieve high sensitivity and selectivity for sensing specific food contaminants.

The electropolymerization of carbazole-modified dendrimer molecules as recognition sites for E-MIP application was first reported by Taranekar *et al.* [57] for nanomolar detection and specific recognition of toxic nerve agent marker pinacolyl methyl phosphonate (PMP). In this system, fourth-generation polyamidoamine (CBZ-PAMAM) dendrimers with end-tethered carbazoles were used as active components for making PMP imprints. This CBZ-PAMAM component actually serves two purposes: first, imprinting of PMP happens through interaction with amine functional groups within the PAMAM structure; second, the carbazole units at the outer periphery of the dendrimer act as cross-linking (potentiodynamic, cyclic voltammetry method) component to make cavities and link the dendrimers to form a uniform film. Of the various films synthesized, the E-MIP film composed of

Cu(II)-modified CBZ-PAMAM with a thiol-carbazole SAM ad-layer gave the best performing sensor film. Dual sensing of PMP was achieved by doing simultaneous SPR monitoring and potentiostatic measurement in a Kretschmann-type configuration equipped with electrochemical flow cell (Figure 33.8). As low as 10^{-9} M PMP can be detected by the E-MIP-SPR system, which gives a promising procedure for aqueous-based sensing of nerve agent derivatives.

Functionalized terthiophenes and carbazoles were also used as monomers in preparing tailored E-MIP films for sensing theophylline [58], paracetamol, and naproxen [26] with SPR angle-reflectance scanning detection (Figure 33.9). Terthiophenes are beneficial in E-MIP preparation as electropolymerization can be set at lower-oxidation potentials, and hence lessening over oxidation of films. Advincula's group used mono- and bifunctional terthiophenes having orthogonal moieties (particularly –COOH, –OH, and $-NH_2$), which were expected to complex with selected template molecules by noncovalent interaction, specifically H-bonding. To ensure most favorable formation of binding site cavities, theoretical modeling was initially performed to determine optimum monomer:template ratios (generally 2 : 1), after which solutions of monomer:template were prepared and allowed to stand for 24–48 h before use. This ''prepolymerization step'' condition allows further contact and complexation between monomer and template in the synthesis medium before electrochemical polymerization. The use of the Autolab ESPRIT instrument, which enables simultaneous electrochemical SPR monitoring, allowed for further characterization of MIP film deposition from angular domain-based sensogram. Cyclic voltammetry was employed for the electrochemical polymerization of terthiophene monomers (0–1.1 V) and carbazole monomers (0–1.3 V). It was noted that the electropolymerization of the terthiophene monomers resemble cross-linking polymerization, suggesting that the regular α,α-coupling (2,5 position) could result in an ordered conjugated polymer network (CPN) film. On the basis of their results, it was also observed that –COOH and –OH functionalized monomers resulted in higher MIP rebinding ability compared with $-NH_2$ functional groups, which they claim as being attributed to weak H-bonding capability of amines. The SPR detection signal of bifunctional monomers bearing the –COOH and –OH functional groups was shown to be higher than that of monofunctional monomers, which was attributed to a higher number template–monomer complexes formed per unit volume of the MIP film. Another innovation shown in these works is the successful application of potential-induced template washing/removal at 0.4 V in acetonitrile (original porogen), which effectively reduces the washing time. It is possible that this process leads to an increase in swelling ability of polymer films, which then leads to easier release of imprinted molecules. For the theophylline-imprinted polyterthiophene sensor film, the linear concentration range was observed at $1.0–5.0 \times 10^{-5}$ M and has an LOD of 3.36 μM. Finally, good selectivity properties were demonstrated in all the systems, indicating the feasibility of this approach.

Most of the monomers used to prepare E-MIPs described earlier require anodic conditions, or application of oxidizing potential, to form the radical ion and therefore initiate polymerization. The first E-MIP prepared via cathodic electropolymerization

condition is reported by Dutta and coworkers [59] for sensing dopamine using SPR-based detection. *p*-Aminostyrene was chosen as electroactive monomer because of its ability to interact with dopamine molecule through H-bonding interactions. The prepolymer solution consisted of *p*-PAS, *N*,*N*′-methylene bisacrylamide (cross-linker), and dopamine in dimethylformamide solvent, with $LiClO_4$ acting as supporting electrolyte. Electropolymerization was performed by cyclic voltammetry in the cathodic potential window of 0–1.0 V at 50 mV s^{-1} scan rate of (30 cycles) on the surface of Au substrate. The resulting polymer film was then washed with aqueous HCl to remove most of the imprinted dopamine molecules. Subsequent rebinding test using SPR detector (Multiskop, Kretschmann-ATR) showed that the film indeed has binding capability toward dopamine (aqueous). The group further optimized the sensing conditions by varying the amount of active monomer *p*-PAS, and their results revealed that more sensitive binding toward dopamine is observed when MIP is prepared from prepolymer solution containing 0.3 M *p*-PAS. Further tests showed that the E-MIP-SPR sensor can detect dopamine at a low concentration of 1×10^{-12} M, as well as having higher selectivity toward the original template compared with structural analogs (epinephrine, catechol, tyramine, and 2-(3,4-dihydroxyphenyl)acetic acid). Overall, the research demonstrates the feasibility of cathodic electropolymerization method in preparing E-MIP, which could be applied to other vinyl-based monomers, as a substitute for initiator-based free-radical polymerization.

Recently, Willner's group reported several E-MIP-SPR sensor platforms derived from the electropolymerization of *p*-aminothiophenol (*p*-ATP) or *p*-thioaniline together with *p*-ATP-capped AuNPs. The use of poly(*p*-ATP-AuNP) nanocomposite films gave exceptional levels of sensitivity, which may be attributed to the coupling effects of LSPR coming from the AuNPs and SPR of the Au substrate. This enhanced coupling process allows sensing of even minute changes in refractive index of the film during rebinding of target molecule, resulting in amplified signals at low sensing levels. In their first report [60], they prepared poly(*p*-ATP-AuNP) on a *p*-ATP SAM-modified Au substrate (Figure 33.10). Picric acid was initially used as "pseudotemplate," for the subsequent sensing of trinitrotoluene (TNT) analyte. Electropolymerization was done by applying 10 voltammetric cycles between −0.35 and +0.85 V versus Ag quasireference electrode, followed by an application of a fixed potential of 0.85 V for 30 min. This was probed *in situ* by the SPR shifts of

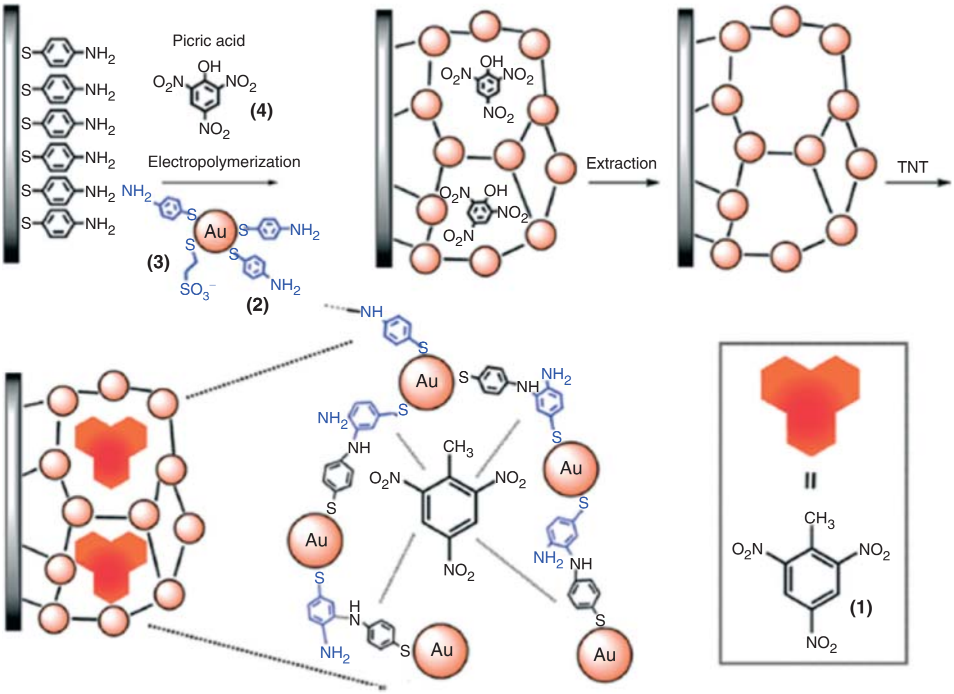

Figure 33.10 Imprinting of TNT molecular recognition sites using picric acid into the bis-aniline-cross-linked AuNPs composite associated with an Au substrate. (Adapted from Ref. [60].)

the SPR instrument (reflectance intensity domain, Kretschmann-type spectrometer NanoSPR 321). Aside from the effects of LSPR-SPR coupling, enhanced sensitivity is observed due to highly specific noncovalent interactions between template and monomer. With picric acid as template, strong $\pi-\pi$ donor–acceptor interactions are observed between the electron-rich ring of *p*-ATP and electron-deficient rings of picric acid. The imprinted poly(*p*-ATP-AuNP) composite revealed a two-step response that included an ultrasensitive analysis region in which TNT was detected at a limit of 10 fM, and was attributed to the analysis of TNT by the high-affinity imprinted association sites ($K_{\mathrm{ass.}}{}^{\mathrm{I}}$) $6.4 \times 10^{12}\ \mathrm{M}^{-1}$. A second detection region was observed in the 10^{-10} M TNT range and was attributed to the association of TNT by the nonimprinted bis-aniline π-donor sites ($K_{\mathrm{ass.}}{}^{\mathrm{NI}}$) $3.9 \times 10^{9}\ \mathrm{M}^{-1}$. By adding the molecule (*p*-mercaptophenyl)boronic acid to the same poly(*p*-ATP-AuNP) nanocomposite, the resulting film could now be used to imprint molecules with vicinal diol functionalities. In a separate research work, antibiotic template molecules neomycin (NE), kanamycin (KA), and streptomycin (ST) were successfully imprinted in the poly(*p*-ATP-AuNP-mercaptophenyl boronic acid) composite film [61]. After subsequent washing, the rebinding studies revealed exceptionally high sensitivities toward original antibiotic templates using identical SPR instrument (Kretschmann configuration). The reported calculated detection limits for analyzing NE, KA, and ST correspond to 2.00 ± 0.21 pM, 1.00 ± 0.10 pM, and 200 ± 30 fM, respectively. The MIP composite films were also successfully applied to analyze the presence of antibiotics in real milk samples. Selectivity analysis of specific antibiotic-imprinted MIP composite films suggests that the system could be used as an array-type of sensor for a possible lab-on-a-chip-based parallel SPR analysis of antibiotic samples. Using this same poly(*p*-ATP-AuNP-mercaptophenyl boronic acid) composite, imprinted films for enantioselective sensing of mono- and disaccharides were prepared, which were also shown to be sensitive down to pico- and femtomolar levels [62]. An extended application of the original poly(*p*-ATP-AuNP) MIP film was made for the imprinting of oligocarboxylic acid molecules [63]. These oligocarboxylic acid molecules served as ‘‘pseudotemplates’’ in preparing MIPs, which were subsequently used for sensing target nitrosubstituted molecules. The carboxylic acid residues present in the template molecules should exhibit similar dimensions and structural features to the nitro groups found in the target explosives. Possible ionic and/or H-bonding interactions between the carboxylic acid and the anilinium residues should generate imprinted sites with proper shape, size, and orientation of functional groups to structurally analogous nitrocompounds. This was proved to be the case as results showed higher affinity and sensitivity toward pentaerythritol tetranitrate and nitroglycerine using citric acid-imprinted film; and ethylene glycol dinitrate using fumaric acid-imprinted film. Overall, these series of works prove that with proper tuning of conditions, MIP films prepared from poly(*p*-ATP-AuNP) nanocomposite are very useful and applicable for sensing various important analytes, with remarkable sensitivity and selectivity resulting from amplification of detection signal by LSPR–SPR coupling.

33.4.2
MIP-SPR Configurations and Possible Commercial Applications

As emphasized earlier, the overall success of a sensing method – quantitatively determined in terms of figures of merit for sensitivity and selectivity – is dependent on the collective effects of the signal generating (recognition element) and signal transducing components used in the sensor device. Similarly, with other sensor formats, research is mainly focused on modifications in the signal-generating component for direct enhancement of analytical parameters. The improvements made on SPR instruments are based on the demands for more sensitive and robust biochemical sensing. Most of the SPR instruments described in Chapter 32 have already been applied for biosensor research; therefore, the improvements in these SPR instruments would also be beneficial for MIP-based sensing. Development of increasingly efficient SPR biosensors in terms of speed, throughput, and accuracy was pioneered by BIAcore, which launched the first commercial SPR biosensor on the market in 1990. Since then, other SPR instrument designs have been invented, which were geared toward specialized applications. On-site sensing can be achieved with the use of compact Spreeta^{TM} sensor system from Texas Instruments. Autolab developed the ESPRIT (dual channel) and Springle (single channel) SPR devices that have programmable-automated sampling capability, which makes it suitable for multiple batch analysis. The Autolab ESPRIT and Springle systems are also capable of carrying out simultaneous electrochemical analysis when connected with the PGSTAT electrochemical station that is convenient for most E-MIP film preparation. In general, these SPR instruments utilize the angular scanning of surface plasmon waves excited using prism couplers and are monitored by array-based detectors. The range of angles that can be scanned by the instrument is limited with the use of nonmobile detector or sample holder, which means that it cannot be used with high-refractive index MIP films. For wide-angle sampling ($>30^\circ$), SPR configurations with the sample stage connected to a dual-motor goniometer is more advantageous. This type of design enables complete scanning of angle versus intensity (or wave number vs intensity) that can be modeled with Fresnel formalisms. Wide-angle scanning SPR setups (manufactured by RES–TEC, Multiskop, or can be home-built) are therefore useful in analysis of MIPs with high-refractive index, as well as relatively thick films that approach waveguide modes [25]. Waveguided surface plasmon excitation for the use on MIP-SPR design has also been reported previously [38].

The SPR instruments just described are usually equipped with flow injection apparatus to enable real-time monitoring of target molecule interaction at the binding site cavities. Microfluidics fabrication technology can also be applied to facilitate the development of miniaturized instrumentation for SPR. Micromachined systems have several advantages over the common bulky flow injection counterparts, such as lower overall cost, disposability, low reagent and sample consumption, portability, and lower energy consumption. Microfluidics technology also enables preparation of multichannel SPR sensors vital for high-throughput analysis. Lee and coworkers [64, 65] developed a novel microfluidic system that incorporates a

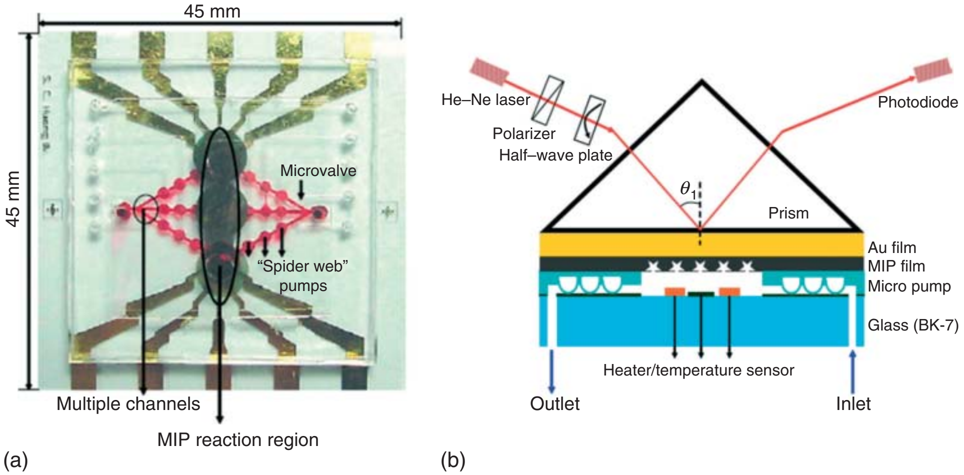

Figure 33.11 (a) Photograph of the assembled microfluidic SPR/MIP biochip with dimensions of 4.5 cm × 4.5 cm. (b) Schematic illustration of the microfluidic SPR/MIP biochip system designed for the detection of multiple nanoscale biomolecules. (Adapted from Ref. [65].)

"spider web" design (Figure 33.11) of micropumps and microvalves aimed to automate the transportation of samples on an SPR Au chip. The MIP films for sensing progesterone, testosterone, and cholesterol were synthesized by a "localized MIP deposition" technique in which different MIP films are spin-coated inside separate reaction chambers of the microfluidic system. The integrated micropumps and microvalves facilitate automation of the sample introduction process, which enables precise control on the amount of sample injected to the MIP-SPR-sensing chambers. The resulting apparent association rate for testosterone binding was reported to be 8.0×10^3 deg s^{-1} at optimum flow rate of 24 μl min^{-1}. The proposed microfluidic sensor chip has been shown to have significant potential for a variety of automatic nanoscale biosensing applications. A more recent study by Taguchi *et al.* [66] reported a slab-type optical waveguide (s_OWG) design that contains consecutive parallel Au and Ag deposition bands, which enabled double SPR signal analysis for sensing bis-phenol A (BPA). Two SPR peaks around 600 nm (Au band) and 550 nm (Ag band) were detected at an optimized angle of 12° between the propagation direction of light and horizontal direction. This procedure permitted the study of binding behaviors on both deposition bands independently and simultaneously. Their molecular recognition element is based on MIP NPs prepared from styrene, divinylbenzene, and template monomer *N*,*N*′-bis(3-vinylbenzylidene)-4,4′-diaminodiphenylmethane via seeded emulsion polymerization (same composition of seed NPs). To enhance SPW signal generation, BPA-modified AuNPs were synthesized and were made to interact on the surface of MIP-NP beads. On injection of BPA solutions, the SPR signals shifted owing to competitive binding of the free BPA molecules with the BPA-Au NPs. The final MIP-SPR design was tested for BPA sensing, and showed detectable response at low (0.1–1.0 mM) and high (1.0–2.0 M) concentration levels in toluene:methanol solvent medium. The proposed s_OWG-based coupling MIP-SPR device allows for label-free sensing in conjunction with the use of MIP-NP and BPA-AuNP, and can be further extended in other applications that could use other kinds of SPR-active metal pairs for multiple differential plasmon characterization.

33.5
Conclusions and Future Perspectives

Over the last two decades, a substantial amount of work has been given to MIP-based SPR sensing, and majority of the developments reported for this technique appeared only on the last decade. In order to illustrate the benefits of this new family of sensing method, namely MIP-SPR, the description of the MIPs used and corresponding SPR instrumentation have been reviewed. This therefore highlights the important views that – (i) MIP-SPR sensors can adequately be used for highly sensitive and selective measurements of substances in priority fields and (ii) MIP-SPR devices can provide solutions for the various problems encountered in detection and analysis of substances. MIP films prepared on the surface of sensor substrates present great potential as substitute to biomolecules acting as recognition element in sensors, mainly due to their comparable sensitivity and selectivity, while using low-cost materials and generally simple preparation steps. However, MIPs still possess inherent problems that arise from various conditions that can be traced starting from preparation to washing and finally rebinding tests, which essentially put certain limitations to their use. SPR spectroscopy as signal transduction method offers further enhancement of sensing properties as it possesses high flexibility and versatility in terms of its ability to modify instrument components depending on particular applications of the device. Nevertheless, other signal transduction strategies are now capable of high-throughput multianalyte sensing (e.g., electrochemical techniques and solution-based spectrophotometry), of which SPR (with MIP recognition) is still on its initial stages of development. With these in mind, it is therefore envisioned that further research and development of MIP-SPR-sensing strategies should focus on the following possible modifications:

1) *Better MIP preparation strategy*: imprinted polymers that allow multiple analyte recognition can be achieved by combining the MIP polymerizations described. An example would be SIP-electropolymerization approach, which could be developed to allow for two or more molecules to be imprinted in the final film. SIP based on living polymerization methods such as ATRP and RAFT could also be studied in the preparation of block copolymers, which may also have multiple-molecule imprinting capability. Other surface-based techniques that could be used are the layer-by-layer approach of polyelectrolytes for sensing charged templates, and self-assembly of oligomers following a molecularly imprinted monolayers (MIMs) format. Use of these surface imprinting strategies should enable the formation of recognition sites with high-homogeneous

binding site distribution and stable morphological characteristics while maintaining thin film thicknesses. In addition, the role of LSPR–SPR coupling should also be fundamentally considered in amplifying the recognition event signal, which can be done by adding appropriately modified AuNPs on the MIP system.

2) *Improvements on SPR instrumentation*: optical waveguide coupling using fiber optics is a key strategy in making lightweight, compact, and portable MIP-SPR sensors. Existing fiber optic-based SPR setups should be tailored to match the various MIP film preparation strategies, or find unique MIP systems that could be tailored with the SPR-fiber optic. Multichannel capability has already been demonstrated as an actual microfluidic sample platform for MIP-SPR setup, and this should also be considered in connection with SPR-fiber optic for possible advancements in miniaturization in the future.

LC-MS in Environmental Analysis

Sophie Bourcier and Michel Sablier

34.1

Introduction

Liquid chromatography-mass spectrometry (LC-MS), or alternatively high-performance liquid chromatography-mass spectrometry (HPLC-MS), is an analytical technique that combines the physical separation capabilities of LC (or HPLC) with the mass analysis capabilities of MS. LC-MS is a powerful technique that has very high sensitivity and specificity and, therefore, is currently used for many analytical applications. MS, which gives information on both molecular weight and structure of chemical compounds, is more specifically oriented toward the specific detection and identification of target compounds in the presence of other chemicals in complex mixtures. Development of the concept of linking analytical instrumentation is motivated by the need for chemists to detect unequivocally, characterize, and quantify compounds in unknown mixtures: GC-MS represents the first example of chromatography hyphenated successfully to MS. The development of LC-MS arose initially from the need to extend the range of compounds studied to polar and thermally labile molecules not amenable to GC-MS or necessitating prior derivation steps for the analysis.

Experimentally, the major problem in the development of LC interfaces has been the incompatibility between a high mobile-phase flow rate in LC and MS pumping requirements for normal conditions of use. Two solutions have been proposed during the first years of development based on two different strategies to eliminate the solvent: (i) evaporation of solvent before the ionization and (ii) evaporation and ionization at the same time. Finally, the second strategy was chosen, and the development of atmospheric pressure ionization (API) has greatly facilitated the combination of LC with MS, as exemplified by the numerous applications found in the literature. The large possibility offered by API methods allows analyzing both polar and non-polar compounds. Electrospray ionization (ESI) is suitable for analyzing polar compounds, whereas atmospheric pressure chemical ionization (APCI) and atmospheric pressure photoionization (APPI) allow more specifically ionization of nonpolar compounds. All of these ionization techniques can be used in both positive and negative ion modes. Each method can be associated with either

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

triple quadrupole (QqQ), quadrupole ion trap (QIT), quadrupole linear ion trap (QLIT), quadrupole time-of-flight (Q-TOF), ion trap time-of-flight (IT-TOF): this large panel of mass spectrometers allow solving different problems of identification, quantification, and detection of pollutants and their metabolites. Moreover, LC-MS is used in combination of sample preparation and/or sample preconcentration to improve selectivity. All these elements have largely contributed to the development of environmental LC-MS.

Many aspects of LC-MS are reported in the literature. In addition, Handbook (Method 3) covers the general principles and the applications of MS. Rather, this chapter describes briefly the principles of operation and the developments that have permitted routine analysis by LC-MS coupling. This chapter focuses also on some of the most striking examples of applications of LC-MS in the environmental field, and highlights recent developments in this area.

34.2
Developments in Interfacing for LC-MS

34.2.1
General Principle of Operation

The operational principle of most API interfaces is as follows: the column effluent from the LC is nebulized into an atmospheric pressure ion source region, ionized and sampled by a skimmer into a second pumping stage containing an ion-focusing and ion-transfer device to optimally transport and focus the ions to the mass analyzer region. In most systems, the ion-transfer device consists of a radio-frequency (RF)-only quadrupole, hexapole, or octapole, which should transfer onto the mass analyzer the maximum of ions.

Concerning vacuum pumping requirements, it is no longer important whether a high flow rate or a low flow rate of liquid is nebulized because the technical solution ultimately chosen for sampling orifice in the recent design of API source employs a fixed restriction between the atmospheric pressure region and the first pumping stage of the mass spectrometer. The trade-off between a high-throughput of liquid sample and ionic current detection has been solved by the use of off-axis geometries and optic transmission improvement (see subsequent text). The historical development of API interfaces for LC-MS has been well reviewed in detail elsewhere [1, 2] and the interested readers are invited to refer to these reviews.

A general schematic diagram of an API source is depicted in Figure 34.1. An API interface source consists in five parts: (i) the liquid introduction device or spray probe (not shown); (ii) the atmospheric pressure ion source region, where the ions are generated by means of an electric field (ESI), by a corona discharge (APCI), or by photoirradiation (APPI); (iii) an ion-sampling aperture; (iv) an atmospheric-pressure-to-vacuum interface; and (v) an ion optical system, where ions are subsequently transferred into the mass analyzer. Ion losses cannot be avoided in the transfer region, but must be kept to a minimum.

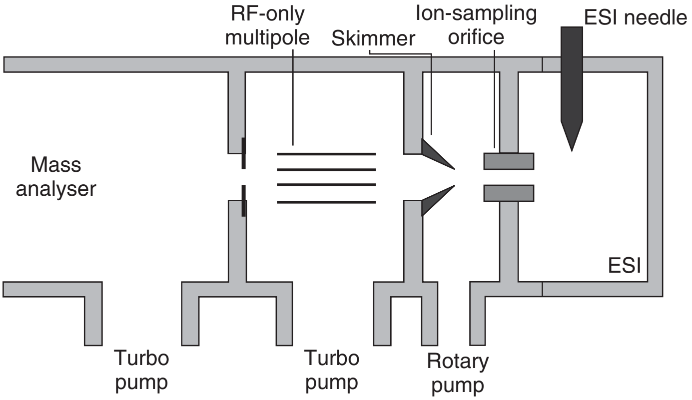

Figure 34.1 General schematic diagram of an ion source for atmospheric pressure ionization with, from the right to the left: (i) the atmospheric pressure ion source region, (ii) the ion-sampling aperture, (iii) the first pumping stage, and (iv) the ion optical system. (Reproduced from Ref. [3], with permission from Elsevier, copyright 2003.)

A large variety of API interfaces is now commercially available from a number of manufacturers. Initially, the spray probe was positioned on-axis. The major disadvantage of this setup is that all material in the spray may start clogging the ion-sample orifice. Several instrumental developments have been proposed to avoid such contamination problems : (i) a nitrogen curtain gas that flows between the orifice plate and curtain plates in the first pumping stage, (ii) a countercurrent of heated gas flow that promotes the desolvation of the droplets in the atmospheric pressure ion source region, and (iii) the orthogonal positioning of the spray probe by off-axis sampling that constitutes the most successful source modification to reduce contamination. This latter solution is applied in most commercial systems available for LC-MS currently. In LC-MS applications, one aims at introducing the highest possible flow rate into the ion source interface, manufacturers have optimized ESI interfaces in this purpose to permit increased introduction flow rates up to 1 ml min^{-1} of effluent. Moreover, to assist in the evaporation of the high flow of LC effluent, the source can be heated to increase desolvation processes. These modifications allowed the implementation of high-throughput methods, applied in particular for the newly developed ultrahigh pressure liquid chromatography (UPLC). This technique uses small diameter particles and short columns to reduce time analysis with the highest efficiency for the chromatographic separation.

34.2.2
Interfacing and Operations

34.2.2.1 Electrospray Ionization (ESI)

Several reviews [4–8] have documented the mechanisms of the electrospray process. Schematically, this process of ionization includes both the nebulization of a liquid into an aerosol of highly charged droplets and the ionization of solvated molecules

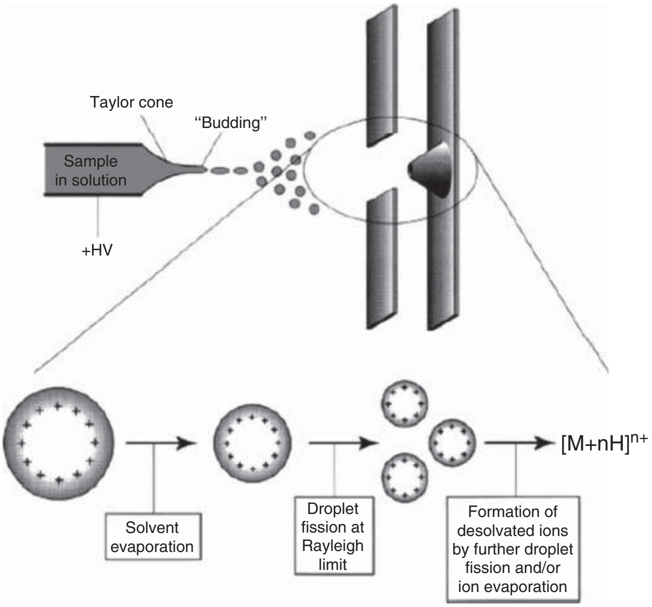

Figure 34.2 Droplet production in the electrospray interface. (Reproduced from Ref. [7], with permission from John Wiley & Sons Ltd., copyright 1997.)

after desolvation of the charged droplets (Figure 34.2). The electrospray process is initiated by applying a potential of several kilovolts to a liquid introduced through a capillary or a needle in the atmospheric pressure ion source region. By increasing the potential difference between the needle or capillary and the counter electrode, a series of processes takes place involving three main steps: (i) droplet formation, (ii) droplet explosion, and (iii) finally gaseous ion formation. Stability of spray depends on several parameters including solvent properties, liquid flow rates, and applied voltages. ESI is the result of the decrease of the size of the droplet by the evaporation of neutral solvent molecules. This size reduction is accompanied by an increase in the electrical field strength at the droplet surface favoring droplet explosion. ESI was originally a low flow rate ionization technique (allowing a few microliters per minute flow input). Compatibility of ESI with typical LC flow rates (0.2–0.5 ml min^{-1}) have been achieved by pneumatically assisted electrospray (also called *ionspray*), by the use of a heated gas (called *turboionspray*), and/or the adjunction of a heated sampling capillary.

34.2.2.2 **Atmospheric Pressure Chemical Ionization (APCI)**

In a heated-nebulizer APCI interface (Figure 34.3), the column effluent is nebulized into a heated vaporizer probe (350–500 °C) to evaporate the solvent [9]. The resulting vapor enters the atmospheric pressure ion source, where sample ionization is initiated by a corona discharge. The mobile phase vapor acts like a reagent gas. The ionization conditions in APCI are considered to be "harder" than those observed in

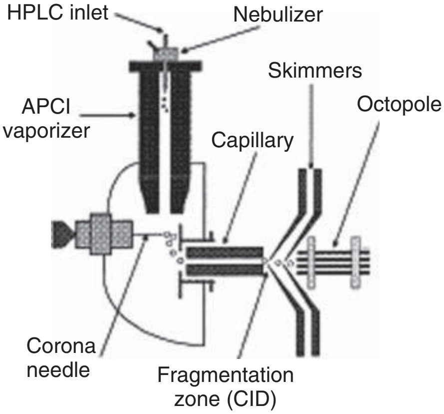

Figure 34.3 Schematic diagram of an atmospheric pressure chemical ionization source. (Adapted from Ref. [9], with permission from Elsevier, copyright 1998.)

ESI [10], and acid–base reactions are still the most frequently observed ionization mechanisms. This technique is currently reported as more suitable for less polar compounds. It is noteworthy that the effective higher flow input capacities of APCI constitute a potential drawback because the use of these high flows increases the propensity of source contamination, affecting both the sensitivity and the reproducibility of APCI experiments [3].

34.2.2.3 **Atmospheric Pressure Photoionization (APPI)**

APPI is the most recently developed methods among the soft ionization methods available currently in MS. Several authors have described the ionization methods in the recent years [11–14].

APPI complements the other two API techniques previously described and was principally developed to extend the range of compounds amenable to LC/MS analysis to nonpolar compounds, ordinarily inefficiently ionized by ESI and APCI. The technical setup for an APPI source is closely related to that of APCI sources, with a heated nebulizer for both eluent spraying and desolvation, but including a vacuum ultraviolet (VUV) lamp for the ionization process instead of the corona discharge used in APCI [14, 15]. A large number of reactions could be involved in the photoionization (PI) process. APPI is characterized as an alternative ionization process that is showing evidence of being relatively nondiscriminant for nonpolar compounds. The different steps taking place for the APPI process can be schematically described as follows: (i) photoexcitation of samples and/or solvent molecules, (ii) photodissociation, and (iii) ionization (by proton transfer and charge exchange for the positive mode of ionization and proton transfer; electron capture, and halide attachment for the negative mode of ionization). The nature of ions formed depends on the mixture of constituents and their associated physicochemical properties, (proton affinity (PA), and ionization energy (IE), [16]). For example, proton transfer from a reagent ion to a neutral molecule having higher PA can act as a common ionization reaction in APPI (Figure 34.4).

Bruins *et al.* [17] have introduced the use of ''dopants'' to increase ionization efficiency, taking advantage of the ion–molecule reactions observed during APPI: schematically, dopants are chosen for their propensity to be efficiently photoionized and form quantitatively dopant ionized species able to ionize molecules through proton transfer or charge transfer. Consequently, the molecule used as a dopant must be selected with an IE lower than the photon energy of the emitted light. The dopant is mixed with the sample stream in the liquid phase, often with a tee situated upstream from the source. The dopant-assisted APPI method is now the standard method in APPI source designs. Under conventional reversed-phase conditions, proton transfer reagent ions are generated via PI of toluene or acetone commonly used as a dopant. Toluene is known to generate photoions that react rapidly with either methanol or acetonitrile. To orientate the formation of ions between solvents or analytes, and to simplify the interpretation of mass spectra, the ultraviolet (UV) source energy can be modulated in such a manner that the operating photon energy is bracketed between sample IEs and solvent IEs (or molecules present in air). Table 34.1 gives PAs and IEs of some common solvents used together with the energies of some lamps commonly used in PI.

Table 34.1 Gas phase IE and PA values of commonly used solvents and gas in APPI.

Lamp	Gas and solvent	PA[a] (kJ mol^{-1})	IE[a] (eV)
—	Nitrogen	493.8	15.58
Ar 11.2 eV	Water	691	12.62
—	Acetonitrile	779.2	12.2
—	Oxygen	421	12.07
—	Methanol	754.3	10.84
Kr 10.0 eV	Isopropanol	793	10.17
—	Acetone	812	9.7
Xe 8.4 eV	Toluène	784	8.83
—	Triethylamine	981.8	7.53

[a] Reference [16].

Depending on the characteristics of the sample, the solvent and the dopant (if any), the APPI method has shown applications exceeding the field of nonpolar compounds and has proved to be effective for detecting a broad range of compounds, placing APPI as a complementary tool for LC-MS besides the ESI and APCI methods.

34.2.2.4 **Comparison between Ionization Methods**

API ionization techniques are soft ionization techniques, and cover different ranges of applications in terms of polarity and molecular mass of samples analyzed. ESI is particularly well adapted to polar compounds, while APCI and APPI ionizations are most suitable for nonpolar compounds. For a given sample, in order to choose between the various API methods, one must keep in mind that ESI more properly transfers ions in solution, whereas APCI and APPI ionize compounds in the gas phase [18]. Moreover, only the ESI ionization technique can be efficiently used for the analysis of high-molecular mass compounds because it is the only ionization technique leading to the formation of multicharged ions. One disadvantage of ESI is its reported likelihood of matrix effects [19–21]. A matrix effect consists in some suppression or an enhancement of sample response due to the co-eluted matrix components and/or conjugated counterions. It can be easily evaluated by comparing the response obtained from a standard solution and that from a spiked solution with internal standards (mostly labeled compounds) or chemical analogs. A matrix effect is essentially a liquid-phase process found to be related to the amount of nonvolatiles in the sample. Indeed, nonvolatiles appear to reduce the ion evaporation of preformed sample ions from solution. For this reason when combining LC with MS, it is necessary to optimize the LC separation carefully. In particular, LC additives must be suitable to LC-MS: for example, phosphate and borate buffers must be replaced by volatile mobile phase additives. The sensitivity of API-MS can then be optimized in improving the formation of ions and supporting the nebulization enhancing the desolvation process. Depending on the API method processed, the choice of solvent, dopant, pH, or flow rates consists of several parameters that must be taken into account to improve sensitivity and to obtain the best results. Post-column techniques can be used to set the optimal conditions of pH or solvent after the separation. Figure 34.5 reports the experimental design for the use of a post-column system [22], and Figure 34.6 illustrates the results obtained for the analysis of a mixture of β-lactam antibiotics [23]. In this application, the ion-pair reagent heptafluorobutyric acid (HFBA) for the reversed-phase LC separation was added to improve the chromatographic separation of compounds, but HFBA forms stronger ion pairs with the sample, reducing in return ESI sensitivity. The post-column addition of weaker acid such as propionic acid can displace adduct formation toward the more volatile counter-acid adduct formation depending on volatility or boiling point of this counter-acid (b.p.): for example, b.p. propionic acid >b.p. HFBA. The formation of weaker ion pairs between sample and propionic acid results in an improvement on the API sensitivity.

We can notice that the use of the post-column infusion system is limited to target compound analysis. In general, the matrix effects can be decreased by improving sample pretreatment or/and optimizing chromatographic separation parameters, as well as changing the ionization mode [15, 24–26]. It has been estimated that APCI and APPI sources can reduce matrix effects by a factor of 3–10. Moreover, this latter benefit observed with APPI over ESI is not restricted to nonpolar compounds [13].

Matrix effect can also be evaluated using post-column techniques. As such, Hanold *et al.* [15] proposed a test of ion suppression by introducing a continuous flow of a standard solution of fluphenazine after the LC column and noting the change in ion signal level due to LC elution of components from an injection of rat plasma. The results are reported in Figure 34.7, and give a comparison between ion suppression susceptibility during APPI, APCI, and ESI.

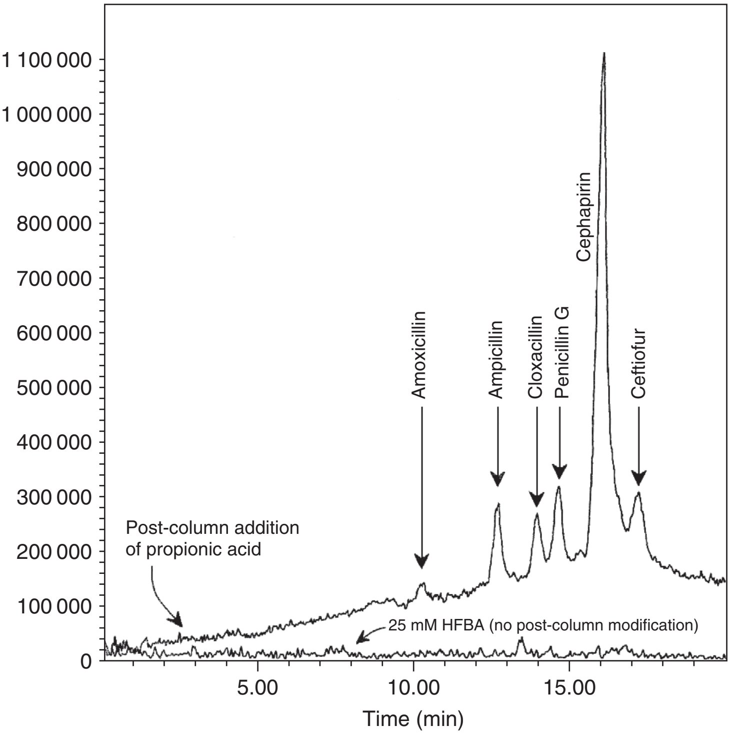

Figure 34.6 The LC-ESI-MS total-ion current chromatographic separations of a mixture of β-lactam antibiotics with and without the post-column addition of propionic acid. (Reproduced from Ref. [23], with permission from John Wiley & Sons Ltd., copyright 1997.)

The linear dynamic range of APPI has been reported at several times to be higher than those of ESI [15, 27]. Disadvantages of both APPI and APCI relative to ESI include a (mild) propensity to induce fragmentation or other changes in labile samples during the vaporization and/or chemical ionization steps. However, qualitative analysis using APPI may also be complicated by the presence of multiple peaks in the spectrum of a single compound, due to different ionization pathways. Additional practical disadvantages of APPI relate to the need to supply a dopant, which increases method complexity, so that some understanding of the mechanisms involved in the ionization process is generally required to achieve optimum results.

34.3
Developments in Mass Analyzers for LC-MS

The identification of compounds in complex matrices at very low levels with high selectivity and specificity implies the use of tandem MS. In this part, we present the tandem mass spectrometers currently used for environmental analysis and

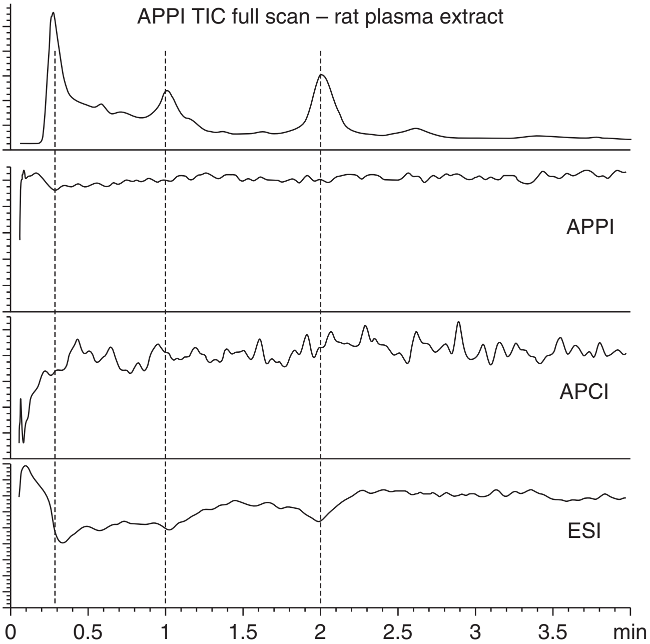

Figure 34.7 Comparison of ion suppression susceptibility for APPI, APCI, and ESI by post-column addition of fluphenazine to an LC separation of a rat plasma sample. (Reproduced from Ref. [15], with permission from ACS Ltd., copyright 2004.)

remind about their specificities. MS/MS allows a variety of experiments, which, in general, tends to improve the selectivity, specificity, and/or sensitivity of detection over single-stage-instrument experiments. Two mass analyzers in series, or two stages of mass analysis in a single instrument, are currently used in that purpose.

34.3.1
Triple Quadrupoles

The QqQ is the most frequently used mass analyzer to quantify target compounds on biological matrices with respect to the dynamic range, repeatability, and sensitivity. In a QqQ mass spectrometer, there are three sets of quadrupole filters, although only the first and third function as mass analyzers. The first quadrupole (Q1), acting as a mass filter, transmits and accelerates a selected ion toward the second quadrupole q, which acts as a collision cell. Although in some designs, q is similar to the other two quadrupoles, RF is imposed on it only for transmission, not mass selection. The pressure in q is higher, and the ions collide with a neutral gas in this collision cell. These collisions result in fragmentations by collision-induced dissociation (CID). The fragments are then accelerated into the third quadrupole Q3, another scanning mass filter, which sorts them before they enter a detector. Several acquisition modes are available on a QqQ: (i) multiple-reaction monitoring

(MRM) and selected reaction monitoring (SRM) modes, (ii) neutral loss (NL) scan, and (iii) precursor ion scan. The latter two acquisition modes allow identifying molecules belonging to the same chemical family.

The MRM mode is the most widely used for sensitive and selective quantification of target compounds. MRM operation is performed at fixed m/z values of the quadrupole Q1 and Q3. This acquisition mode allows obtaining of very low limits of detection (LODs) of target compounds present in complex matrices. We can notice that tandem MS coupled with ESI ionization provides an effective MS/MS/MS device because ESI ionization permits "in-source CID" to obtain additional structural information. Despite the high specificity of LC-QqQ, target compounds can still be mistakenly identified because of interferences from matrix components and metabolites. To further improve data quality and avoid false-positive results, the European Commission Decision 2002/657/ECD [28] requires two and more transitions to be used for the identification of any molecule in MRM mode. In addition, response ratios that arise from different transitions must be calculated and compared with those of a standard. Comparison of retention times for similar chromatographic conditions can be used to confirm identifications [29].

NL and precursor ion scans give the opportunity to detect other metabolites. In the NL scan, both Q1 and Q3 are scanned with a constant offset for Q3. In the precursor ion scan, Q1 is scanned while Q3 set at a fixed m/z value. To illustrate applications in the field of environmental analysis, NL scans have been used for identification of acidic naphthalene derivatives using the CO_2 NL corresponding to an m/z 44 ratio in the negative mode of detection [30, 31], while precursor ion scans have been well employed by Pozo *et al.* [32] to identify unknown anabolic steroids. One must concede that the efficient use of both NL and precursor ion scans imply the knowledge of fragmentation pathways.

34.3.2
Quadrupole Ion Trap

Three-dimensional (3D) QITs have found large application specifically in structure elucidation studies [33]. A QIT mass spectrometer has three electrodes; that is, one ring electrode between two hyperbolic end-cap electrodes to form a 3D ion trap. The main advance of QIT technology was the development of the mass-selective instability mode of mass analysis, which revolutionized the use of the ion trap as a mass analyzer. In this mode of operation, an RF voltage is applied to the central ring electrode of the ion trap, while the two end-cap electrodes are held at ground potential. By definition, each ion confined within the ion trap is associated with a value of the functioning q_z parameter correlated with a particular mass-to-charge m/z ratio. To record a mass spectrum, the RF voltage is increased with time so that ions of successively greater m/z ratio are ejected and detected as they develop unstable trajectories. The scanning sequence of the ion trap consists of three periods performed repeatedly: (i) ionization and storage of ions above a chosen m/z ratio, (ii) ejection of background ions below the m/z range of interest, and

(iii) ejection and detection of ions. The oscillating potential difference established between the ring and end-cap electrodes creates finally a store or pass ions in and out of the traps. Such a system combines ejection sequences for mass determination and multiples stages of MS/MS with high collision efficiency. All stages of ion manipulation occur within the same volume but at different times. This in-time operation procedure increases the scanning sensitivity of QIT relative to QqQ mass spectrometers.

34.3.3
Triple Quadrupole Linear Ion Trap

A triple quadrupole linear ion trap(QqQLIT) consists of a QqQ mass spectrometer with Q3 operated as a linear ion trap spectrometer with axial ion ejection. These instruments enable the accumulation of a higher number of ions with no loss due to charge effects compared to QIT. These instruments combine the advantages of QqQs for the quantification of target molecules and possess ion accumulation and fragmentation capacity for structural elucidation while softwares allow obtaining both quantitative and qualitative information. To analyze complex mixtures, the use of information-dependent acquisition (IDA) [34], where the m/z ions of highest intensities in the full-scan mode are automatically selected to conduct fragmentations, are currently processed.

34.3.4
Time-of-Flight Mass Analyzers

Time-of-flight (TOF) analyzers are conceptually the simplest mass analyzers: the ions are accelerated with the same kinetic energy from the exit of the ion source, the ions of different m/z values are separated in the field-free flight tube and are detected sequentially depending on their arrival time on the detector. TOF instruments are configured either alone or in tandem with a quadrupole analyzer Q-TOF. Both instruments offer a high resolution, accurate mass measurement, and good sensitivity on full scan. A Q-TOF instrument gives the opportunity of obtaining product ion spectra with high mass accuracy. This advantage allows the confirmation of compounds suspected to be present. A significant feature of a TOF instrument is the necessity for pulsed ion introduction, which is readily achieved by the use of a pulsed voltage to a repeller plate positioned at the opposite to the accelerating grid. However, this results in a reduced effective duty cycle: while ions are generated continuously, only part of these ions is sampled for mass analysis. To achieve higher duty cycles, in-line ion storage devices are used. With the programmable ‘‘dynamic range enhancement’’ function, the quantification with a Q-TOF instrument is feasible, but some applications demonstrate that the LODs are lower than those obtained with tandem quadrupole (TQ) instruments.

34.3.5
Other Instruments

Cyclotron instruments trap ions electrostatically in a cell using a constant magnetic field. Pulses of RF voltage create orbital ion motion, and the orbiting ions generate a small signal at the detection plates of the cell (the ion's orbital frequency). The frequency is inversely related to the ion's m/z ratio, and the signal intensity is proportional to the number of ions of the same m/z ratio in the cell. At very low cell pressures, a cyclotron instrument can maintain the ion's orbit for extended periods, providing very high resolution measurements. Fourier transform-ion cyclotron resonance (FT-ICR) mass spectrometers represent the extreme capability of measuring mass with the ability to resolve closely related masses. A 14.5-T magnet can then achieve a resolution of more than 3.5 million and thus display the difference between molecular entities whose masses vary by less than the mass of a single electron.

On-line electrospray FT-ICR-MS resulted in a more extensive analytical use of FT-ICR-MS instruments. As a consequence, electrospray interfaces for FT-ICR-MS instruments are commercially available. The instrumental problems related to ESI coupling to an FT-ICR-MS system relate to the working pressure in the FT-ICR ion cell, the kinetic energy that ions gain in the nozzle-skimmer region, which can limit ion trapping efficiency in the cell. Furthermore, drawbacks of FT-ICR in the environmental analysis relates to the lack of sensitivity. Recent instrumental improvements for ESI-FT-ICR-MS are the use of a capacitively coupled open cell to improve the signal-to-noise ratio and the use of an electrostatic ion guide in the post-source region to further enhance the sensitivity.

Magnetic instruments are almost abandoned in LC-MS applications for environmental analysis. The major difficulties in coupling an LC-API source to a sector instrument reside in the high acceleration voltage required in the ion source and the large pressure difference between ion source and analyzer. This pressure drop necessitates extensive pumping to avoid discharges and electrical breakdown, as well as extensive collision activation of the ions incompatible with high-resolution applications. All these factors have drastically limited the implementation of magnetic LC-MS instruments in environmental laboratories.

The newly developed hybrid linear ion trap (LIT) FT-Orbitrap mass spectrometer [35] could revolutionize the domain of environmental high-resolution analysis, but this apparatus is still in its infancy in LC-MS for environmental analysis.

34.4
Sample Preparation

As compounds of interest or degradation compounds are found at very low concentration in environmental samples, sample preparation is a determining step before the LC-MS analysis and depends on the nature of sample and on the analytical problem to be solved. Typically, liquid sample extraction can be done without presteps, whereas with homogenized solid samples it is often necessary. Several authors have reviewed recent advances in sample preparation [36–43]. Several operations are included in this preparation: (i) sample dissolution step, (ii) sample clean-up, and (iii) sample fractionation and preconcentration. According to the nature of the sample, several methods can be used: solvent extraction under reflux, liquid–liquid extraction (LLE), solid-phase extraction (SPE), and solid-phase microextraction (SPME). The two latter extraction procedures are the procedures more described in the literature. SPE allows a multitude of chemical specific phases to prepare the sample before LC-MS analysis. The SPE is very well adapted to extraction of target compounds. In the case of multiresidue methods, compounds are extracted in two or more SPE according to the chemical properties of compounds [40]. Most SPE procedures are used off-line but development and use of automated on-line sample preparations have been recently reported [44, 45]. Higher sensitivity is achieved under on-line configurations owing to the higher transfer efficiency and the resulting analysis of the totality of the sample. Moreover, this solution is attractive when large numbers of samples have to be analyzed. SPME [46, 47] can be easily coupled on-line with LC/MS. Moreover, new SPME–HPLC systems known as *in-tube SPME* are now available using an open tubular-fused silica capillary column as the SPME device instead of the SPME fiber. In-tube SPME is suitable for automation, provides better accuracy and precision relative to manual techniques, and such SPME methods have been reported for the determination of drugs and environmental contaminants by coupling with LC/MS/MS [48]. Another possibility to improve the selectivity in SPE can be obtained with molecular imprinted polymers (MIPs) [49, 50]. In addition to these methods, other sample pretreatment methods are described: on-line column switching with a restricted access media (RAM) column, liquid phase membrane extraction, and microdialysis [51, 52].

In association with the important step of sample preparation, one must not forget the crucial role of the chromatographic separation mode depending on analyte properties. The most used separation technique for environmental compounds is reversed-phase HPLC chromatography. Environmental contaminants are often polar compounds and their transformation products even more. Besides, monolithic LC columns have been introduced by column manufacturers to facilitate the analysis of very polar molecules and to conduct fast LC/MS analysis [40, 51].

34.5
Examples of Application

34.5.1
General

In the field of LC-MS, recent years have shown a tremendous increase in the use of time-of-flight-mass spectrometry (TOF-MS) and quadrupole time-of-flight mass spectrometry (Q-TOF-MS) for structural elucidation and compound confirmation.

TOF-MS and Q-TOF-MS provide increased resolution capability, which allows precise empirical formula assignments for unknowns and provides confidence for positive identification in quantitative work [53]. LC coupling to ESI and APCI continues to dominate the new methods developed for emerging contaminants, and the use of MRM with MS/MS has become commonplace for quantitative environmental analysis. As a consequence, the use of LC/MS/MS allows in most cases identification of highly polar organic pollutants down to nanogram per liter levels, avoiding derivatization [53, 54]. Also, the use of MRM provides increased selectivity and sensitivity, greatly reducing the presence of chemical background in LC/MS analysis. Of note, APPI is also increasingly being used with LC/MS because of its ionization efficiency for nonpolar compounds.

Besides instrumental developments in MS, trends in sampling and extraction include use of traditional SPME and SPE cartridges. One of the fastest growing trends in chromatography is the use of UPLC, a recently developed LC technique that uses small diameter particles in the stationary phase and short columns, to allow higher pressures and, ultimately, narrower LC peaks. In addition to better chromatographic separation, UPLC dramatically shortens total analysis times.

New analytical methods continue to push detection limits lower, while regulation law drastically decreases authorized LODs and limits of quantification (LOQs). Currently, it is common to see LODs that lay in the low-nanogram per liter range. A drop in these detection limits will continue to allow the detection of analytes at concentrations not attainable before, as well as their degradation products. Indeed, pollutants are generally present at nanogram per liter to low-microgram per liter levels in wastewater influents, and detection limits at the low-nanogram or sub-nanogram per liter level are necessary to determine their percentage removal.

The past years have seen some major successes in terms of global measurement and regulation of persistent, bioaccumulative, toxic chemicals, and persistent organic pollutants. There has been a major expansion of measurements and risk assessments of new chemical contaminants in the global environment. However, the list of chemicals measured represents only a small fraction of the thousands of chemicals widely used in commerce. One must concede that the vast majority of existing and new chemical substances in commerce are not monitored in environmental media [55].

LC-MS analysis in the field of environmental analysis commonly refers to the terms *persistent organic pollutants* or *emerging contaminants*. The definition of ‘‘emerging contaminants’’ has been addressed in the Editor’s introduction of a recent issue of Environmental Science and Technology [56], emphasizing the elusiveness of the term *emerging contaminant* itself due to the matter of perspective and timing inscribed in its acceptation. Indeed, better analytical methods have allowed for the low level detection of emerging organic contaminants, such as pharmaceuticals, antibiotics, endocrine-disrupting compounds, and so on. Analytical advances now permit the routine analysis of organic chemicals that cannot be observed previously, and led to the early discovery of many persistent organic pollutants. Once a substance is quoted as an emerging contaminant, assessing the effects of these contaminants in the environment remains a major time-consuming and a resource-intensive challenge. Therefore, it is not surprising that advances in the understanding of the potential adverse effects of the many thousands of chemicals being spread in the market are often rather slow. This fact introduces the concept of ''perspective'' and ''timing'' in the ''emerging'' character of these contaminants. As a consequence, a contaminant may be considered for several years to be ''emerging.'' *Emerging contaminants* can then be defined more properly as ''unregulated contaminants, which may be candidates for future regulation depending on research on their potential health effects and monitoring data regarding their occurrence'' [54].

Moreover, the issue of emerging contaminants is closely related to analytical capabilities. The increased sensitivity in MS, as a result of more efficient ionization techniques and better detectors, has enabled detection of virtually any new and potentially harmful contaminant at a very low level. Consequently, previously ignored or unrecognized contaminants as well as new contaminants have come under scrutiny. Analysis of emerging pollutants encompasses the monitoring of known environmental contaminants that have the potential to adversely affect human health: for example, chlorinated dioxins, pesticides, and metals [57]. As analytical instruments evolve, detection limits improve, and new analytical methods are developed, new compounds of potential concern emerge. Several groups of compounds [58] have emerged as particularly relevant: algal and cyanobacterial toxins, brominated flame retardants, disinfection by-products, gasoline additives, hormones and other endocrine-disrupting compounds, organometallics, organophosphate flame retardants and plasticizers, perfluorinated compounds, pharmaceuticals and personal care products, polar pesticides and their degradation products, and surfactants and their metabolites. All of these compounds will not be addressed here; only analysis of a few of them will be detailed later in the textto illustrate LC-MS capabilities in environmental analysis.

34.5.2
Pharmaceuticals, Veterinary Pharmaceuticals

Pharmaceuticals have become important emerging contaminants owing to their presence in environmental waters, threat to drinking water sources, and concern about adverse effects, both to wildlife and humans [59]. It is estimated that few thousands of different substances are used as pharmaceutical ingredients, whereas only a very small subset of these compounds has been investigated in environmental studies (less than a few hundred). Moreover, pharmaceuticals are an important group of potential endocrine-disrupting compounds that have recently attracted much attention to their likely detection in environmental samples. Pharmaceuticals are introduced not only by humans but also through veterinary use. Veterinary pharmaceuticals have been gaining interest, and, recently, a global perspective on the use, sales, exposure pathways, occurrence, fate, and effects of veterinary antibiotics in several countries was reported [60]. Veterinary antibiotics are widely used worldwide for treating diseases and protecting the health of animals. They are also incorporated into animal feed to improve growth rate and feed efficiency, as veterinary antibiotics became integrated into the growing animal food industry. Veterinary pharmaceuticals fall into several pharmaceutical categories, for example, anesthetic, steroidal, and nonsteroidal anti-inflammatory, antibacterial, antiseptic, tranquilizer, and are mainly delivered to the animals through feed or water. As antibiotics are poorly absorbed in the organism of the animals, they can be excreted unchanged in feces and urine, and, consequently, there is a potential for antibiotic resistance. This represents the main question remaining on the likely adverse effects of pharmaceuticals on humans or wildlife at low environmental levels (generally nanograms per liter), and a major concern for pharmaceuticals includes the development of bacterial resistance from the release of antibiotics in the environment. In order to guarantee safety of pharmaceuticals for human and environmental health in the future, the European Agency for the Evaluation of Medical Products has recently released a draft guideline based on EU (European Union) directives aimed at providing evaluation criteria for environmental risk assessment [61].

The ecotoxicology of human pharmaceuticals was recently reviewed [62], and the benefits of chemical analysis methods able to determine more polar compounds such as LC–tandem MS was emphasized. Examples of applications with the development of multiresidue analytical methods in groundwater and surface-water samples are reported in the subsequent text.

For identification of pharmaceuticals, LC-QqQ MS in the MRM mode has proved its suitability for target analysis [59]. The availability of Q-TOF MS has recently enlarged the scope of LC-MS-MS as a powerful identification tool. The accurate masses obtained by Q-TOF MS for both parent ion and transition ions, and the possibility of obtaining a full-scan product ion spectrum of the analytes present a great interest for final confirmation of compound identities in complex matrices. In this purpose, Stolker *et al.* [63] described a screening method based on LC-Q-TOF MS for the confirmation of the identity of residues of 13 pharmaceuticals in surface, drinking, and groundwater. Most of the pharmaceuticals investigated were medium-polar and polar compounds; therefore, placing reversed-phase LC as the separation method of choice. The use of MS-MS for detection enabled combination of screening and confirmation in one procedure. The set of pharmaceuticals investigated included analgesics (acetylsalicylic acid, diclofenac, ibuprofen, and paracetamol), antibiotics (sulfamethoxazole, erythromycin, and chloramphenicol), blood-lipid regulators and β-blockers (fenofibrate, bezafibrate, clofibric acid, bisoprolol, and metoprolol), and one antiepileptic drug carbamazepine. Reported LOQs ranged from 5 to 25 $\mathrm{ng\,l^{-1}}$. The analysis of a large number of samples (66) showed that 80% of the samples of groundwater contained up to three pharmaceuticals, while almost all surface waters showed the presence of two to eight pharmaceuticals. The concentrations of the individual target analytes were typically 10–100 $\mathrm{ng\,l^{-1}}$.

The development, optimization, and validation of an analytical method for the simultaneous detection and identification of 73 pharmaceutical residues, covering various therapeutic groups, in both surface and wastewaters has been recently described by Petrovic *et al.* [64]. The originality of the method resides in combining the simultaneous extraction of target compounds by SPE, using a hydrophilic–lipophilic balanced polymer with LC–tandem MS, and QqLIT. LODs ranging from 0.1 to 55 ng l^{-1} (depending on the matrix) were reported with SRM procedures of operation for the QqLIT mass spectrometer. This multiresidue analytical method based on off-line SPE-LC-MS/MS allowed the simultaneous extraction of 73 multiple-class pharmaceuticals in a single extraction step, simplifying noticeably the sample preparation. This work well demonstrated the potential of QqLIT, for an unambiguous and accurate identification of target compounds in effluent wastewaters. While Q-TOF is suitable for confirmation purposes, as well as identification of unknown compounds or metabolites because of their ability to provide exact mass measurements, QqLIT was shown to be appropriate for both quantitative and confirmational purposes owing to its unique scanning properties.

Hernández *et al.* [65] investigated the different approaches provided by the use of LC-MS with both QqQ and Q-TOF analyzers for the detection of antibiotics in environmental waters. A basis set of more than 100 groundwater and surface-water samples was used to further discuss the main achievements and pitfalls of LC-MS in the confirmation of positive findings. Confirmation of the identity of pollutants in environmental samples based on the acquisition of only one MS/MS transition in QqQ instruments proved insufficient for a safe confirmation. The acquisition of two specific SRM in QqQ instruments associated with the measurement of the retention time and the ion-intensity ratio is the minimum required for a safe confirmation. Meanwhile, the use of two transitions drastically reduced the risk for false positives. The use of Q-TOF instruments proved to eliminate definitely this risk of false positives, but at higher concentration levels. Nevertheless, one must keep in mind that the most reliable way of reducing the limitation observed in tandem MS is to improve chromatographic resolution, which undoubtedly helps confirmation by resolving interferent and analyte peaks, if any. The lower sensitivity of Q-TOF in comparison to QqQ can be one drawback of this approach, which can hamper the confirmation at very low analyte concentration levels.

An analytical methodology combining the use of two LC-MS techniques, LC-hybrid QqQ/LIT and LC-TOF instruments, has been investigated by Aguera *et al.* [66] to achieve both accurate and reliable target compound monitoring and identification of nontarget compounds. The strategy for the analysis was applied to a selected group of 56 organic pollutants in wastewater, comprising 38 pharmaceuticals and 10 of the most frequent metabolites. Quantification was performed by LC-QIT-MS operating under SRM mode in both positive and negative ESI. Unequivocal identification was provided by the acquisition of three SRM transitions per compound in most of the cases and by LC-TOF-MS analysis, which allows obtaining accurate mass measurements of the identified compounds with errors lower than 2 ppm. In addition, the use of TOF-MS allowed postanalysis from the full spectrum recorded at all times during the data acquisition. Methodology was applied to wastewater effluents of six sewage treatment plants in Spain. Mean concentration values ranged from 9 ng l^{-1} in the case of atrazine to 15 μg l^{-1} for paraxanthine, while LODs lie between 0.04 and 50 ng l^{-1}. The stimulants caffeine and nicotine, the antiseptics biphenylol and chlorophene, and the pharmaceuticals hydrochlorothiazide and furosemide (diuretics), atenolol (β-blocker), codeine, ketorolac, naproxen, and ibuprofen (analgesics/anti-inflammatory), gemfibrozil (lipid regulator), and ofloxacin (antibiotic) were the compounds present at the higher concentration level ($>1\,\mu g\,l^{-1}$).

Obviously, analytical methods for the pharmaceutical active compound analysis have evolved considerably and optimization of analytical instruments and specific methods – especially those based on use of LC-MS-MS systems – have reduced detection limits in such a manner that pharmaceuticals are being reported with increasing frequency worldwide. Nevertheless, further reduction of detection limits may be required to enable proper assessment of the true extent of the effect of pharmaceutical active compounds on human and ecosystem health. State-of-the-art of LC-MS-MS in the field of pharmaceutical active compounds has been reported in several reviews, and further information can be obtained there [29, 67].

A recent target analysis search for pharmaceuticals in the area of chemical water analysis provided the first example of application for the newly developed hybrid linear ion trap (LTQ) FT-Orbitrap mass spectrometer [68]. The use of the LTQ FT-Orbitrap MS–MS combines the tandem MS capability of the linear ion trap with the high-resolution and mass-accuracy capability of the FT-Orbitrap, allowing high-quality accurate mass MS^n spectra to be acquired. High-accuracy mass measurements in the LTQ FT-Orbitrap MS–MS are currently reported within the 2 ppm range using internal standard and within the 5 ppm range with external calibration [35]. Surface, ground, and drinking water samples searching for accurate masses corresponding to target compounds and their product ions known from priority lists of emerging pollutants and full-scan screening of water samples in search of ''unknown'' or unexpected masses followed by MS^n experiments were presented and discussed. In this work, results are reported for target analysis search for pharmaceuticals, benzotriazoles, illicit drugs, and for the identification of unknown compounds in a groundwater sample and in a polar extract of a landfill soil sample.

34.5.3
Endocrine-Disrupting Compounds: Estrogenes

There is growing alarm about the potential effects of endocrine- disrupting pollutants on wildlife and humans. Indeed, certain synthetic and natural chemicals have the ability to mimic hormones and, consequently, are able to interfere or disrupt normal hormonal functions of living creatures. In wildlife, endocrine-disrupting compounds are suspected in the decline of certain species favoring sterility, or change of sex in fish and shellfish [53]. Natural estrogens can easily reach the aquatic environment and particularly fishes through wastewater discharges, while humans can become exposed through the intake of this water into drinking water treatment plants. Compounds associated with these effects include natural compounds, such as estrogens and phytoestrogens, synthetic estrogens, and a wide variety of organic pollutants, including pharmaceuticals, pesticides, surfactants, plasticizers, and so on. Among them, estrogens are of particular interest owing to their high estrogenic potency, and their wide distribution in the aquatic environment [69]. According to recent reports [53, 70] physiologically active concentrations of these estrogens in the environment are ranging from picogram per liter to nanogram per liter. Furthermore, the reformation of estrogens from conjugates might be an explanation for the concentrations measured in many sewage treatment plant effluents: the less active conjugated forms, glucuronides and sulfates, excreted by the organism, can be deconjugated during wastewater treatment to regenerate the more potent parent compound. The key topics associated with the assessment of endocrine-disrupting activity in complex environmental mixtures reside mainly (i) in the improvement in chemical analysis to reduce LODs of target and (ii) in the development of integrated procedures combining chemical analysis and specific bioassays to identify the causes of the observed endocrine-disrupting effects [71]. The last key topic relates to the fact that chemical identification of all compounds responsible for the observed endocrine-disrupting effect represents an impossible task if one considers the number of new chemicals released per year in the environment. Consequently, the current state of new monitoring strategies implies the application of integrated chemical-biological procedures for the determination of endocrine-disrupting compounds [70]. These strategies are based on the effect-based analysis of environmental samples enabling determination of the causative agents. The results obtained by applying bioassays in the first step are used to direct attention to detailed chemical analysis of fractions until the correlation is achieved.

Many efforts have been undertaken for the accurate analysis of estrogens in aqueous and solid samples down to nanograms per liter and even subnanogram per liter concentrations. The first methods at the end of the 1990s used primarily GC/MS or GC/QIT-MS/MS detection [72]. Currently, an increasing number of methods use LC/MS and LC/MS/MS with the main benefits of lowering statistical errors and the absence of derivatization steps during analysis.

Moreover, the high polarity of many endocrine-disrupting compounds necessitates the use of LC/MS (or LC/MS/MS) for their analysis to typically measure compounds in environmental samples at low nanogram per liter levels. ESI and APCI are the most commonly used LC interfaces, even if APPI is sometimes used. Increasingly, tandem MS and MRM are being employed to provide added selectivity and sensitivity to these analyses. Coupling of API technology and TOF-MS combines high accuracy and excellent sensitivity due to the high-frequency sampling of all ions simultaneously recorded across a full mass range [70]. The advent of orthogonal-acceleration TOF-MS coupled to LC demonstrated its advantage for identification of endocrine-disrupting compounds in complex mixtures with accuracy of 5–10 ppm: an impressive improvement if one compares with the conventional nominal-mass information gained using a quadrupole instrument. Moreover, the tandem hybrid combination of a quadrupole analyzer to an orthogonal-acceleration Q-TOF increases the accuracy of mass measurement in diminishing accuracies down to 5 ppm: this gain in precision allows ruling out ambiguities in data interpretation, and makes easier the interpretation of decomposition tandem mass spectra.

The great concern at detection of trace quantities of endocrine-disrupting substances and their reported impact in the environment has led to the development of new methods for their characterization. As stated, endocrine-disrupting substances include a broad spectrum of compounds with large differences in polarities, structures (acidic or basic functional groups), and molecular weights, making the development of analytical techniques quite challenging. Efforts have been oriented to extraction steps in the recent work of Trenholm *et al.* [73] with the development of a comprehensive method for the analysis of several target potential endocrine-disrupting substances in various water matrices using sample volumes of 100 ml to 1 l and a single SPE step.

Description of the application of ultra-performance LC to Q-TOF-MS to the analysis of estrogens and phytoestrogens in water, associated to a semi-quantitative analysis of estradiol by ELISA (enzyme-linked immunosorbent assay) test combined with confirmatory analysis of estrogens was reported by Farré *et al.* [74]. This work has been developed for the need of cost-effective and rapid methods of screening, allowing the preselection of positive samples for further analysis, if necessary. Classical HPLC-MS/MS based on the use of QqQ or QIT analyzers operated in the SRM mode allows most often the determination of endocrine-disrupting compounds in the aquatic environment with enough sensitivity. Nevertheless, a trade-off remains between the gain of qualitative information needed to support the structural elucidation of analytes and the operation of mass analyzers in the full-scan mode associated with an inherent lack of sensitivity. Under such conditions, UPLC-Q-TOF-MS and UPLC-Q-TOF-MS/MS permitted quantitation and confirmation of target estrogens found in samples, and the screening of other structurally related compounds, phytoestrogens.

Zenobi *et al.* [75] demonstrated the potential of nanoelectrospray ionization mass spectrometry (nanoESI-MS) for the screening of suspected endocrine-disrupting compounds using chip-based nanoESI-MS. This method allows to detect specific noncovalent ligand binding to the human estrogen receptor α-ligand-binding domain (hERα LBD). As a wide variety of molecules, known as *endocrine disruptors*, can bind to the estrogen receptor and induce adverse health effects in wildlife and humans, this system represents an important environmental interest through the characterization of the binding affinity of sampled compounds toward the estrogen receptor by nanoESI-MS. NanoESI-MS allows ranking their relative affinity in consistence with binding affinities in solution. Speed of analysis (1 min/ligand), low sample consumption (90 pmol protein/ligand), and sensitivity for ligands (30 ng ml^{-1}) demonstrate how this technique must be promising as a screening method for suspected endocrine-disrupting compounds and to qualitatively evaluate their binding affinity in relation to expected adverse health effects.

34.5.4
Pesticides, Herbicides

Numerous extensive reviews on pesticide residue determination in environmental and food applications have been published in the past years [76–79]. In particular, these reviews stated how pesticide analysis initially carried out by means of GC-MS multiresidue methods evolved toward LC-MS analysis as new active ingredients appear in the industry of pesticide formulations with physicochemical properties (thermal instability and polarity) not anymore compatible with GC separation. Moreover, this trend is obviously favored by the recent improvements in LC-MS/MS instrumentation (sensitivity, selectivity, and robustness of the methods), enabling the increase in the number and diversity of pesticides that can be included in a single analysis [77]. This ability to measure more pesticides in a single run by LC/MS/MS compared to GC/MS stems from the broader peak width of LC versus GC. As stated by Richardson [53], the resulting longer cycle time in LC/MS compared to GC/MS allows more characteristic ions to be analyzed during a single analysis through MRM transitions monitoring.

Besides these potentialities of LC-MS/MS, the use of this technique allows, in most cases, reduction of the sample pretreatment, even facilitating the direct injection of the extracts due to the specificity of API. One of the major problems encountered in the quantitative analysis of pesticide residues using LC-MS is that compound and matrix-dependent response suppression or enhancement may occur, leading to the above-mentioned matrix effects. Related matrix effects of combined LC-MS using ESI or APCI have been well reviewed by Niessen *et al.* [21]. The use of LC coupled to LC-Q-TOF-MS to determine the presence of target and nontarget pesticides in water and food is detailed in the paper of Lacorte and Fernandez-Alba [80]. López de Alda *et al.* [81] reviewed the various works published from 1997 to 2005 for the determination of pesticides and their transformation products in water by means of LC coupled to tandem MS, with applications more specifically related to tandem quadrupole MS. The SRM transitions selected for the analysis of pesticides in water by QqQ tandem MS were reported in this chapter for about 70 compounds relevant to pesticide analysis in water.

In the field of pesticide residue determination, the majority of methods applied until now are mainly focused on the determination of parent compounds. However, the occurrence of pesticide transformation products can be often higher than unchanged pesticides [82]. Their inclusion in multiresidue methods represents an analytical challenge for several reasons: (i) they are still not well known, (ii) the number of potential analytes in water increases drastically, and (iii) they are usually more polar than the parent compounds and their extraction/preconcentration is consequently more difficult. Moreover, in adding more compounds in QqQ-based methods, analysis leads to a noticeable increase in the number of transitions to monitor, resulting in a likely decrease in sensitivity. The use of LC-MS/MS for residue determination can be employed to increase the selectivity of the method but the complexity of the sample can exceed the selectivity of MS detection. To circumvent these drawbacks, Hernández *et al.* [82] developed two on-line SPE-LC-ESI-MS/MS methods with the aim of rapid determination and confirmation of parent compounds and transformation products in surface and groundwater samples. This methodology allowed the simultaneous quantification and confirmation of 27 pesticides and transformation products after injection of only 2.2 ml of water sample. Quantitative recoveries in both types of samples were at the 0.025 and

$0.1\,\mu g\,l^{-1}$ levels, and LODs lower than $10\,ng\,l^{-1}$ by using the most intense MS/MS transition for quantification.

Obviously, future investigations on pesticide determination in environmental samples will focus on transformation products. Physical properties of these products can be noticeably modified compared to the parent molecule, rendering their detection more difficult. Kolpin *et al.* [83] proposed an illustration of this fact in their recent study on the widely used herbicide active compound glyphosate and its degradate aminomethyl phosphonic acid. The purpose of this study was to provide a better understanding of the potential contribution of glyphosate and its degradate aminomethyl phosphonic acid to streams derived from the urban use of this herbicide. The analytical results of 29 stream samples and 11 treated effluent samples collected around the United States during 2002 were described. LC-MS results documented the apparent contribution of waste water treatment plant effluent to stream concentrations of glyphosate and aminomethyl phosphonic acid with reporting limit of $0.1\,\mu g\,l^{-1}$ for both compounds. This confirmed that the urban use of glyphosate has contributed noticeably to glyphosate and aminomethyl phosphonic acid concentrations in the stream samples investigated. Finally, the overall results suggested that glyphosate and aminomethyl phosphonic acid are more mobile and persistent in aquatic environments than earlier researches have indicated.

One can expect that the success and future application of LC-MS instruments for trace determination of pesticides in complex matrices will be dependant on the development of accurate and precise quantification procedures using appropriate internal standards and on the availability of compound databases and mass spectral libraries. With no contest, the possibility of exact mass determination of unknown compounds in combination with the fragmentation pattern is a very valuable tool for screening polar nontarget pesticides or pesticide degradation products. In this aim, LC-TOF-MS might become one of the most applicable techniques to achieve LOD at the low parts per billion level, avoiding at the same time many difficulties related to matrix effects [80].

34.6
Conclusion

No one now disputes that LC-MS is really needed in a routine environmental laboratory to carry out monitoring of emerging contaminants (i.e., pesticides, herbicides, endocrine disruptors, pharmaceuticals, etc.). Clearly, the coupling of LC to MS has been a driving force for the development of commercial instruments, showing a mature setup that has greatly contributed to the customization of operating procedures for analytical purposes. As a matter of fact, LC-MS and LC-MS/MS has become increasingly important for both qualitative and quantitative analysis of a wide range of organic pollutants, the so-called emerging pollutants, and a large number of applications are now being found as reported in the numerous review articles quoted here.

There is still a question over which instrument should reflect better the most striking advances observed in the domain of LC-MS during the past few years. The answer seems a bit complex; nevertheless, exact mass seems more and more required in environmental analysis to identify unknown compounds. Thus, TOF and Q-TOF instruments provide sufficiently accurate mass to carry out unequivocal confirmation of target compounds, and to investigate complex environmental matrix. In this respect, it is rather easy with a TOF mass spectrometer to look for a comprehensive list of metabolites of a known target pesticide in a complex sample, even if it is still much more difficult to investigate real unknown samples. A point remains about the improvement on sensitivity in Q-TOF technology compared to QqQ mass spectrometers. The use of other types of high-resolution, that is, accurate mass instruments (e.g., Orbitrap) is well established for the environmental analysis.

However, we are sure that efforts are being made by mass spectrometer manufacturers, and, most probably within a few years, instruments will achieve improved sensitivity, linear range, and resolution in accordance with the most demanding field represented by environmental analysis.

Ion Attachment Mass Spectrometry for Environmental Analysis

Yuki Kitahara, Seiji Takahashi, Masamichi Tsukagosi, Juhász Márta, and Toshihiro Fujii

35.1

Introduction

Mass spectrometry (MS) has proved to be one of the most powerful, sensitive, and versatile research techniques and has been applied analytically in a great variety of qualitative and quantitative studies. As a consequence, mass spectrometers have undergone endless cycles of optimization for a great variety of applications; however, so far, no completely satisfactory method has been developed for measurements on free radical intermediates and molecular and atomic species in ordinary gas-phase chemical reactions at the low, steady-state concentrations at which they usually occur. The combination of low concentration and short lifetime of intermediate radicals has provided a real challenge to scientists in identifying and quantifying particular compounds/mixtures in the chemical environment. Many radicals have been detected and characterized using low-energy electrons [1] and photons [2]; in practice, however, encountering a large number of interfering factors is unavoidable.

In 1971, a new method known as *alkali metal ion attachment chemical ionization mass spectrometry* (ACIMS) was proposed by Beauchamp [3] and others [4, 5]. In this method, alkali metal ions such as Li^+, Na^+, and K^+ form adduct ions (also referred to as *cationized molecules*) with molecular species through association reactions. In general, these cationized molecules are more stable than radical molecular ions or protonated molecules in the gas phase. Rollgen and Schulten [6] explored this approach for achieving cationization using the field desorption technique.

Introducing some additional features to this method, Beauchamp and coworkers [7] described a technique for obtaining mass spectra solely of quasi-molecular ions formed by the addition of Li^+ ions to the sample molecules. Several research groups have actively attempted to detect many organic complexes by attaching alkali metal ions to the sample molecules [8, 9]; however, all these experiments have generally been employed to investigate the chemical ionization reactions rather than to provide a complementary tool to identify the chemical species.

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

Twenty years ago, Fujii and his group [10] developed the novel method for detection of radical species in the gas phase using Li^+ ion attachment (IA) to chemical species. As the potential of lithium ion attachment in mass spectrometry (Li^+IAMS) had not yet been realized, they attempted to reveal and explore some of the unique properties of Li^+IAMS [11–18]. It provides mass spectra of quasi-molecular ions formed by Li^+ IA to the radical species under high pressure [19–21]. Results are obtained in the form of trace of Li^+ adduct ions ($R+Li^+$) (also referred to as *cationized molecules*).

In this chapter, the development of a Li^+IAMS that is used to study the occurrence of free radical intermediates and molecular and atomic species (which are not found under ordinary conditions) on a real-time basis in the gas phase is briefly described. The newly developed device, IAMS, exhibits several advantages over conventional mass spectrometers. The performance of this equipment and unique features are also presented. Finally, the interesting applications for environmental analysis and possible future perspectives of this approach are reviewed.

35.2
Principle

Thermal IA (association) reactions are described [22, 23] by the termolecular process in this equation:

$$A^+ + R + N \rightarrow [A - R]^+ + N \tag{35.1}$$

where A denotes a positively charged alkali metal ion, R is a radical species, and N acts as a third body. The binding energy of the radical R to the alkali cation A^+ is defined by the enthalpy change for the preceding reaction. Deriving primarily from electrostatic forces, the binding energy of the reagent alkali metal ion A^+ to the radical must be high enough to permit a significant number of adducts to be formed at the partial pressure used in the experiments. As indicated, most association reactions are reversible, although not necessarily appreciably so for all experimental conditions. The bonding between ion and neutral species is generally found to be weak relative to normal chemical bond strengths; for (A–M) is typically $200\,\mathrm{kJ\,mol^{-1}}$ or less, often much less. It seems likely that the A–M bond derives primarily from electrostatic forces such as ion–dipole attraction.

Sensitivity is influenced by a large number of factors. Only a limited number of factors, however, can potentially contribute to a significant gain in sensitivity: (i) kinetic energy of the Li^+ ion and (ii) Li^+ affinity of the sample molecule. For stabilization of the adduct ionic complex, the cationization process should be carried out in a high-pressure environment because the added gas molecules serve as third bodies in the analyte addition reaction with the alkali metal ions. The voltage applied to the repeller provides sufficient kinetic energy to the reactant ion. The relationship between the Li^+ ion intensity and the repeller voltage should be considered at various ion source pressures: at higher ion source pressure, more adduct ions are produced at a higher repeller voltage. Low repeller voltage (E)

and high ion source pressure (P) favor adduct formation; as E/P is raised, the probability of this process decreases. This ion energy dependence is consistent with the reported mechanism of the IA reaction: the initial combination step of an ion–molecule association reaction is brought about by ion–dipole attraction between the reactants without any activation energy.

35.3
Instrumentation

35.3.1
Basics of Instrumental Design

An overview of the Li$^+$IAMS is sketched in Figure 35.1 [24–27]. It is composed of four major functional blocks: the sample inlet system, the reaction chamber (RC), the ion focusing system, and the mass analyzer. Three different vacuum pumps are employed to evacuate various sections of the system: the RC is maintained at 1–760 Torr by a rotary pump, and the ion focusing system and mass analyzer are held at $<2 \times 10^{-4}$ Torr and around 5×10^{-7} Torr, respectively, by two turbomolecular pumps (diffusion pumps). These functional blocks are discussed in more detail in the following sections.

35.3.1.1 Sample Inlet System

Samples may be introduced into the present MS system by several different methods, such as leaks, insertion probes, and online combinations with chromatography. Owing to the high-vacuum conditions, a controlled leak is a simple method to introduce samples but is restricted to samples with high vapor pressure. Solid and liquid samples can be introduced with a heatable insertion probe via

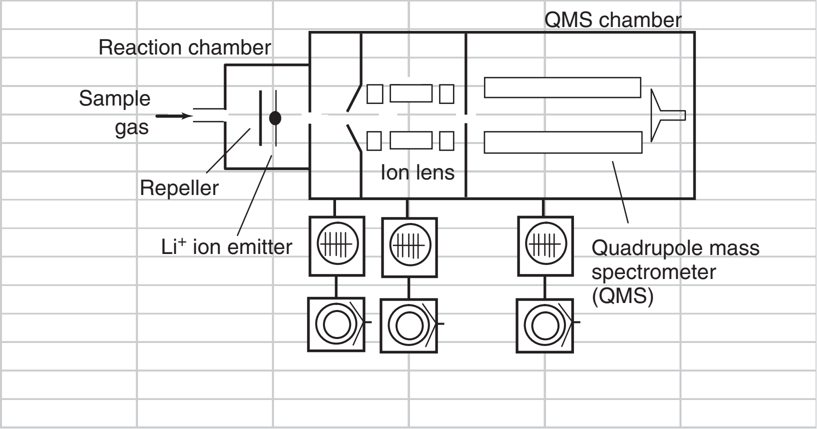

Figure 35.1 Basic scheme of ion attachment mass spectrometry.

a vacuum lock into the high vacuum. Either gas chromatography (GC) or liquid column chromatography can be easily applied as sample inlet systems. In principle, any gaseous sample whose components are to be identified can be introduced into the RC.

35.3.1.2 Reaction Chamber

The RC is a cylindrical tube (i.e., 5 cm) with a lithium ion source centered along one side. The chamber can be evacuated through a cone aperture with a rotary pump and can be maintained at high pressure by altering the pumping speed or the carrier gas flow rate.

The lithium ion source consists of a lithium ion emitter and a repeller. The Li^+ emitter is a small mineral bead (about 0.2 cm in diameter) fused to a 0.25-cm-diameter Ir wire; the bead is prepared [28] by thoroughly grinding a mixture of $Li_2O : Al_2O_3 : SiO_2$ (1 : 1 : 1 mole ratio), and primary Li^+ ions are produced by heating the bead. The emission of contaminants along with the Li^+ ions is unavoidable as emission begins, but in due course decreases to <0.1% of the total emission. The repeller electrode, consisting of a 1.5 cm diameter stainless steel disk, was placed 1 cm behind the emitter bead; its voltage was maintained at the same potential as the emitter.

35.3.1.3 Ion Focusing System

Adduct ions from the RC pass through an aperture and are directed into the differentially pumped lens region through a 1 mm diameter orifice drilled into the tip of a skimmer. No potential was applied to the skimmer. The ion focusing system is an electrostatic lens system (ELS).

35.3.1.4 Mass Analyzer and Detector

The mass analyzing chamber was equipped with a quadrupole mass spectrometer with rods biased below ground by connecting the DC-rod-driven circuit to separate DC supplies. Two possible modes of ion detection, analog and pulse counting, can be employed using a channeltron electron multiplier detector. In the pulsed mode, the channeled output from the multiplier is fed to the preamplifier–discriminator–counter system operated in the multichannel scaling mode.

35.3.2
IA-Lab

This type of mass spectrometer has recently become available commercially in a complete form [29]. It allows an easy linkup with GC, and hence the acquisition of the mass spectrum of pseudomolecular ions.

35.3.2.1 System

The optimal utilization of “direct measurements” is facilitated by the constitution of the IA-Lab (ion attachment Lab), which includes state-of-the-art features such as

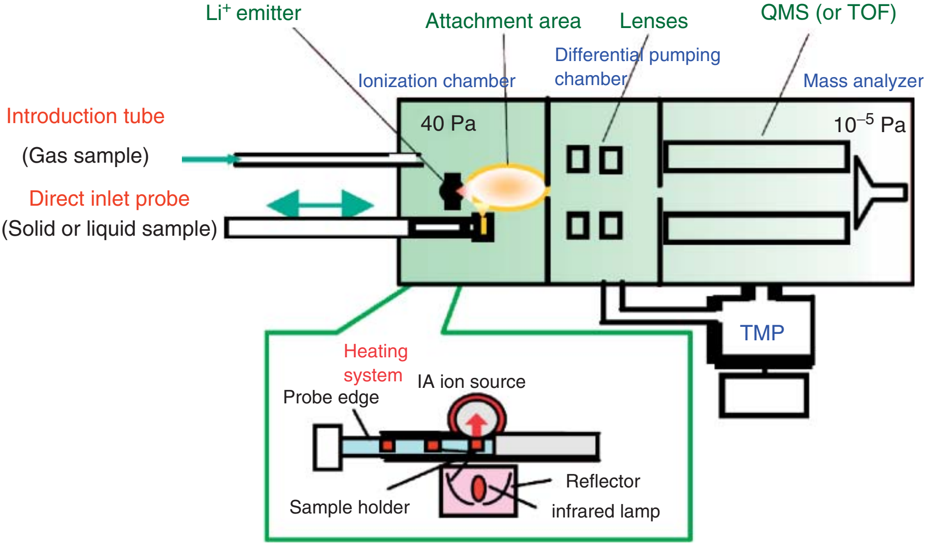

Figure 35.2 Schematics of IA-Lab. Li^+ is supplied by an Li^+ emitter. There are two types of interface for sample introduction: an introduction tube for gases and a direct inlet probe for solids and liquids. Using the direct inlet probe, the sample is heated by an infrared lamp and the temperature is controlled by the program. The range is room temperature to 500 °C. Li^+ attaches to the evolved gas in the attachment area. The ion $[M+Li]^+$ is then introduced to the mass analyzer after passing through focusing devices (lenses) in the differential pumping chamber.

a five-series direct probe, a mass spectrometer operating to 1000 m/z, and an easily maintained ion source. The sample is heated and vaporized with the infrared (IR) lamp, and ionized in the ion source, and its constituents are measured in the mass spectrometer (Figure 35.2). For vaporization in vacuum immediately under the ion source, there is little influence of pyrolysis or adsorption. In addition, use of the electron ionization (EI) source can furnish complementary fragment information. The IA-Lab can analyze not only liquid/solid samples but also adsorptive gases via a heating entry port (GC interface). A GC connection is possible, too.

35.3.2.2 **Sample Entry**

In "direct measurements," a small sample is introduced. The sample is weighed with a precision balance in the case of quantitative analysis.

35.3.2.3 **Operation**

After sample introduction, all operations are performed on a PC. In a measurement screen of standard heating, the selected ion monitoring (SIM) and a spectrum are displayed at the same time. The mass spectrometer is fully equipped with the software necessary for quantitative analysis calculations.

35.3.2.4 Application (Thermoresolution Process)

In thermogravimetric analysis-mass spectrometry (TG-MS) (outbreak gas analysis), a change in every constituent is not possible. Moreover, a continuous time change in pyrolysis gas chromatography mass spectrometry (py-GC/MS) is likewise not possible. However, thanks to the ‘‘direct measurement’’ feature of IA-Lab, a continuous change in each product generated by pyrolysis could be measured.

35.3.3
IA-TOF

Recently, the Japanese group made a unique development in this area. The alkali metal IA reaction has been applied to time-of-flight (TOF) MS [30]. Preliminary results have revealed the high efficiency of the lithium cation (Li^+) attachment reaction in the TOF mass spectrometer. The TOF MS/IA RC setup appears interesting, especially for the analysis of nonvolatile and thermally labile compounds. Studies are ongoing in a number of laboratories to develop this combination.

35.3.3.1 Main System

The tabletop IA-TOF system consists mainly of an IA ion source, a differential pumping system, and a TOF mass spectrometer. The main body of the IA-TOF system measures 50 cm × 80 cm. The adduct ions are transported by a guiding electrostatic field between the aperture at a DC potential and the skimmer at ground potential (Figure 35.3). The adduct ions that pass through the skimmer

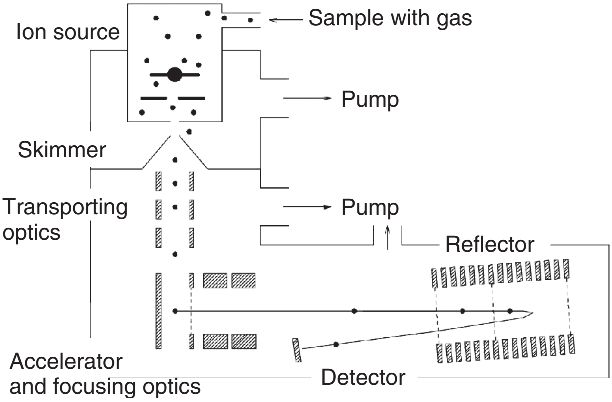

Figure 35.3 Schematic view of the IA-TOF system. Gas-phase sample molecules are ionized by alkali metal ion attachment and become adduct ions in the IA ion source. The adduct ions are extracted through the aperture into the differential pumping region, pass through the skimmer, and are introduced into the TOF mass spectrometer. Because 100 Pa of N_2 gas is introduced into the IA ion source, a differential pumping system is used to evacuate the gas as the TOF mass spectrometer must be kept in a high vacuum condition. The orthogonal acceleration reflector TOF mass spectrometer realizes mass spectrometry with a high mass resolution over a wide mass range.

are focused on the starting point in the acceleration region of the TOF mass spectrometer by an Einzel lens. Scattering of the adduct ions by collision with gaseous N_2 at the aperture and in the differential pumping region introduces spreading of the initial position and initial velocity (energy) in the acceleration region that reduces the mass resolution.

35.3.3.2 **Orthogonal Acceleration Reflector**

A TOF mass spectrometer consists mainly of a single-stage accelerator, ion focusing optics, a two-stage reflector, and an ion detector. Ions are accelerated by a pulsed electric field in the accelerator, then pass through a field-free TOF drift region, are next reflected by the reflector, and finally reach the detector. If all the ions have the same flight path and the same kinetic energy, their TOF (t_{TOF}), from the acceleration point to the detection point, is proportional to the square root of the mass m.

The mass resolution R of a TOF mass spectrometer is defined by the ratio of m to the detectable mass difference Δm:

$$R = \frac{m}{\Delta m} = \frac{t_{TOF}}{2\Delta t} \tag{35.2}$$

where Δt is the temporal broadening width of the TOF profile.

For the ion detection system, a fast-response microchannel-plate detector is used with a detection diameter of 14.5 mm (Hamamatsu F4655). The data-recording system involves a digital oscilloscope with a bandwidth of 2 GHz or a digital multistop time digitizer with 0.25 ns resolution (FAST ComTec P7887). Although the current-detection mode, where the ion signal is measured by accumulating the waveforms of the individual ion currents on the oscilloscope, is useful for qualitative measurement of the relative abundance of ions, the pulse-counting method with the multistop time digitizer permitted attainment of a wide dynamic range and sufficient ion count accuracy for quantitative measurement of the TOF spectrum. In the pulse-counting method, the intensity of the ion signal (the ion flux) should be reduced to a sufficiently low level so that multiple ions of identical mass do not hit the detector simultaneously. Mass measurements in this work were obtained by the pulse-counting method.

35.3.3.3 **IA-TOF Mass Spectrum**

Figure 35.4 depicts the mass spectrum of Ultramark 1621. Ions over a wide mass range up to m/z 3400 are clearly observed. Ions of $m/z < 350$ are due to traces of residual styrene monomers, dimers, and trimers from the pyrolysis of polystyrene samples. Two reference time peaks were adopted to obtain the conversion parameters: the time peak at m/z 111.079, corresponding to the styrene monomer $[^{12}C_8H_8 + {}^7Li]$, and the peak at m/z 1628, corresponding to Ultramark 1621 [31].

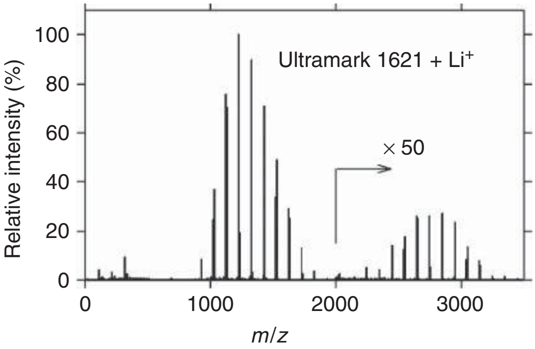

Figure 35.4 Typical mass spectrum of the mass marker Ultramark 1621. Compounds over a wide mass range up to *m*/*z* 3400 are clearly mass analyzed with high mass accuracy.

35.4
Performance and Response Characteristics and Features

35.4.1
Sensitivity

When an acetone sample was introduced at a rate of $2.6 \times 10^{-10}\,\mathrm{g\,s^{-1}}$ from the permeation tube at 25 °C, measurement of the adduct ion current was 2.9×10^{-10} A (with an ion multiplier gain of 2×10^3); hence, the sensitivity was calculated as $1.12\,\mathrm{A\,(g\,s^{-1})^{-1}}$.

The minimum detectable amount (MDA) can be estimated using the actual noise level of the system as the ultimate limitation on the minimum detectable sample size. A signal-to-noise ratio of 10 is a practical and conservative lower limit for quantitative detection; then, in pulse mode, a signal of $100\,\mathrm{counts\,s^{-1}}$ is required. For acetone, the MDA was estimated around $14.2 \times 10^{-18}\,\mathrm{g\,s^{-1}}$. On the other hand, in the analog detection mode, the MDA was calculated as $8.93 \times 10^{-15}\,\mathrm{g\,s^{-1}}$ (with a signal-to-noise ratio of 3), on the assumption that the capability of the ion detection system was around 1×10^{-14} A.

35.4.2
Linear Response Range

The signal response was linear over the chosen range of 7×10^{-11} to $8.2 \times 10^{-10}\,\mathrm{g\,s^{-1}}$. A plot of four introduction rates of acetone versus the corresponding peak heights produced an essentially straight line up to $8.2 \times 10^{-10}\,\mathrm{g\,s^{-1}}$ (data not shown); at this point, >5% of the total $\mathrm{Li^+}$ reactant ions have been used for attachment. As the cationized samples are depleted of alkali metal ion density, the response follows Beer's law, similar to that of the electron capture detector; hence, it could be concluded that for a linear response, the sample size must ensure a large excess of reactant ions in the cationizing chamber.

35.4.3
Li^+ Affinity

From Li^+ affinity data, the relative sensitivity of any organic of interest can be estimated. The production rate of the Li^+ adduct depends on the strength of the Li^+ affinity of the molecule or radical species under consideration, which ranges up to about 50 kcal mol^{-1}; this value, in turn, is heavily dependent on the polarity or polarizability of the target species. In other words, the chemical species captures the Li^+ ions and yields the $(M+Li)^+$ adduct if the Li^+ affinities are sufficiently high. Under conventional Li^+MS experimental conditions, compounds with Li^+ affinities weaker than 10 kcal mol^{-1} were barely detectable, even if they were present in abundance. Li^+ affinities of molecular species may be helpful in predicting whether the species can be detected using a minimum sample concentration.

35.4.4
Features

Some of the essential advantages and applications of the present IAMS system are as follows:

1) No dissociative ionization takes place. There is no possibility of fragmentation of the adduct ions; Li^+MS provides only molecular ions and hence can be exploited for the determination of molecular weight and the analysis of mixtures where no fragmentation is desired.
2) Mass spectra from a Li^+IAMS tend to be simple and hence it is easy to determine which form of which radical species is reacting.
3) Its sensitivity is high, especially for polar molecules, because of ion–molecule reactions.
4) Direct continuous measurements on a real-time basis of many radical species and stable molecules in a dynamic system are feasible.
5) It makes possible the analysis of any plasma via identification of both the ionic and neutral radical species and the correlation between them.
6) The detection of interstellar species and the identification of unfamiliar species, which would be immensely useful in astrophysical and astrochemical studies, are possible with this method.

These features can help widen the applications of MS.

35.5
Applications

Li^+IAMS has been done already for the interesting environmental analysis; (i) RoHS (restriction of hazardous substances) rapid analysis of brominated flame retardant (BFR); (ii) organic pollutants in atmospheric environment, exhaust gases from the automobiles, formaldehydes in doors, offensive odor species; (iii) pyrolysis of Teflon; (iv) BPA (bisphenol A) from polycarbonate (PoC) (EGA probe) (EGA, evolved gas analysis); (v) PFC (perfluoro compound); (vi) NO_x; and (vii) others such as pesticide residue in rice a volatile organic compound (VOC) in soil. Some of the studies are presented here.

35.5.1
RoHS Rapid Analysis of Brominated Flame Retardants

35.5.1.1 RoHS (Restriction of Hazardous Substances) Directive

No electronic electric apparatus can be marketed in an EU member state after July 2006 if it contains materials (e.g., polybrominated biphenyls (PBB), polybrominated diphenyl ethers (PBDEs), or heavy metals) in excess of a designated value of RoHS [32]. A fast analytical method is therefore required to quantify certain BFRs in plastic materials with a combination of instrumental techniques such as X-ray fluorescence spectrometry, thermal desorption GC, and MS. In practice, the differentiation of the various possible compounds (second screening) after bromine (Br) has been detected by X-ray fluorescence is important because many kinds of BFRs are used besides PBB and PBDEs, which are restricted by the RoHS directive in plastics products. After the second screening, an accurate measurement by GC/MS is usually carried out as for PBDEs, which are restricted by the RoHS directive. However, this may require a total of 20 h or more including the pretreatment (extraction and concentration) and calculations of the GC/MS.

IAMS is a method that can measure burned snippets or powders of RoHS samples directly, using a direct inlet probe; the peaks of the molecules of each component can be detected without separation and in real time. The total analysis time required with this method is generally 40 min, that is, very short. The IAMS method is faster than the GC/MS method and results in exact differentiation of Br compounds because there is no fragmentation. IAMS is a new method that is able to satisfy this demand. Examples of the measurement of Br compounds by IAMS are presented in Figure 35.5. Although the product of octabromodiphenyl ether is a mixture of homologs containing different numbers of Br atoms, the mass spectrum correctly shows the composition ratio.

35.5.2
Organic Pollutants in the Atmospheric Environment

Many kinds of pollutants can coexist in the atmospheric environment. Real-time measurements of pollutants are essential for the conformation of hazards and for safeguarding against chemical disasters. In this section, IAMS has been used to measure numerous kinds of volatile organic pollutants in the atmospheric environment.

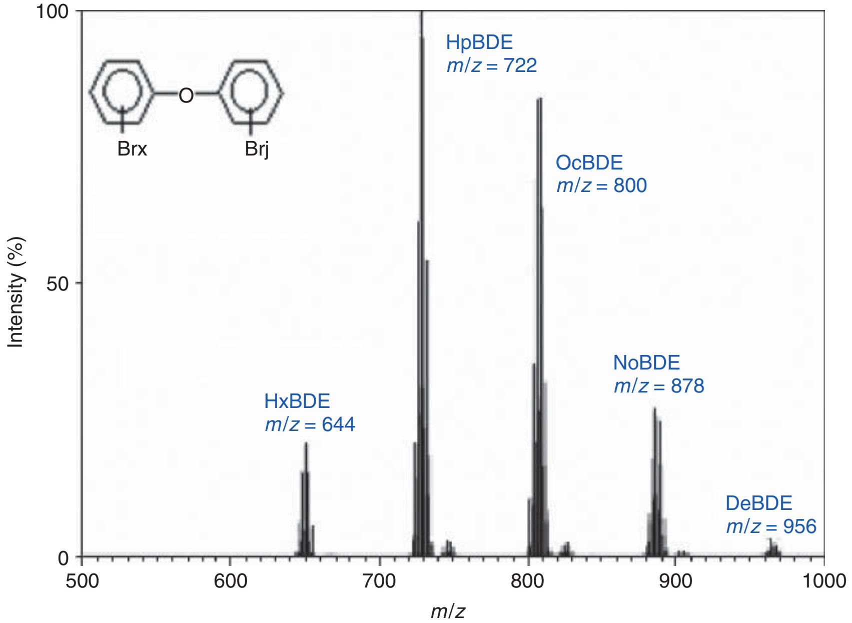

Figure 35.5 Mass spectrum of polybrominated diphenyl ethers (PBDEs).

35.5.2.1 Exhaust Gases from Automobiles

The hydrocarbon content of automobile exhaust gases varies with the engine speed; it approaches a steady state at high speed [33]. The harmful effects depend on the compounds in the exhaust gases, which can vary in nature and in concentration hour by hour. A real-time measurement of each element is demanded.

The Canon ANELVA people used the IAMS method to measure the fumes emitted by gasoline- and diesel-powered cars. The benzene content was followed in real time (Figure 35.6). The exhaust gases were measured by IAMS, with a detection limit of 0.03 ppm and a measurement interval of 10 s in selected ion monitoring. IAMS detected 1 ppm benzene 1 min after the start of the new gasoline engine instead of no detection after 3 min. It seemed that the elimination by the catalyst was not adequate after 1 min. Many kinds of organic compounds, such as aromatics, alkanes, alkenes, and dienes, were detected. The total amount of organic compounds from the new engine 3 min after the engine start was 0.05 ppm, that is, three orders less than from the old engine.

35.5.2.2 Formaldehydes Indoors

Formaldehyde (HCHO) emitted from the furniture and walls in rooms injures the eyes, the nose, and the respiratory organs and causes allergies; this is the sick house syndrome. Formaldehyde was a suspected carcinogen and in group 2A in the International Agency for Research on Cancer (IARC) classification system until 2004, when the working group of IARC reclassified it as a human carcinogen (1G) [34].

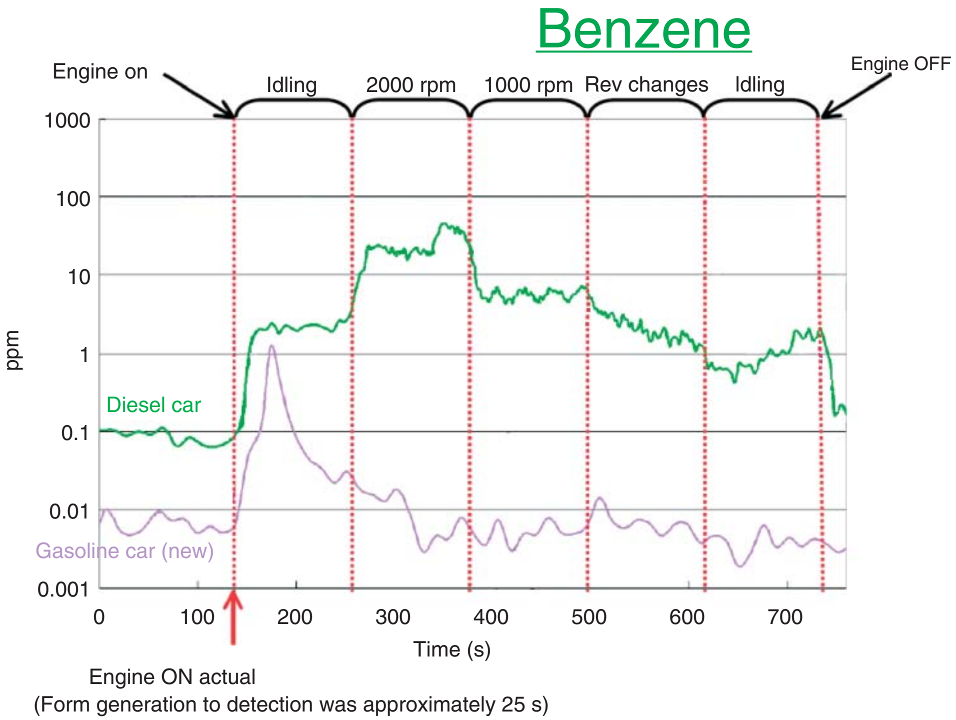

Figure 35.6 Emission behavior of benzene by revolution change of gasoline engine.

Direct measurements of formaldehyde have been attempted. As formaldehyde is a very unstable compound, pretreatment for derivatization is essential for GC, but not for IAMS. IAMS detects for formaldehyde itself in the mass spectrum and demonstrates changes in its concentration in real time in the selected ion monitor mode. The reported detection limit was 9.2 ppb and the correlation coefficient (R^2) was 0.999. The results indicate that IAMS can simultaneously monitor other atmospheric odorous substances (Figure 35.7).

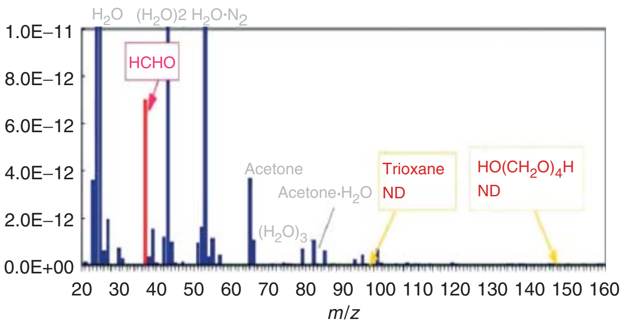

Figure 35.7 Detection of formaldehydes in doors.

35.5.2.3 Offensive Odorous Substances

Sulfide-containing compounds are among the most intense-smelling substances. The aromatic substances most generally found in food are H_2S, mercaptans, and thioalcohols present in coffee and onions, sulfides and thioethers in garlic, disulfides in garlic and leeks, trisulfides in garlic, and isothiocyanate, mustard oil, and others in Brassica nigra [35]. H_2S is responsible for most of the odor problems associated with brewing and food processing wastewater treatment. Heavier than air, colorless, corrosive, and extremely toxic, it raises serious workplace health and safety concerns [36].

H_2S was measured directly by IAMS, which yielded a calibration curve with 0.996 (R^2) and a detection limit of 0.05 ppm. On the other hand, the limit of detection by conventional MS with EI was 100 ppm, due to interference by the O_2 isotope. The IAMS mass spectrum of gases from putrefied onion indicated many kinds of sulfur compounds (Figure 35.8). These results demonstrate the possibility not only of measuring odors but also of monitoring the quality control of foods, industrial facilities, and so on.

35.5.3
Pyrolysis of Teflon

A well-established IA mass spectrometer has been combined with an IR image furnace specifically for thermal analysis studies [37]. With this system, it is

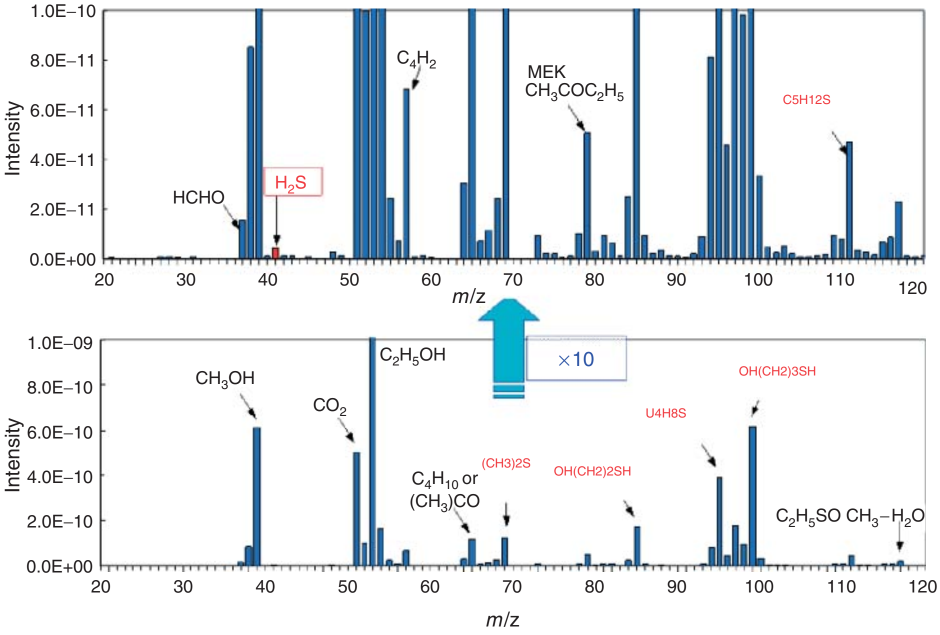

Figure 35.8 H_2S substances from decayed onion.

possible to detect any chemical species at atmospheric pressure, including radical intermediates, on a real-time basis, especially for the analysis of temperature-programmed pyrolysis products. The performance and applicability of the system is illustrated by polytetrafluoroethylene (PTFE) samples. The potential of the system for the analysis of oxidative pyrolysis has also been considered. The temperature-programmed decomposition of PTFE gave constant-slope plots of temperature versus signal intensity in a defined region and provided an apparent activation energy of 28.8 kcal mol^{-1} for the PFTE decomposition product $(CF_2)_3$.

35.5.3.1 Infrared Image Furnace (IIF)-IAMS System

The atmospheric pressure IIF interface system, and part of the Li^+IAMS developed by Canon Anelva Corporation (Kawasaki, Japan) is shown schematically in Figure 35.9. A Sinku-Riko IIF (Model RHL-E45P, Sinku-Riko, Tokyo, Japan) was used as heat source. We have developed a skimmer interface system between the IIF sample at atmospheric pressure and the high vacuum inside an MS. With this system coupled with Li^+IAMS, it is possible to detect any chemical species at atmospheric pressure, including radical intermediates, on an EGA basis.

35.5.3.2 Pyrogram

When an analyte at atmospheric pressure is introduced through the 70 μm orifice in the sample skimmer inlet, the pressure in the RC reaches 100 Pa. No deterioration or marked changes in the leak rate have been noticed over a long period of use.

The EGA of a PTFE polymer was carried out at atmospheric pressure with programmed temperature increases. The temperature was increased at a rate of

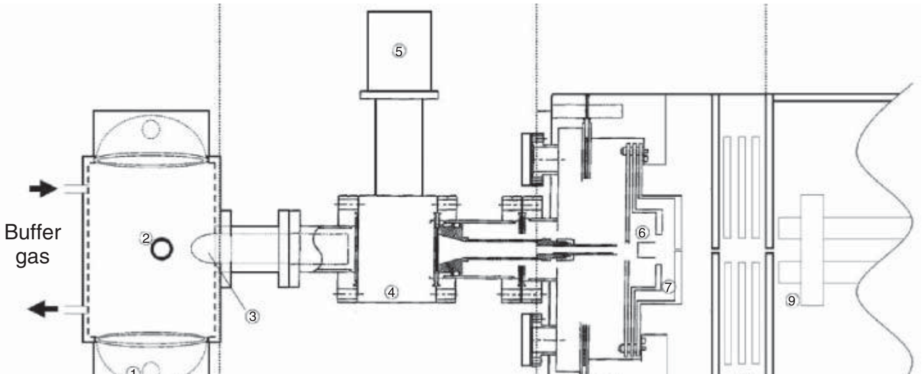

Figure 35.9 General scheme of the IIF attached to the Li^+ IAMS used in this study: (a) the IIF, showing the IR lamp unit (1) and position of the sample holder (2); (b) the interface, which has a concentric quartz tube with a 70 μm orifice at its center (3) and exit stainless steel tube (4), both of which are fixed to the flange of the gate valve (5); (c) the reaction (ionization) chamber, with the Li ion emitter bead fused onto the Ir wire (6), RC (7), and ELS (8); (d) the envelope for quadrupole MS (9).

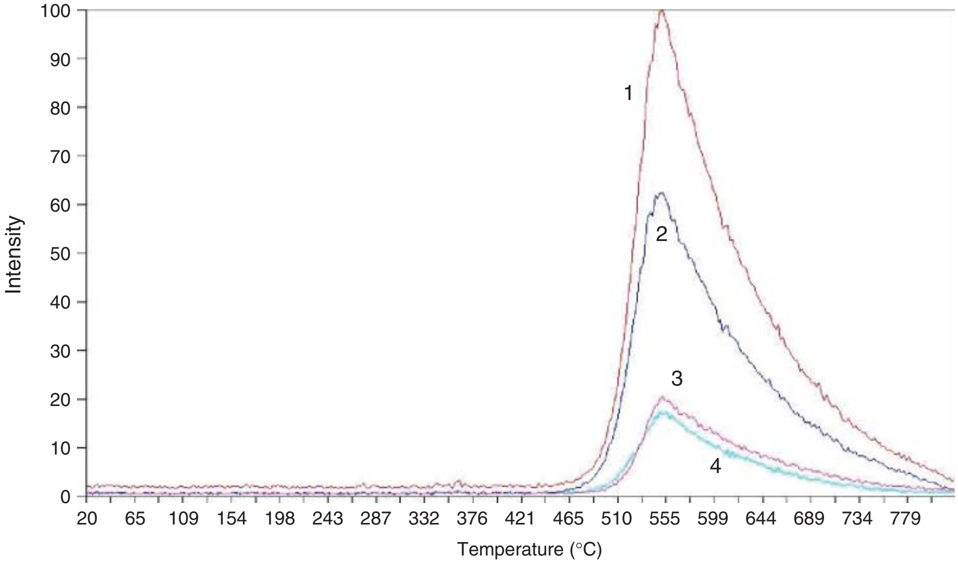

Figure 35.10 Evolution profiles of the thermal products from the pyrolysis of PTFE polymer as shown by total ion and selected ion chromatograms. (1) Total ion, (2) $(CF_2)_3$, (3) $(CF_2)_4$, and (4) $(CF_2)_2$.

$20\,^\circ\mathrm{C\,min^{-1}}$ until it reached 800 °C, after which the temperature was kept constant. In EGA, peaks caused by the decomposition products started to appear after the IIF temperature reached around 480 °C. The total ion yield of all the products increased continuously (Figure 35.10) to a maximum at 550 °C.

35.5.3.3 **Apparent Activation Energies for the Decomposition Products of PFTE**

The ionic signal (i) acquired from the real-time multiple ion detection of chemicals (Figure 35.10) released from thermally decomposed PTFE polymer is used to obtain the functional form of the kinetic rate expression. From ln[i] versus $1/T$ plots, the Arrhenius parameters (apparent activation energy) can be determined [38, 39]. We investigated the intensities of the $(CF_2)_3$ signals at m/z 157 over the temperature range 485–510 °C in order to obtain the rate expressions for PFTE degradation, on the assumption that (i) equilibrium is established between the chemical species via thermal degradation and the products are detected by $\mathrm{Li^+}$IAMS; (ii) a simple correlation exists between the adduct ion signal, the product concentrations and PFTE degradation; and (iii) the overall rate of decomposition of a heated polymer sample is constant within the limited ranges for which the degree of conversion (fraction of material decomposed, C) of the sample is in a defined range. According to the isoconversional method of Flynn and Wall, the apparent activation energy (E_a) values are invariant for conversions >5%. Therefore, we take the defined range to be from a C of 5% up to the percentage at which the slope of the ln[i] versus $1/T$ plots is no longer constant (better than $R^2 = 0.99$). The

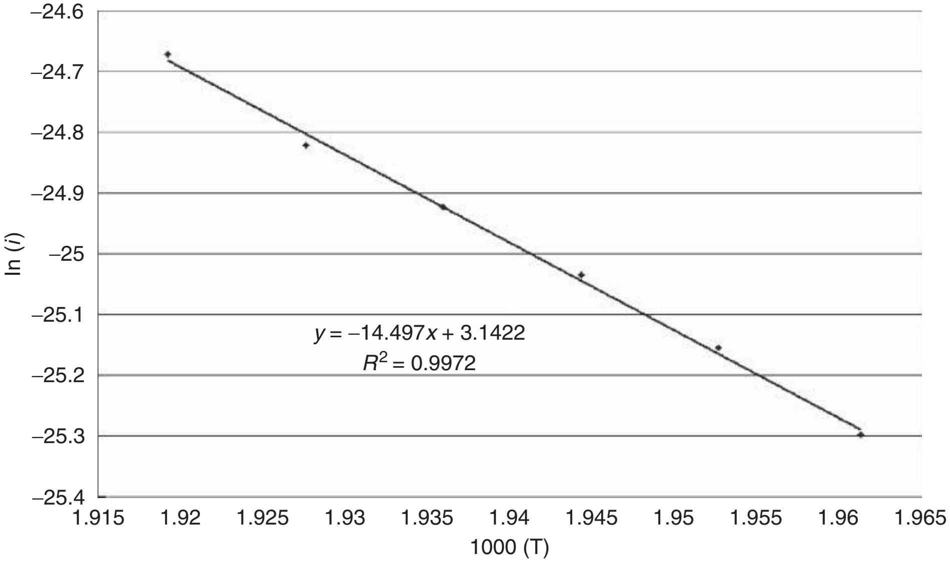

Figure 35.11 Plots of temperature versus signal intensity of $(CF_2)_3$ in the temperature range 485–510 °C.

slopes of the plots of temperature versus signal intensity in this limited region are constant (Figure 35.11). An E_a of 28.8 kcal mol^{-1} was calculated from the plots of $(CF_2)_3$. This value may be associated in some way with the nature of the bonding.

35.5.4
BPA from PoC (EGA-Probe)

The group of Fujii recently developed [40]a simple EGA system to act as an interface between solid samples at atmospheric pressure and the high vacuum inside a mass spectrometer. The newly designed stainless steel EGA system is simple, small and rugged, and fulfills all the basic requirements for EGA. With this system coupled with a Li^+IAMS, it is possible to study the temperature-programmed decomposition of a number of polymer materials by detecting any chemical species on a real-time basis. For illustrative purposes, pyrolysis experiments of some polymers were conducted.

35.5.4.1 EGA Probe

A schematic drawing of the cutaway side view of the EGA probe inlet system fabricated in this study, and part of the Li^+IAMS developed by Canon Anelva Technix Corporation (Fuchu, Japan) is shown in Figure 35.12. The newly designed inlet system for the mass spectrometer consists of a gas inlet set up as follows to ensure a consistent and streamlined entry of analytes into the mass spectrometer. There is a gas inlet in the inner tube through which a buffer gas is introduced to

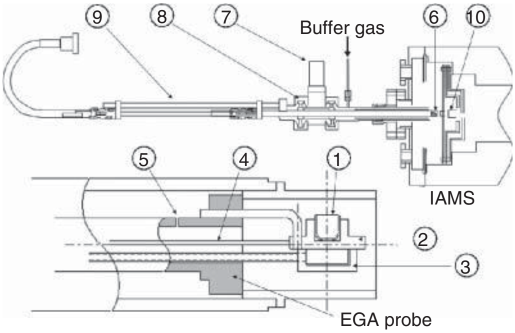

Figure 35.12 General overview of the EGA probe attached to the lithium ion attachment mass spectrometer used in this study; Extended view of EGA probe showing (1) sampler, (2) sampler holder, (3) heater, (4) thermocouple, (5) gas inlet, and the whole system of EGA probe and IAMS, showing (6) sampler, (7) isolation valve, (8) detachable flange, (9) slide guide, and (10) Li^+ emitter.

carry the product gas. This arrangement ensures that the analyte flows in a constant stream from the sampler into the mass spectrometer. The EGA probe consists of two concentric stainless steel tubes (200 mm long, 15.8 mm in outer diameter and 280 mm long, 6.4 mm in outer diameter); a holder with a sampler on it at its center is fastened to the end of this probe. The EGA probe is placed in front of the reaction (ionization) chamber of the mass spectrometer with a Conflat flange in such a way that the sampler is located 10 mm from the Li^+ emitter. The distance from the Li^+ emitter is adjustable, but 10 mm was found to be optimum.

The sample is introduced through a vacuum isolation valve into the MS. The purpose of the isolation valve is to permit the sampler, which is at atmospheric pressure, to be injected into the vacuum system while still keeping a good vacuum for the MS operation.

The sampler (Figure 35.12) is made of heat-resistant tantalum alloy. The heating element (a microceramic heater, 15 V, 15 W) is contacted on a holder body that holds the sampler on the upper end and a thermocouple at the bottom. An EGA probe controller (UP, UP150-VN) controls the programmable heating, in which the goal temperature, the rate of heating, and the length of constant-temperature periods in each step can be set up. The maximum operating temperature is 600 °C.

While the analytes are introduced directly into the mass spectrometer, the pressure of the RC is maintained between 60 and 133 Pa, which is the optimum pressure for the formation of Li^+ adducts through a termolecular association reaction.

35.5.4.2 **Pyrolysis of Polycarbonate: EGA/IAMS**

The accumulation of plastics in the environment is a matter of great concern [41–43]. One of the available solutions is waste reconversion; on the other hand, incineration can be used to transfer the waste plastics into energy. However, the combustion of plastics can produce many gaseous products, the nature of which depends mainly on the external conditions, that is, temperature and oxygen availability. Accordingly a series of experiments were conducted either in nitrogen or in an air atmosphere, to mimic the reductive environment and the conditions in incinerators.

Pyrolysis experiments were conducted with the EGA/IAMS systems (Figure 35.13). Li^+ IAMS has considerable advantages for product monitoring in the gas phase in comparison with traditional EI MS. Unlike traditional MS, employing ionization by high-energy electrons, IAMS much better preserves the profiles of the product molecules, allowing their detection as adduct ions without any fragmentation. The fundamental mass spectra are considered for the decomposition of polycarbonate. The present work also focuses on BPA, generated on increases of the pyrolysis temperature in the presence of metal chlorides. The source of BPA in nature is through contamination from incineration and it can be leached from the waste in landfills. From there, it passes into the soil and aquatic environment and potentially into water sources. BPA is an endocrine disruptor; although its acute toxicity is low, there is concern that long-term exposure to low doses of BPA may induce chronic toxicity in humans. Therefore, it is important to lower BPA emissions if possible.

Figure 35.13 illustrates the results of single ion experiments conducted with polycarbonate in nitrogen and air atmospheres respectively (Figure 35.13a,b). The mass peak at $m/z = 235$ indicates the amount of BPA emitted. It may be seen that in air (Figure 35.13b), another BPA emission peak is observed at lower temperature than in the case of the nitrogen atmosphere (Figure 35.13a). This clearly shows that there are two different mechanisms of BPA production, but at the moment this cannot be discussed in detail. Figure 35.13 c presents the results of experiments where a mixture of polycarbonate and $CuCl_2$ in a ratio of 1 : 3 was pyrolyzed [44]. The amount of BPA evolved is almost 100 times less than when no $CuCl_2$ is present. Thus, BPA emission can be successfully reduced by the addition of metal salts.

35.5.5
Perfluoro compounds

PFCs, widely used as fluorine sources in semiconductor manufacturing processes such as CVD (chemical vapor deposition) chamber cleaning and dry wafer etching, can be emitted as gaseous by-products, along with hazardous air pollutants (HAPs) and various other gases. There is a need for reliable methods [45] that are capable of measuring PFCs in the exhaust gas, in real time.

The Li^+IAMS method provides mass spectra of quasi-molecular ions formed by lithium IA to the chemical species under high-pressure conditions [13, 25, 26]. Results are obtained in the form of mass spectrum of Li^+ adducts. As an example, the method was successfully applied to the study of neutral species that emerge from CH_4/O_2 microwave (MW) discharge plasmas [46, 47], demonstrating that Li^+MS combines sensitivity with the capability of quantifying amounts of reactive products in detecting even free radical species [48].

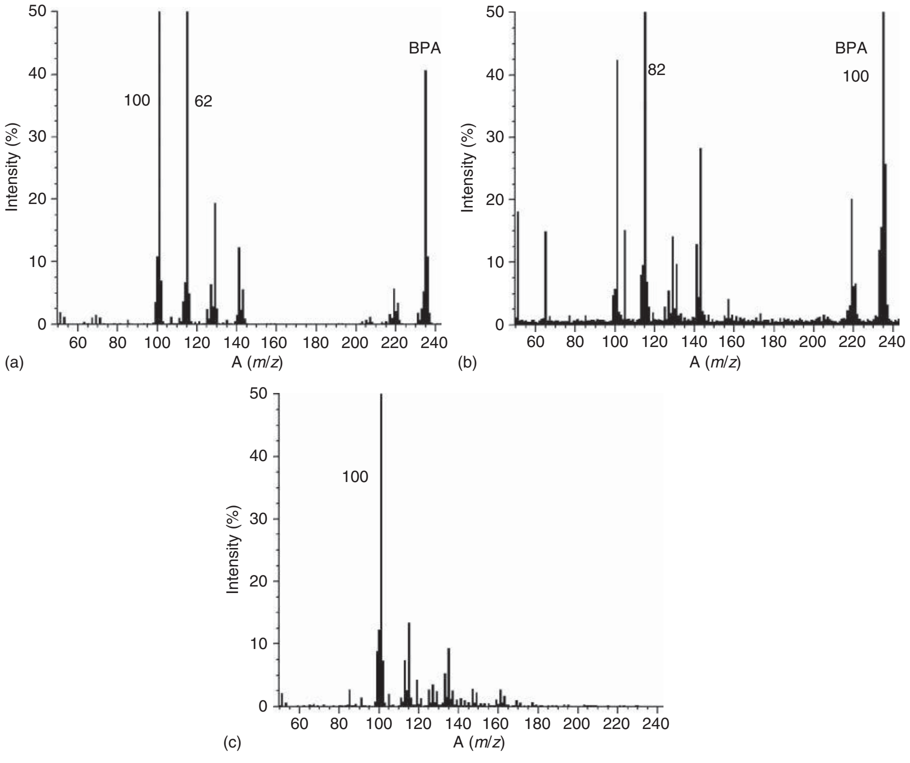

Figure 35.13 Spectra measured at 450 °C in N_2 atmosphere, air atmosphere, and with addition of $CuCl_2$ (ratio 1 : 3 in favor of $CuCl_2$) in N_2 atmosphere.

In order to support the emission reduction objectives of the semiconductor industry, the development of standardized analytical methodologies is necessary. To meet this requirement, we applied the Li^+IAMS technique to the development of a direct, real-time monitoring method for PFCs emitted from integrated circuit (IC) manufacturing facilities that we expect will significantly improve these areas of PFC measurement technology. The compounds studied were sulfur hexafluoride (SF_6), tetrafluoromethane (CF_4), trifluoromethane (CHF_3), perfluoroethane (C_2F_6), and perfluorocyclobutane (c-C_4F_8).

The c-C_4F_8 example was selected to show the performance and response characteristics possible with this analytical instrument in the optimal case. Figure 35.14a shows a typical mass spectrum in the mass range up to m/z 210 and Figure 35.14b a background spectrum, with no sample in the N_2 carrier gas. Only peaks due to Li^+ adduct molecular ion, with no fragmentation, are observed for the test compound, c-C_4F_8 (Figure 35.14a); this spectrum is completely different from the 70-eV EI mass spectrum (not shown), which shows many fragment ions, such as $C_2F_4{}^+$, $C_3F_5{}^+$, and CF^+ ions, but no molecular ions.

The c-C_4F_8 sample, diluted by 12 ml min^{-1} of N_2, was introduced at a rate of 1.8×10^{-6} g s^{-1} (0.012 ml min^{-1} of c-C_4F_8) from the needle valve at a temperature

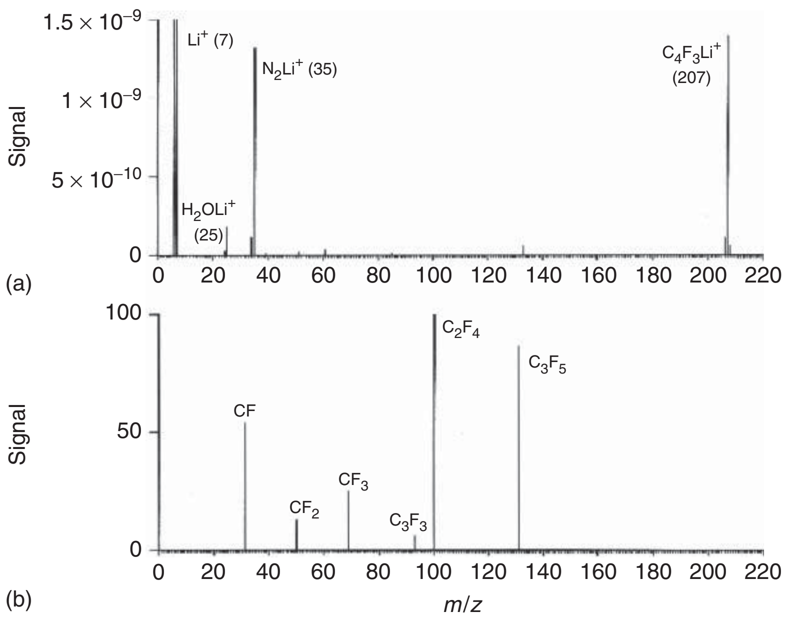

Figure 35.14 Ion attachment mass spectrum (a) obtained from 1000 ppm c-C_4F_8 in the N_2 gas, showing c-$C_4F_8Li^+$ (m/z 207). For comparison, the 70 eV electron ionization (EI) mass spectrum (b) was measured; the abundant ions observed and their relative intensities are C_2F_4 (100), C_3F_5 (87), CF (54), CF_3 (25), CF_2 (13), and C_3F_3 (6). The background mass spectrum of EI was measured with no c-C_4F_8 in the N_2 carrier gas.

of 25 °C. The measurement of the adduct ion current yielded a value of 4.4×10^{-9} A, which is the output of the ion multiplier with a gain of 7.8×10^2. Thus, the sensitivity coefficient is 2.4×10^{-3} A $(\mathrm{g\,s^{-1}})^{-1}$.

The study demonstrates [49, 50] the feasibility of measuring PFC concentrations in air by generating ions by Li^+ IA and mass analysis. The analytical method exhibited the following features: (i) high sensitivity, with the ability to detect 7 ppb c-C_4F_8 molecules in air; (ii) the ability to accept high-capacity sample introduction from atmospheric pressure and to allow easy coupling of various sample introduction sources to the MS analysis; (iii) the opportunity for real-time detection of any PFC species, including radical intermediates; (iv) the ability to identify compounds by the generation of ions that do not fragment, which is especially useful for determination of molecular weight; and (v) analysis of mixtures where no fragmentation is desired.

35.5.6
NO_x

Interest in NO_x species is fueled by the desire to understand their complex spectroscopic characteristics on a fundamental level, as well as by their importance in the Earth's atmosphere, especially with regard to key processes relating to ozone (O_3), hydroxyl radicals, and acid formation [51]. Model calculations indicate that background concentrations of NO_x in the troposphere may have risen by as much as 100%, causing a 20% increase in O_3 levels during much of the year. Beck and Ehhalt [52, 53] reported significant evidence that 30–50% of the NO_x in the upper troposphere is due to aircraft emissions.

Although nearly all (>90%) of the NO_x in the atmosphere is emitted as NO, NO is quickly converted to a variety of other species such as NO_2, HNO_3, N_2O_5, and HNO_2 [54]. There are indications that all these species may be involved in a complex way in the behavior of NO_x. A full understanding of atmospheric NO_x has not been achieved, and the existence of ionic ${NO_x}^+$ has not yet been reported. Atmospheric NO_x has been studied with the help of simulation experiments using plasma systems.

The use of an electric discharge to partially decompose a chemical compound so that the various free radicals, ions, excited molecules, and so on generated by the discharge react almost immediately with the undecomposed parent compound to generate daughter compounds is a technique that should have general applicability [55].

The Li^+IAMS technique provides mass spectra of quasi-molecular ions formed by lithium IA to chemical species under high pressure [13]. Results are obtained in the form of MS traces of Li^+ adducts. As an example, the method has been successfully applied to the study of neutral species that emerge from N_2/O_2 MW discharge plasmas [56]. This study demonstrated that Li^+MS produces only molecular ions, thus permitting the direct determination of unfamiliar and reactive species.

Because MW discharges through N_2/O_2 in the presence of water are used for simulations [57] of atmospheric chemistry, we believed that it would be desirable to examine the effects of water in detail. Therefore, we used Li^+MS with a flow system to qualitatively detect the product species, paying special attention to the effects of water.

Fujii reported on a series of experiments in which we measured the products of an MW discharge in airlike gas mixtures (80% N_2, 20% O_2, and water). The products of the discharge are molecules that are thought to exist in the atmosphere and are relevant to the study of atmospheric chemistry. The products are compared with species observed in the field. We believe that the nature of the $N_2/O_2/H_2O$ discharge plasma can be best understood after all the products have been fully identified.

The product species detected in this study were compared with the species detected in field observations [58]. Table 35.1 reveals that the neutral species observed in our laboratory resemble the constituents observed in the Earth's atmosphere. On the basis of this resemblance, we concluded that the MW-discharge-induced chemistry observed in the $N_2/O_2/H_2O$ plasma may be helpful for understanding atmospheric chemistry. We demonstrated that laboratory simulation experiments can yield results directly applicable to the Earth's atmosphere. It should be noted, however, that there are significant differences in the relative amounts of the products, especially for NO and HNO_2. They compared the ionic products we detected with those detected by Eisele *et al.* [59, 60] in a remote desert area of southeastern Arizona and on top of Mount Washington in New Hampshire. We found no agreement in terms of the products, except for one species

Table 35.1 Analysis of neutral products formed the MW discharge of the mixture of N_2 (80 Pa) : O_2 (20 Pa) : H_2O (2 Pa) and comparison with literatures.

[d] Volume mixing ratio (ppt).

at m/z 60. We detected various kinds of ionic clusters of NO^+ and H_2O^+, but we did not detect the NH_4^+ products observed by Eisele. This difference remains unexplained at this time. The as-yet-unidentified ionic species at m/z 60 in both studies is probably $NO^+(NO)$, which is present with considerable intensity in our plasma at a H_2O partial pressure of <1 Pa. We predict that some of the ionic products found in our study that have not been reported by field investigators may eventually be detected in more sensitive *in situ* observations, especially in polluted areas.

In conclusion [61], MW discharge in an 80% N_2/20% O_2 gas mixture in the presence of water was used to simulate the Earth's atmosphere. In addition to the familiar NO and N_2O species, significant amounts of gas-phase neutral NO_2, NO_3, HNO_2, and HNO_3 were produced and detected in the form of their Li^+ adducts. A number of ionic clusters with NO^+ and H_2O^+ produced by gas-phase ion–molecule reactions were also detected.

35.5.7
Miscellaneous

35.5.7.1 Pesticide Residue in Rice

The fate and residues of pesticides in a rice paddy ecosystem were monitored because this is thought to contribute more to pesticide pollution of the environment than any agro-ecosystem in the tropics. The usual practice of harvesting rice 30–40 days after the last application of pesticide may be considered safe from the standpoint of consumption. In chlorpyrifos-treated rice fields, residues in soil were detected up to 15 days after application from high-pesticide users' farms while remaining only up to 5 days in the low-pesticide users' fields [62]. GC/MS and LC/MS are used for the analysis of the pesticide residue in fruits, vegetable, and grain. And the measurement conditions are extremely different; depending on agricultural chemicals, the demand for a rapid measurement has risen. The pesticide residue in the rice can be measured without any pretreatment other than lyophilization in IAMS at all (Figure 35.15).

35.6
Prospective

Applications to GC/MS mode are promising analytically in view of the simple mass spectra obtained where pseudo-molecular ions dominate. The compatibility of TG with Li^+MS may provide excellent temporal correspondence [63, 64] between TG and mass spectral data and the ability to identify and resolve complex coevolving products; this method appears to hold great promise for the analysis of nonvolatile d-metal complex [65] and thermally labile medicinal compounds [66–68].

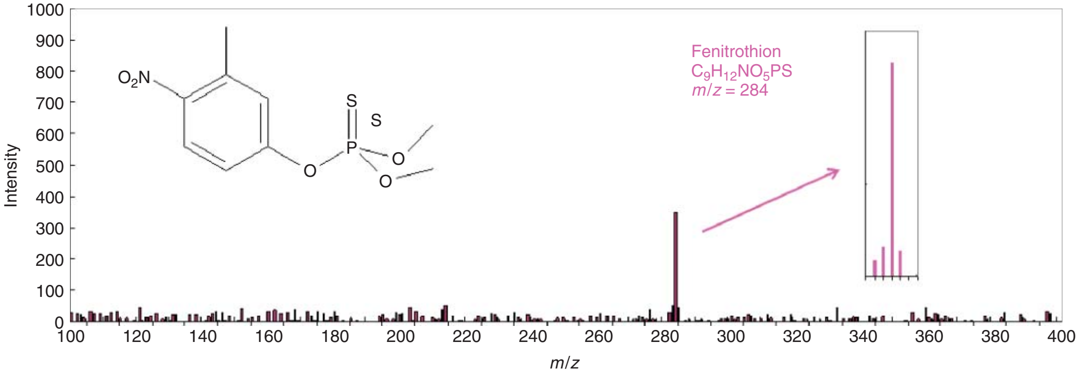

Figure 35.15 Mass spectrum of pesticide residue in rice by direct measurement.

Acknowledgments

The authors are very grateful to Canon ANELVA Technix people, especially to Dr. Y. Shiokawa, Dr. M. Nakamura, and Ms. H. Maruyama, for providing original results and for their assistance in collecting mass spectral data. This work was supported in part by a grant from the France–Japan Sasakawa Foundation (Code: 08-PT/6 & 12-PT/2).

Immunoassays

Günther Proll and Markus Ehni

36.1
Introduction

Immunoassays are biochemical tests based on the antibody/antigen interaction and can look back on a successful history of almost 50 years [1]. With this technology it is possible to measure the concentration of a compound in various matrices. Their commercial impact nowadays as a quantitative analytical technology is enormous. Thereby the area of application of immunoassays ranges from medical diagnostics to trace analytics in environmental and food samples. In the beginning, mainly radioimmunoassays (RIAs) and enzyme-linked immunosorbent assays (ELISAs) have been used in many variations [2]. These predominant test formats are commonly combined with the microplate format.

With the development of automated biosensors including flow injection analysis (FIA) [3–5] the drawback of complicated automation could be overcome. On the basis of this, new technologies have been developed for the automated handling of aqueous samples [6] and together with new test formats new fields of application were opened up. Within the past two decades, bioanalytics has become a well-established field of science. Since the introduction of biomolecules for quantitative analysis [7], the combination of FIA and biomolecular interactions could be established. For the combination of FIA with immunoassays, the term ‘‘flow injection immunoanalysis’’ (FIIA) was introduced by Fintschenko and Wilson [4]. Together with an ELISA-based test format, this technology was established for the automated, selective, and sensitive detection of small organic molecules in aqueous samples [8], especially in combination with fluorescence-based detection [9]. The main advantage of immunoassays compared to conventional analytical methods is the reduced complexity of sample pretreatment, especially the omission of the preconcentration step before the analysis. This leads to a significant saving of time and manpower. Furthermore, immunoassays allow simultaneous detection of chemical compounds of different chemical classes within a single measurement. This multianalyte approach is well established for environmental applications [10]. Current developments in microfluidics and microarray technology are the basis for multiplexed quantitative measurements in the area of environmental and food

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

analysis as well as in clinical diagnostics [11–14]. Apart from the mentioned advantages, immunoassays are also very specific and cost effective.

This chapter focuses on automated immunoassays performed with biosensors at the heterogeneous phase. Therefore, after an introduction to antibodies and their properties, aspects related to thermodynamics and the particularities of biomolecular interactions at the sensor surface are discussed. The validation section is based on recommendations given by relevant institutions and covers the topics calibration and determination of validation parameters such as limit of detection (LOD) and limit of quantification (LOQ). Research in the area of automated immunoassays for biosensors is a very active field. Besides, the improvement and creation of new transduction technologies, especially the new recognition elements introduced in the last section, are a very important driving force in the development of new increasingly powerful biosensors.

36.2
Theory

Antibodies are the analytical tools in immunoassays. Their unique properties to bind an antigen with high specificity and high affinity have been designed by nature to protect vertebrates against microorganisms or other pathogens [15]. To set up an immunoassay, it is of great importance to have a good knowledge of the biochemical behavior and the structure of these glycoproteins. The best-known class of immunoglobulins used in immunoassays are the IgG antibodies with a molecular weight of approximately 150 000 Da. An IgG molecule (Figure 36.1) consists of two identical light chains (L-chains) with approximately 220 amino acid residues and two identical heavy polypeptide chains (H-chains) with approximately 450–600 amino acid residues.

These four chains are linked by covalent disulfide bonds and noncovalent forces [17]. Each H-chain is covalently linked to a carbohydrate chain, which varies from

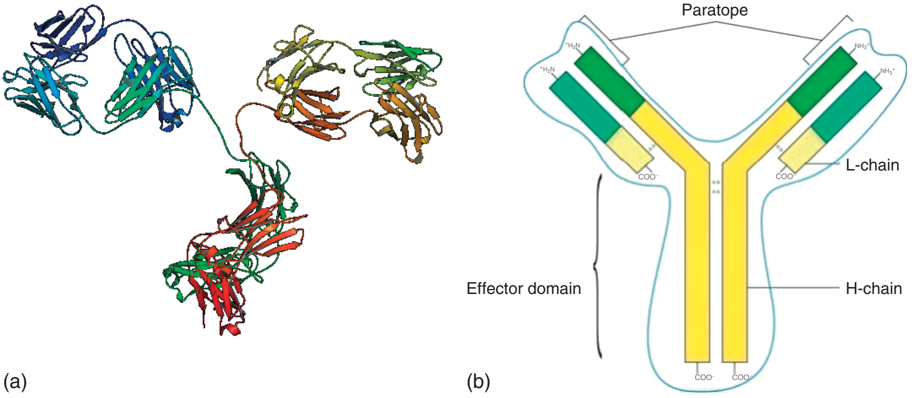

Figure 36.1 (a) Three-dimensional structure of an IgG antibody molecule based on X-ray data [16] and (b) schematic drawing of an IgG antibody molecule.

specie to specie. The typical Y-form of the molecule is the result of a bend in the middle of each H-chain. The site of an antibody molecule that binds to the antigen is called *paratope* and is complementary to the epitope of the antigen [18]. An IgG molecule has two paratopes and is therefore called *bivalent*, whereas an antigen can be monovalent or multivalent, offering multiple identical or different epitopes. Paratopes are formed by variable domains (V-region) at the N-terminal end of L- and H-chains. This variable region, composed of 110–130 amino acids, gives the antibody its specificity for binding an antigen.

Treating the antibody with a protease can cleave the V-region, producing the so-called Fab fragment, including the antigen-binding variable ends of an antibody. The use of Fab fragments can be interesting, especially in terms of a reduced molecular weight compared to a complete antibody. As will be discussed later in this chapter, a critical step during immunoassays is the diffusion-limited binding between antibodies and antigens, which can be accelerated by molecules offering a lower diffusion coefficient.

Antibodies are divided into five major classes, IgM, IgG, IgA, IgD, and IgE, based on their constant region (Fc domain) structure and immune function (Table 36.1). An overview of the different antibody classes and subclasses can be found in [16]. For most applications, for example, in molecular diagnostics or environmental analysis, antibodies from different IgG subclasses are used. For special applications such as the agglutination test during blood group typing, IgM antibodies offer interesting properties.

In nature and during the classical antibody production process [19, 20], the immune system of a vertebrate will produce many different IgG antibodies specifically for the same or for different epitopes of the antigen. These polyclonal antibodies are mixtures of antibodies with different paratopes. Using the so-called hybridoma technology [21], it is possible to produce identical antibody molecules, so-called monoclonal antibodies, all offering the same properties. Currently, there are hundreds and thousands of polyclonal and monoclonal antibodies commercially available. In addition, specialized companies offer custom antibody production. For example, in the case of monoclonal antibodies, many of these monoclonal antibodies are derived from mice cell lines and belong to the subclass IgG1. The information of the type and host is very important if an adaptor protein such as protein A or protein G will be used to bind antibodies oriented via their Fc region

Table 36.1 Antibody classes.

	IgM	**IgD**	**IgG**	**IgE**	**IgA**
H-chain	μ	δ	γ	ε	α
L-chain	κ or λ	κ or λ	κ or λ	κ or λ	κ or λ
Number of four-chain units	5	1	1	1	1

Molecular weight (kDa)	950	180	150	160	190

to a surface. Furthermore, the chemical stability of an antibody is related to the host specie. Especially for applications working under nonphysiological conditions, this has to be taken into account during antibody selection. Interestingly, extreme thermodynamic stability has been reported, for example, for camelid antibody fragments [22].

The specific noncovalent binding of an antibody to an antigen is based on different distance-dependent binding forces, namely, hydrogen bonds, electrostatic, dipole–dipole, and dispersion interactions. For a stable and specific binding according to the induced fit model, the dissociation energy has to be higher than the association energy. The type of predominant binding forces responsible for an individual interaction changes with the chemical nature of an antigen, for example, whether it is more hydrophobic or hydrophilic. Nevertheless, antibodies do not bind a specific epitope at a perfect specificity. In fact, antibodies can bind other epitopes at a higher or lower specificity if there is a structural similarity. This phenomenon is called *cross-reactivity* and will be discussed in detail later.

36.2.1
Thermodynamics

After mixing an antibody with an antigen in solution, the biomolecular interaction process starts and after a short time – depending on concentrations and diffusion properties – the equilibrium between free antigen, free antibody, and antigen–antibody complex is reached:

$$\mathrm{Ag} + \mathrm{Ab} \underset{k_\mathrm{d}}{\overset{k_\mathrm{a}}{\rightleftharpoons}} \mathrm{AgAb} \tag{36.1}$$

where k_a and k_d are the association and the dissociation rate constants, respectively. According to the law of mass action, the equilibrium constant, here identical with the term *affinity constant* (K), is defined by

$$K = \frac{k_\mathrm{a}}{k_\mathrm{d}} = \frac{c_\mathrm{AgAb}}{c_\mathrm{Ag} \cdot c_\mathrm{Ab}} = \frac{c_\mathrm{AgAb}}{(c_{0,\mathrm{Ag}} - c_\mathrm{AgAb}) \cdot (c_{0,\mathrm{Ab}} - c_\mathrm{AgAb})} \tag{36.2}$$

with

K	affinity constant
Ag	antigen
Ab	antibody
AgAb	antigen–antibody complex
c_AgAb	equilibrium concentration of the antigen–antibody complex
c_Ab	equilibrium concentration of the antibody
c_Ag	equilibrium concentration of the antigen
$c_{0,\mathrm{Ab}}$	initial concentration of the antibody
$c_{0,\mathrm{Ag}}$	initial concentration of the antigen

For most antibodies, K is between 10^5 and 10^{11} M^{-1} [16]. However, it has to be pointed out that the term *affinity* describes the interaction between one paratope and one epitope. If the interaction takes place between multivalent antibody molecules and multivalent antigen molecules, multiple different bindings occur and the equilibrium constant is called *avidity* [23] or *functional affinity* [24]. The same applies to polyclonal antibodies, where the average functional affinity is the sum of the affinities provided by each clone taking into account the individual concentrations.

If the interaction between an antibody and a small antigen takes place in solution, the paratopes can bind to the epitopes independently without any structural influence on each other. In the case of surface-bound antigens at a high loading, both paratopes of an antibody can bind to an epitope at the heterogeneous phase. For this interaction, the equilibrium constant is equivalent to the avidity as a sum of the individual affinities. This is because of a reduced dissociation rate constant k_d caused by the fact that for dissociation both paratopes have to release their bound epitope at the same time [23]. The kinetics and impact of the heterogeneous phase is discussed in detail in Section 36.2.3.

In case of multianalyte immunoassays or immunoassays based on cross-reactive antibodies, the situation becomes more complicated. Here, many antigens and/or antibodies are present at the same time. Therefore, the interactions between the antigens and antibodies can be described as competing reactions according to the law of mass action reaching equilibrium after some time. To develop a mathematical model for this situation, the following assumptions are made: (i) each single reaction is reversible and in equilibrium; (ii) single binding sites B compete independently from each other against univalent analytes A; and (iii) there are no other reactions taking place:

$$A_i + B_j \rightleftharpoons A_iB_j \tag{36.3}$$

$$i = 1, 2, \ \ldots, \ n \qquad j = 1, 2, \ \ldots, \ m$$

where n is the number of different analytes and m is the number of different binding sites. The composition at equilibrium is given by

$$K_{A_iB_j} = \frac{c_{A_iB_j}}{c_{\mathrm{fA}_i} \cdot c_{\mathrm{fB}_j}} \tag{36.4}$$

$$i = 1, 2, \ \ldots, \ n \qquad j = 1, 2, \ \ldots, \ m$$

$$c_{\mathrm{tA}_i} = c_{\mathrm{fA}_i} + \sum_{i=1}^{n} c_{A_iB_j} \tag{36.5}$$

$$c_{\mathrm{tB}_j} = c_{\mathrm{fB}_j} + \sum_{j=1}^{m} c_{A_iB_j} \tag{36.6}$$

with

$K_{A_iB_j}$	affinity constant for each single reaction
c_{fA_i}	free equilibrium concentration of analyte i
c_{fB_j}	free equilibrium concentration binding site j
c_{tA_i}	total concentration of analyte i
c_{tB_j}	total concentration of binding site j
$c_{A_iB_j}$	equilibrium concentration of the complex formed by analyte I and binding site j

Combining Eqs. (36.4–36.6) yields a system consisting of n equations:

$$c_{\mathrm{tA}_i} = c_{\mathrm{fA}_i} + \sum_{j=1}^{m} \frac{K_{A_iB_j} c_{\mathrm{tB}_j} c_{\mathrm{fA}_i}}{1 + \sum_{k=1}^{n} K_{A_k,B_j} c_{\mathrm{fA}_k}} \tag{36.7}$$

If this system of n nonlinear equations is numerically solved for the concentration of the free binding sites ($c_{f\mathrm{B}_j}$) at known c_{tA_i}, c_{tB_j}, and $K_{A_iB_j}$, then c_{fB_j} can be calculated as

$$c_{\mathrm{fB}_j} = \frac{c_{\mathrm{tB}_j}}{1 + \sum_{i=1}^{n} K_{A_iB_j} c_{\mathrm{fA}_i}} \tag{36.8}$$

36.2.2
Cross-Reactivity

The existence of cross-reactivity is the normal case; however, a highly specific antibody shows a very low cross-reactivity, whereas especially for polyclonal antibodies or for antibodies directed against an antigen with potentially many different chemically similar derivatives cross-reactivity can be very high. Thus, cross-reactivity describes the ability of a specific paratope of an antibody to bind to another, structurally similar epitope. The extent to which that similar antigen is bound by that antibody is called *relative cross-reactivity* and its value is given in percentage (%CR). %CR is usually is determined by a titration experiment of the antibody with its specific analyte and with the potentially cross-reactive analytes. The measured values are normalized and plotted against the logarithm of the antigen concentration, and the test midpoint of an approximated logistic function is calculated (Section 36.4). %CR can now be calculated according to [25, 26]:

$$\%\mathrm{CR} = \frac{c_{\mathrm{saTMP}}}{c_{\mathrm{paTMP}}} \times 100 \tag{36.9}$$

with

c_{saTMP}	concentration of specific antigen at test midpoint
c_{paTMP}	concentration of the potentially cross-reactive antigen at test midpoint

On the one hand, cross-reactivity for many applications has to be carefully checked and minimized to avoid wrong results such as incorrect concentrations. On the other hand, there is a chance to use cross-reactivity as a tool, for example, to establish quantitative assays for the detection of similar compounds resulting in a sum concentration [27–30]. Another possibility can be the combination of cross-reactivity-based assay designs and data evaluation procedures derived from chemometrics to quantitatively distinguish unknown mixtures of similar analytes [31].

36.2.3
Biomolecular Interaction

Automated immunoassays in many cases include a heterogeneous phase, which at the same time can also be the transduction element, for example, of a biosensor setup. Having a look at the possible biomolecular interactions taking place in parallel, the situation compared to homogeneous assay formats becomes more complex. Figure 36.2 shows the interaction processes of an antibody with an antigen in solution and an antigen bound at the heterogeneous phase. In solution, according to the law of mass action, equilibrium is reached between free antigen, free antibody, and free antigen–antibody complex. Close to the surface, a diffusion layer is formed where no flow takes place independently from the situation of the bulk solution even in a flow cell. If the flow speed increases or the dimension of the flow cell is downsized, the thickness of this diffusion layer is reduced [32].

On the basis of this model, the interaction of an antibody with a surface-bound antigen can be divided into two steps because the antibodies have to come to the surface by diffusion before the binding event. Thereby, diffusion within a laminar

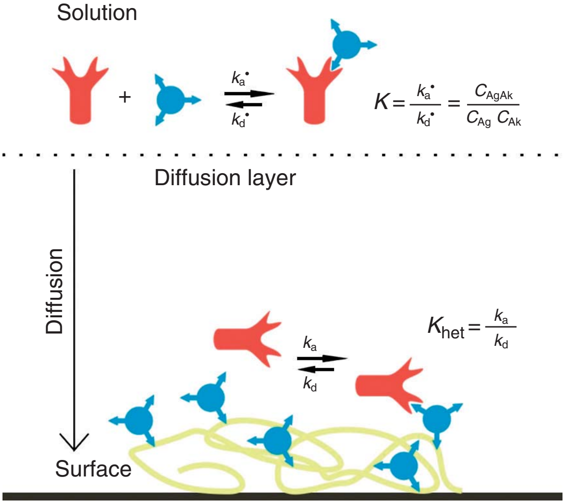

Figure 36.2 Biomolecular interactions at the heterogeneous phase.

flow can be described according to Fick's first law, which relates the diffusion flux to the concentration field:

$$J = -D \cdot \frac{dc}{dx} \tag{36.10}$$

with

J	diffusion flux
D	diffusion coefficient
c	concentration
x	length

If there is a steady state for the concentration gradient, as is the case for the flow through assay designs including a FIA, the diffusion speed depends only on the diffusion coefficient. Because D depends on the molecular weight [33], the diffusion speed increases with smaller molecules. For a typical IgG, the diffusion coefficient is approximately 4.1×10^{-7} cm^2s^{-1}. In case the diffusion of the antibody molecules to the surface is the rate-determining step, the reaction is called *mass transport controlled* or *diffusion controlled*. If the interaction between antibody and antigen at the surface determines the rate, the reaction is kinetically controlled [34].

With respect to the chosen test format (Section 36.3), it is important to consider the complex relationship between the interaction at the heterogeneous phase, diffusion and flow conditions with the performance of an immunoassay especially in terms of achievable LOD and needed incubation time.

36.3
Test Formats and Assay Design

During the past four decades, many different types of immunoassays have been developed. Each assay type or test format together with the applied detection principle provides individual properties suitable for various analytical applications. In this chapter, the focus is on six basic immunoassay principles developed for automated biosensor applications at the heterogeneous phase carried out under flow through conditions: direct test format, competitive test format, sandwich assay, replacement assay, displacement assay, and binding inhibition assay. The discussion of these different test formats covers aspects from fluorescence-based and label-free transduction principles as well as the necessity to adapt the chosen test format according to the analytical problem and the affinity of the antibody.

Classification of immunoassays at the heterogeneous phase starts with the immobilized component(s) on a surface (Figure 36.3). The first category is based on immobilized antibodies. Incubation of this sensor surface with antigen followed by label-free detection via surface plasmon resonance (SPR) [35] or reflectometric interference spectroscopy (RIfS) [36] leads to the direct test format which is noncompetitive (Figure 36.3, I.I). Because of its simplicity and easy automation it can be very powerful, for example, in diagnostics. However, there are many

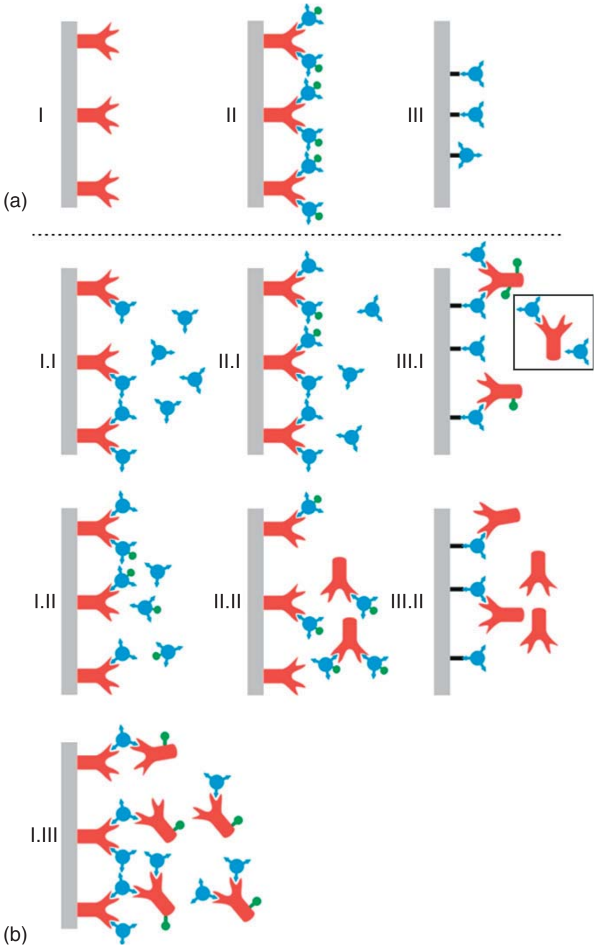

Figure 36.3 (a) Heterogeneous phase modified with antibody molecules (I), antibody molecules loaded with labeled antigen derivatives (II), or antigen derivatives (III). (b) Test formats derived from the different modified surfaces; direct test format (I.I), competitive test format (I.II), sandwich assay (I.III), replacement assay (II.I), displacement assay (II.II), binding inhibition test (III.I), and direct test format (III.II).

critical aspects to be considered: The antibody should provide a high affinity to the analyte (antigen), and during the immobilization process it is necessary to bind many antibodies (high surface loading) in a way that the paratopes are intact and accessible to the antigen. For an oriented immobilization procedure, it can be helpful to use adaptor proteins such as protein A or protein G [37] or a special chemistry protocol as published in [38]. A limitation for all label-free transduction technologies is the rather high LOD due to the mass sensitivity, which correlates with the molecular weight of the analyte [39]. Furthermore, nonspecific binding of matrix compounds to the sensor surface may affect the measurement and is the main source for artifacts. However, the direct test format plays an important role in current research, for example, on new assays for molecular diagnostics.

If a labeled analyte analog is added to the sample before the incubation step with an antibody-modified surface, the test format is called *competitive* (Figure 36.3, I.II) and usually combined with a fluorescence-based transduction method. During assay development for this type of immunoassay, it is necessary to select an antibody that offers good affinity for both analyte and labeled analyte analog, but still allows for competition. Therefore, the dissociation rate constant of the antibody should not be too high. For the sandwich assay (Figure 36.3, I.III), either fluorescence-based transduction, for example, scanning or total internal reflection fluorescence (TIRF) [40] or label-free transduction is possible. Here, either the sample is incubated with the sensor surface in a first step followed by a secondary antibody that can be modified with a fluorescence dye or the secondary antibody is mixed with the sample for preincubation. In case the antigen offers more identical epitopes, this secondary antibody can be the same as the surface-bound antibody, assuming that for this scenario the incubation of the surface with the analyte and the secondary antibody has to be carried out in two steps. In general, it is advantageous to select antibodies with very high affinities because it is a noncompetitive test format. The combination with fluorescence-based detection allows for a very low LOD. Especially for the sandwich assay, there is the additional advantage of very high selectivity because of the involved secondary antibody. Furthermore, this test format in the labeled mode is preferable when resistance against matrix compounds is important. Therefore, many of the currently used immunoassays for molecular diagnostics are based on the sandwich assay principles. The only relevant limitation of this test format exists for small molecules, which do not provide two epitopes to be bound by two antibody molecules simultaneously, for example, because of sterical hindrance.

Starting from a sensor surface modified with antibodies carrying labeled analyte analogs, two basic test formats can be created. The first one is called *replacement assay*, where the analyte in the sample replaces the bound labeled analogs during the incubation step (Figure 36.3, II.I). Replacement assays can handle large and small analytes and should be carried out with an antibody, providing a reasonable dissociation rate constant for the analyte analog. During the incubation step of a displacement assay, the labeled analyte is displaced by an antibody in the sample. This second type of immunoassays, starting from the modified surface shown in Figure 36.3, II.II, is also combined with fluorescence-based transduction methods.

A very powerful test format, especially for small analytes, for example, in environmental applications, is the binding inhibition test (Figure 36.3, III.I). During a preincubation step of the antibody with the sample, according to the law of mass action, the paratope can bind to their epitopes. Antibody molecules with at least one free binding site can bind to an immobilized antigen derivative at the sensor surface. Because the incubation step with the modified surface is mass transport controlled – this requires a very high surface loading with an antigen derivative to prevent a kinetically controlled biomolecular interaction – the binding inhibition test is noncompetitive. If high affinity antibodies are used together with a TIRF setup for the readout, extremely low limits of detection can be achieved [41].

The use of Fab fragments instead of complete antibody molecules is advantageous because of the reduced diffusion constant resulting in a higher mass transport to the surface. This test format can be easily used for multi-analyte immunoassays, when the surface modification is based on a spatially resolved chemistry protocol [42]. In addition, for surfaces modified with antigens coming from chemical classes such as steroid hormones, pesticides, or other small and robust organic molecules, there are regeneration protocols available to regenerate the sensor surface several hundred times [43].

The last test format discussed here is the second way to perform a direct immunoassay based on an antigen-modified surface (Figure 36.3, III.II). Compared to the direct test format discussed according to Figure 36.3, I.I, the only difference is that the analyte is now a specific antibody for the immobilized antigen. Because of the label-free detection mode of this test format, the same critical conditions have to be addressed but with the addition that antibodies offer a high molecular weight and therefore the weakness in terms of LOD is usually not a limitation. Furthermore, the regeneration of a sensor surface with immobilized antigens in many cases is much more robust because of the usually higher chemical stability of these molecules compared to antibodies.

Table 36.2 summarizes some important advantages and disadvantages of the most frequently used immunoassay test formats discussed. Together with the background given in Section 36.2, the choice of a proper test format for a given analytical problem must also take into account requirements coming from authorities, for example, the need for single test disposables or parallelization and miniaturization aspects related to the complete biosensor system.

Finally, the key to the functionality of all the discussed test formats is the introduction of a surface modification on the sensor surface. In addition, the requirements of this functionalization with regard to the different fluorescence-based or label-free transduction methods are different. Therefore, very special

Table 36.2 Comparison of advantages and disadvantages of important test formats.

	LOD	Mixing step	Complexity of automation	Complexity of disposables	Ability for regeneration
Sandwich assay according to Figure 36.3, I.III	+++	y	High	High	Low
Binding inhibition test according to Figure 36.3, III.I	+++	y	High	High	High

Direct test format according to Figure 36.3, III.II	+	n	Low	Low	High

+++, extremely low LOD achievable; ++, very low LOD achievable; +, low LOD achievable; −, not suitable for low LOD.

and smart surface properties are required in terms of selectivity, sensitivity, and stability, which must be provided by the introduced surface chemistry. An overview on biomaterials and processes already in use as well as an outlook for this important field is given in [44]. A review on immunosensor principles is given in [45].

36.4
Evaluation of Immunoassays

The characteristics of immunoassays are different from those of traditional analytical technologies, for example, chromatography. In this way, immunoassays show an indirect response together with a direct or inverse concentration–response relationship. Furthermore, the precision of immunoassays is usually lower owing to the higher interassay imprecision. The most important characteristic discussed here is the nonlinear behavior of the calibration curve owing to the nature of the underlying antibody/antigen interaction with respect to the statistical methods for determining validation parameters.

36.4.1
Calibration Curve

A special challenge is the fact that the classical calibration strategies and determinations of characteristic quantities for the validation described in the ISO (International Organization for Standardization) standards are not fully applicable facing the nonlinear behavior of the calibration curves [46]. If the logical principle of the best approximation of a mathematical function to the measurement results is used for the calibration, the linear model will have to be rejected for all immunoassays as a consequence. A typical calibration curve for an immunoassay – in this case, the test format was a binding inhibition test with typical inverse concentration–response relationship – is shown in Figure 36.4. With the logarithmic scaled abscissa, the data points form a sigmoid curve. Currently, in many publications dealing with calibration of immunoassays the four-parameter logistic function (Eq. (36.11) [47, 26]) is approximated to replica measurements of different concentration steps.

$$y = \frac{A_1 - A_2}{1 + \left(\frac{x}{x_0}\right)^p} + A_2 \tag{36.11}$$

with

A_1	upper asymptote
A_2	lower asymptote
X	analyte concentration
x_0	test midpoint (analyte concentration at inflection point)
p	slope at test midpoint after logarithmic transformation

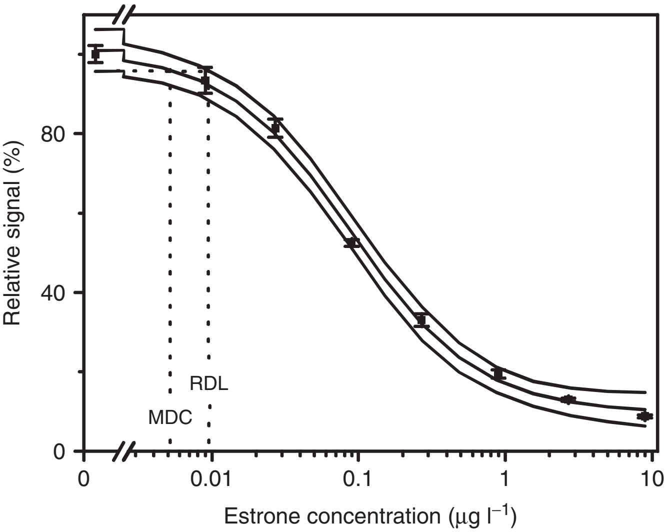

Figure 36.4 A typical calibration curve of an immunoassay performed with the binding inhibition assay as the test format. In this particular case, the sensor surface was covalently modified with an estrone derivative. A labeled polyclonal was used together with TIRF as transduction principle. The calibration curve was obtained by approximating the four-parameter logistic function to replica measurements at eight concentration steps including blanks. On the basis of a 95% confidence belt, the corresponding minimum detectable concentration (MDC) and reliable detection limit (RDL) are marked.

For the calibration shown in Figure 36.4, the parameter A_1 corresponds with the ''zero'' concentration response, and A_2 with the ''infinite'' concentration response. The approximated four-parameter logistic model assumes central symmetry of the curve. If this is not the case, a model taking into account variances of the ideal model, for example, effects caused by a changed binding statistic for bivalent antibodies, or effects of the fluidics, can improve approximation of the concentration–response relationship. Such a model shows also sigmoidal behavior but without central symmetry and therefore a more variable approximation is expressed by the five-parameter-based logistic model [48]:

$$y = \frac{A_1 - A_2}{\left[1 + \left(\frac{x}{x_0}\right)^p\right]^a} + A_2 \tag{36.12}$$

with a the asymmetry factor.

In the case of no asymmetry (asymmetry factor equals 1), the five-parameter-based logistic model changes into the four-parameter-based logistic model. A major disadvantage of the five-parameter-based logistic model is the dependence of the test midpoint from other parameters. Therefore, the test midpoint as an important quantity in assay development and especially the variation of the test midpoint cannot be calculated easily. A reparametrization can remedy this deficiency [49].

$$y = \frac{A_1 - A_2}{\left[1 + \left(2^{\frac{1}{a}} - 1\right)\left(\frac{x}{x_0}\right)^p\right]^a} + A_2 \tag{36.13}$$

Both calibration functions are recommended by the Federal Drug Administration (FDA) within the guidelines for industrial use [50]. If one wishes to benefit from the well-described regulations for linear calibration functions, a mathematical transformation of the sigmoidal curve into a linear response is possible, with limitations in the working range, by using a logit [51].

36.4.2
Validation

The recommendations given by the ISO standards for the determination of the characteristic quantities and the International Union of Pure and Applied Chemistry (IUPAC) for determining the LOD and the LOQ are dedicated to linear calibration responses. However, these rules are usually also applied to the nonlinear case of immunoassays and are partially recommended by the FDA [47]. In compliance with ''The Orange Book'' [52] as well as the ISO 32645, the LOD can be calculated as three times respectively 3.29 times the standard deviation (SD) of the blanks ($\mathrm{SD_b}$) and the LOQ is calculated as 10 times the $\mathrm{SD_b}$. However, one should consider that this is only a preliminary estimate for linear calibration curves, but also applicable to nonlinear curves. These estimations can be improved by taking into account heteroscedasticity, changing the probability of the type I and type II error, or using correct Student's *t*-test depending on the number of measurements [52]. In [53], a possibility of adapting the IUPAC definitions to sigmoidal response curves is given. As an alternative, the use of a 95% confidence belt and the associated minimum detectable concentration (MDC) and reliable detection limit (RDL), which can easily be calculated for the sigmoidal calibration curves [54], is possible. An example is given in Figure 36.4.

Usually, calibrations carried out with polyclonal antibodies providing a moderate avidity show a larger dynamic range (working range) and a smaller slope at the test midpoint compared to high affinity monoclonal antibodies. If needed, the dynamic range and the sensitivity of an immunoassay based on high-affinity antibodies can be tuned toward broader dynamic range and lower sensitivity by lowering the amount of used antibody, but this has to be carefully balanced with the expected analyte concentration range.

For immunoassays, it is important to perform the calibration with the matrix of the later application. A test to verify the accuracy of the obtained calibration curve is to perform measurements using real samples of known analyte concentrations and to determine the recovery rates according to:

$$\mathrm{RR} = \frac{\overline{x}}{x_t} \times 100 \tag{36.14}$$

with

RR	recovery rate
$\overline{x}$	mean value of measured analyte concentration
x_t	true analyte concentration

In addition, further principal analytic quantities, such as selectivity, accuracy, precision, and stability, are useful for the characterization and validation of a developed immunoassay method. In the guideline for industrial use [50], suggestions are made for immunoassays concerning the determination of these quantities. Furthermore, some annotations are given for when and which parameters should be determined.

36.4.3
Multi-Analyte Immunoassay for Water Analysis

For the development of a fully automated biosensor for water analysis, several important requirements have to be addressed. First of all, the concentrations of the small organic compounds that have to be quantified in a multianalyte approach are very low. For example, the EU directive for drinking water sets the limit for a single pesticide to 0.1 $\mu g\, l^{-1}$. Therefore, the LOD and LOQ of the immunoassays have to be below this threshold. Furthermore, a real-world application scenario of this biosensor would be the monitoring of surface water bodies implemented as a quasicontinuous measurement system. This can only be realized by a regenerative sensor element as part of an FIA-based analytical system.

The test format of choice is the binding inhibition test combined with fluorescence-based detection. In the following example, TIRF was used as the underlying transduction principle. In a first step, the biosensor system automated water analyser computer supported system (AWACSS) [43] was calibrated in a multianalyte approach for the analytes estrone, isoproturone, and atrazine. To improve the approximation of the logistic function the parameter A_1 was fixed to 100% as recommended by the FDA guidelines. The obtained validation parameters are summarized in Table 36.3.

Table 36.3 Validation parameters for the multianalyte calibration of the TIRF biosensor.

Validation parameter	Estrone	Isoproturone	Atrazine	Unit
A_1	100	100	100	%
A_2	20.55 ± 2.49	22.08 ± 5.65	20.76 ± 2.04	%
x_0	0.10 ± 0.025	0.70 ± 0.28	0.68 ± 0.09	$\mu g\, l^{-1}$
p	1.15 ± 0.29	0.74 ± 0.21	0.66 ± 0.04	—
LOD	0.003	0.007	0.003	$\mu g\, l^{-1}$
LOQ	0.007	0.040	0.018	$\mu g\, l^{-1}$

During a field test, the calibrated system was used to determine the concentrations of these compounds frequently fully automated and unattended [10]. Reference measurements performed with high-performance liquid chromatography with diode-array detection (HPLC-DAD) have been used to calculate the recovery rates. For the analyte isoproturone, the recovery rate was 80% and for atrazine 97%. Estrone was for both systems below the LOQ; therefore, quantification was not possible. These results demonstrate the reliability of this fully automated biosensor system capable of monitoring surface water quality under realistic operation conditions.

36.4.4
Immunoassay for Medical Diagnostics

The requirements for the development of a fully automated biosensor for medical diagnostics are nearly the same as for water analyses. The concentration ranges to be measured are also very low. The situation is even complicated by the fact that medical samples, such as blood plasma, have a complex composition. That places a lot of demands on the requirements of the developed assay, which can be proved by a detailed validation.

In [55], the inflammation marker CRP (C-reactive protein) was quantified. The test format was the sandwich assay measured in a TIRF-based biosensor system. For the calibration, the four-parameter as well as the five-parameter logistic functions were approximated (Figure 36.5).

It is obvious that the curve characteristics are nearly the same for both calibration curves. Performing a residual analysis leads to the conclusion that the five-parameter logistic function is the better fit in the specified concentration region of

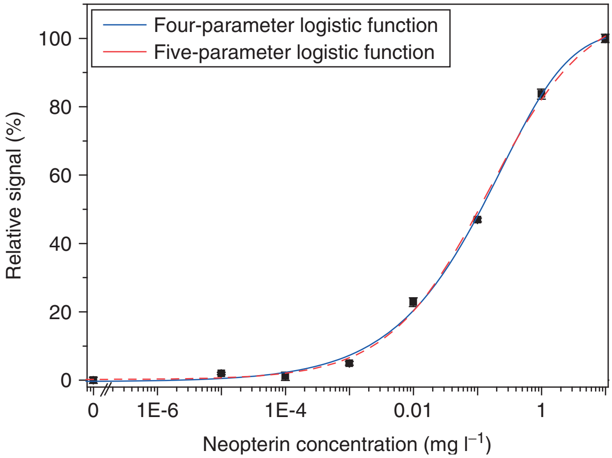

Figure 36.5 Approximation of the four-parameter and five-parameter logistic function. Analyte was C-reactive protein. The capture biomolecular recognition element was a special modified protein and the detection biomolecular recognition element was a fluorescence-labeled antibody.

interest. The calculations of the LOD and LOQ as well as the MDC and RDL are summarized in Table 36.4.

Assuming that the meaningfulness of the LOD and the MDC is quite similar, a discrepancy of several hundred percent can be observed. This leads to the conclusion that only characteristic quantities, calculated exactly the same way, can be compared with each other.

For the validation, parameters such as accuracy, precision, and the recovery rate were determined. Following the FDA validation procedure, multiple measurements in different concentration ranges were performed. At which the deviation should not exceed 15% respectively 20% in the lower concentration range (Table 36.5).

36.5
Trends

New production technologies for antibodies have drastically improved the properties of these molecules regarding affinity and stability. Especially, chimeric antibodies produced by the phage display technology can offer tailored antibodies, for immunoassays [56]. As an alternative to traditional monoclonal or polyclonal antibodies, new biological recognition elements (BREs) offer interesting properties. These BREs are commonly based on proteinaceous affibodies, aptamers, or

Table 36.4 Summary of the characteristic quantities of the CRP measurement.

Validation parameter	Neopterin	Unit
LOD	0.091	$\mu g\, l^{-1}$
LOQ	1.30	$\mu g\, l^{-1}$
MDC	0.417	$\mu g\, l^{-1}$
RDL	2.04	$\mu g\, l^{-1}$

Table 36.5 Analytical quantities for the CRP measurements.

Validation parameter	Real concentration ($\mu g\, l^{-1}$)	Deviation from real value (%)
Accuracy	0.2	12.00
	20	14.80
	2000	10.31
Precision	0.2	15.67
	20	6.76
	2000	3.56
Recovery rate	0.5	8.29
	50	9.18
	5000	8.86

All deviations are within the limits; consequently, the assay is validated within the limits set.

molecular imprinted polymers (MIPs). Besides the improvement of availability, the driving force behind these interesting research activities is the improvement of properties such as chemical stability and affinity.

Affibodies are affinity proteins and have been described for the first time in 1995 as a combinatorial protein engineering approach based on structures derived from protein A [57]. The described engineering approach is used to create a defined new specificity combined with high affinities. Affibodies have since been used for various applications such as diagnostics or biotechnology [58, 59]. Affibodies can be selected from libraries and offer, besides their robustness, usually a smaller molecular weight than that of antibodies, which is advantageous for test formats depending on the diffusion constant of the recognition structure. The smallest class of BREs discussed here are aptamers. These types of BREs include DNA and RNA oligonucleotides with high affinities for their target molecule [60]. The production of aptamers follows a systematic evolution of ligands by an exponential enrichment (SELEX) procedure [61, 62]. The temperature stability of aptamers and their robustness against chemicals and conditions used during regeneration procedures applied with affinity sensors makes these BREs ideal candidates in the area of diagnostics [63] and biosensors [64, 65].

MIPs follow a supramolecular approach, making synthetic recognition sites capable of specifically detecting small molecules in complex environments [66] or even whole cells [67]. The most significant advantages of MIPs are mechanical and chemical stability combined with high storage endurance. Usually, these polymers are used as surface coatings [68] for bioanalytical applications [69].

Besides these new developments of artificial recognition elements for specific targets, there is a trend to use receptors for a new type of analytical assays that are no longer classical quantification assays but effect-based assays. For example, the estrogen receptor in the human body recognizes a large variety of ligands that have estrogen, such as activity. For the estrogen receptor, it could be shown that not only natural estrogens can be detected but also environmental pollutants such as bisphenol A. On the basis of this example, effect-based detection of potential endocrines has been reported [70]. The main advantage of this effect-based analytic is the assessment of known and unknown active compounds. The challenge will be the stabilization of natural receptors and the statistical evaluation of these new assays.

Section XI
Applications 4: Process Control

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

Introduction

Process control is the application of analytical chemistry to a chemical, biological or physical process combined with the control of the process on the basis of knowledge and process understanding. Process control uses process analytical measurement technologies in combination with control technologies. There is a long tradition in the control of many types of physical and chemical transformations and still today fairly simple physical parameters such as temperature and pressure in combination with a clear understanding of the process are used for typical control tasks in many industries.

The definition and understanding of the terms *process control*, *process analytics*, and *process analytical technology* varies from industry to industry and is changing with development of technologies and software. Therefore, the detailed definitions are given in the context of the chapters related to industries in subsequent text. The general drivers for process control are always quality and costs, with variations in the major focus. Besides direct savings, the benefits of process control are typically a more consistent production and savings in raw material use, in less waste, and less energy consumption. High contributions typically arise from reduced cycle times. Examples from industry are unfortunately not often published but sometimes presented in oral presentations. In a few examples presented or published, it was shown that process analytical equipment has increased the product output of available equipment up to a factor of 2 and that the typical pay-off time of a process analytical instrument implementation is below 1 year [1, 2].

In the current sophisticated production systems from basic chemistry, fine chemicals, food production to pharmaceuticals, or many specialty products such as, for example, liquid crystals, even highly sophisticated analytical measurement tools are used in the control cycle. The type of process control strongly depends on the individual production process. In many basic chemical manufacturing systems as in the crude oil distillation physical parameter measurements such as temperature and pressure may be used as process control tools. In the case of these continuous/semicontinuous processes, the production equipment stays unmodified and only the variations in the raw materials and changes in the environment (such as ambient temperature and humidity) or changes in process components (as in the aging of a catalyst) lead to variations in the process. In these continuous processes also, the changes are typically continuous (drifts). In many other production processes, as, for example, in food manufacturing (beer

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

brewing as a well-known example) a ‘‘pseudocontinuous’’ batch production process is applied. This means that a batch is produced in the production equipment and after finalizing the batch and cleaning the equipment the same equipment is used for the manufacturing of the next batch of the same product. In this case, in principle, the situation is the same as found in real continuous processes. The production process parameters are mainly influenced by the raw materials and environmental parameters. The difference is that the influences typically change discontinuously from batch to batch; for example, the changes in raw material from batch to batch. This also is often true for aging of equipment that typically fails suddenly, whereas in real continuous processes parameters drift slightly. In both cases, the implementation of process analytical equipment and control loops are part of the engineering of the equipment. This implementation is therefore discussed in engineering textbooks, taught in courses for engineers, and the basic work in this field is a well-understood part of engineering.

Moving forward to fine chemicals, pharmaceuticals, and specialty products, batch production processes typically dominate the scene. The difference here is that the basic installation is designed by engineers. This installation includes process analytical measurements, for example, temperature, pressure, flow meters, weight measurements, and so on; but for nearly each product, the equipment configuration is modified. For example, in the pharmaceutical industry, for the intermediate manufacturing of a drug substance, two stirred tank reactors are combined in a parallel configuration, whereas for the next chemical conversion step three stirred tanks may be combined in a top-down configuration. Additional equipment such as those for heating and cooling is attached and detached from process step to process step. This means that some parts of the equipment are changed from batch to batch and the combination may be new each time. The number of variations in the process increases and even the process analytics equipment used for one product is changed, moving on to the next production step; therefore, it is often only installed for one or a few batch(es) and is then replaced for the next step of the chemical conversion. Besides the variations from raw materials and the environmental parameters, as mentioned, here additional variations of the equipment may therefore influence the production process.

Besides this, typical calibration procedures are also different for continuous or batch processes. Typically, process control measurements are quantitative measurements. Often, in continuous processes, complex calibrations using, for example, chemometric models are applied to give a quantitative relationship between process information and the desired control unit of the process. Establishing these calibrations is expensive, but in such a process a calibration model can be used for a long time/a high number of batches (in pseudocontinuous processes). In real batch processes, for example, five batches of a drug substance intermediate may be produced using a chemical conversion and after this may be for 1 year or even longer this intermediate is not produced. After such a long time, a number of changes of typical wearing of parts has happened. For example, a seal in the stirrer has been replaced and therefore the stirrer speed is slightly different. Because a chemometric model includes all variables in a process, such slight changes would lead to the need for a recalibration. Therefore, in such processes, establishing chemometric models often would not pay off. This leads to the need for simple calibration models (e.g., linear models) that can be recalibrated with low to medium costs. These limitations sometimes restrict the number of analytical methods to be applied to such analytical tasks.

The more complex the production process the more sophisticated process analytics and control is needed. The control is applied to hold or to bring the product quality into a predefined specification or range, where the control loops may be both feed forward or feedback control. Typically, the spectroscopic tools in process control belong to the sophisticated tools and are therefore applied to the sophisticated process analytical challenges.

The typical control loops may be off-line in an analytical laboratory or at-line, which means that the sample is analyzed off-line but close to the process, for example, in the plant by plant personnel. Typically, these analyses include manual operations, and off-line/at-line analysis is performed if the frequency for adjusting the process needs only few measurements with time intervals of hours or even days. The process often is then adjusted manually. In control situations, where the analysis is needed in minute-to-hour frequency, on-line or in-line sampling technique is applied. On-line sampling means that a sample is taken from the process by an automated system and is analyzed without manual operation, whereas in-line means that the analysis is performed directly in the process without interfering with the process. In both cases, a direct coupling to the process control system is possible. The faster the conversion performed, the faster the process analytical technology is needed. Acquiring classical measurement data such as temperature and pressure is very fast. In the cases where detailed/sophisticated information on molecular basis is needed, chromatographic and spectroscopic information can fulfill this need. Typically, spectroscopic process analytical methods are much faster. This is an important reason why a high degree of spectroscopic technologies are applied in process analytics and control. Especially, if the information is needed within seconds, only an in-line solution using a spectroscopic technique is possible (Figure 1).

In addition, the choice of the applied approach in process control is strongly dependent on the sample to be analyzed. The samples ''in process'' may be solid (e.g., wood, steel, polymers, salts, and pharmaceutical formulations), they may be liquids (e.g., oil, water, and solutions in organic solvents for chemical reactions), or gases (e.g., in combustion plants, in chemical gas phase reactions). The temperature and pressure conditions vary from ambient to, for example, liquid aluminum and the pressure may vary from high vacuum (in semiconductor industry) to high-pressure chemical reactions. For the choice between on-line, in-line, and off-line/at-line process control, access to samples without counterfeiting the sample may be an important issue. Sometimes the concentration of the components of interest limits the use to some special techniques or coupling options. The examples given in the following chapters show an overview of typical sampling and analysis methods.

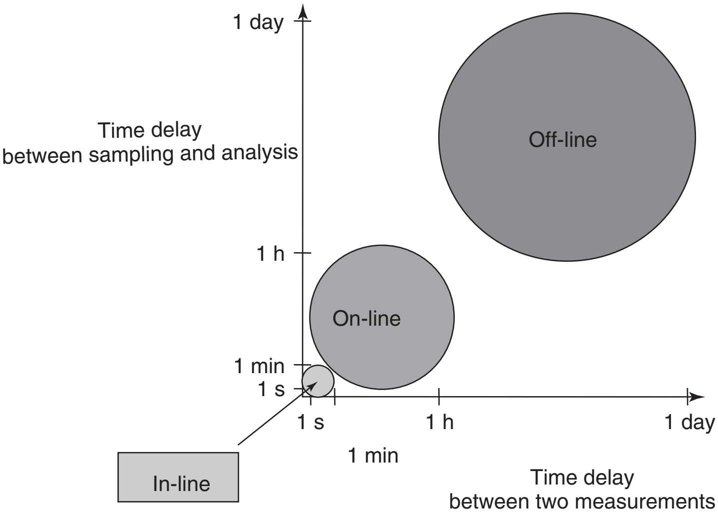

Figure 1 The correlation between off-line (including at-line), on-line, and in-line on the basis of timescales for sampling and analysis versus time delay between two measurements.

Process control is always a tool to support some kind of production process. Therefore, some general requirements for process control can be summarized. The current requirements for process control are as follows:

- Installation of process control equipment should be easy (plug and play).
- Equipment should be service-free (best case).
- Maintenance costs should be low.
- The whole system including the measurement results should be robust.
- Up-to-date equipment should
  - have wired or wireless control capability;
  - contain self-diagnosis of operation;
  - be capable of diagnosis, maintenance, and calibration by wire.
- Costs of ex-capability should be low.

From the very beginning, spectroscopic techniques have been applied to process control. Infrared spectroscopy, for example, was one of the techniques applied in this field for more than 100 years and is still one of the most important ones. In addition, a wide range of spectroscopic techniques are applied in process control currently. Besides spectroscopy, all other analytical techniques are also used in process control. Most of them are mentioned in the examples within the chapter. Although there are also other techniques, spectroscopy dominates the field. As a chromatographic-technique-only process, gas chromatography (GC) plays an important role in process control. A number of sensors such as pH and some selective electrodes are also widely used here. Flow injection analysis is used to couple various analytical techniques to the process; also spectroscopic, these kinds of couplings are only applied if a direct solution to the control problem is not available.

Although market researchers give various figures for market shares of different technologies for process analytical instrumentation in process control, the general figures show that more than 40% of the market are spectroscopic instrumentation, about 30% is dedicated to electrochemistry, and only about 10% of the market is located with chromatographic technologies [3]. The major advantage of spectroscopy for process control is the short analysis time and that most of the techniques can be applied on-line or in-line, which, in addition, allows reduction of the time between measuring a sample and the possibility of adjusting the process.

This section covers an overview of current applications and future trends including the general trends caused by the US Food and Drug Administration's (FDA's) process analytical technology (PAT)-initiative and changes caused by the ongoing globalization in industry. The first contribution of the section takes a look at the chemical industry. Here, process control is typically applied to control a process at minimum costs with a constant quality of the product. A general summary of the benefits of process analytical tools for this field of applications is given in Figure 2. Here, very often the benefits already reach a breakeven point at a few measurements per day, sometimes already at one measurement per day. A detailed discussion about the cost/benefit aspects of process control is included in this chapter.

In the second part of the section, the use of process analytical instruments in the pharmaceutical industry is described. In this industry, the quality of the product, documentation of the quality, and regulatory aspects are the key issues.

As already mentioned, optical spectroscopy techniques are used in many applications of process analytics in the control of chemical or physical techniques.

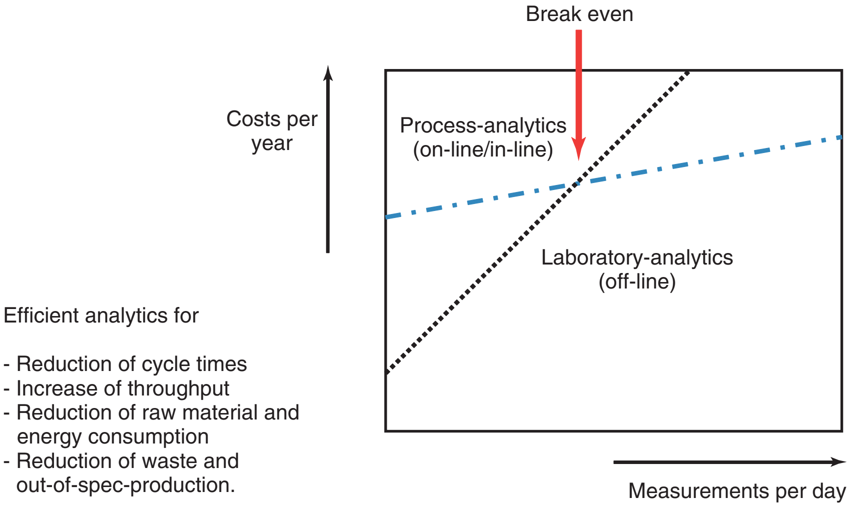

Figure 2 Summary of the benefits of process analytical measurements in production processes.

Therefore, the third contribution takes a look at some special aspects of optical spectroscopy in process environments independent of industry.

A quite young but fast developing field in process control is chemical imaging. Therefore, a contribution is dedicated to the field of chemical imaging in quality and process control.

Finally, one contribution takes a look at a wide number of different developing and special techniques and applications in process control and gives an overview of future trends.

One major issue for process control that is different from many other fields of spectroscopy (such as structure elucidation) is that the signal needs to be proportional to the information needed, but not necessarily is the chemical or physical correlation between the information and the signal known. A second and extremely important issue of process control compared to all other applications given in this book is the implementation of the process analytical instrumentation in a plant environment or any other process environment, together with an integration of data flows inside the control loop. While this contribution tries to look at process analytics from an application and industrial point of view, other contributions take a more technological view toward process analytics. A series of current reviews, which takes a more technological perspective, can be found in [4]. This review series gives an introduction to the technological developments for a short period in time with a strong focus on developments in the United States and from the American point of view. Another current review was given by Chew and Sharratt, who tried to focus on trends in process analytical technology starting from FDA's PAT-initiative [5].

One part of process control is also the data transfer, to control systems, data integration, data safety, the generation of signals for feedback and the feedback by changing a flow rate, a feed rate, the addition of feed, solvents, the maintenance of equipment and data infrastructure in a plant, and so on. This is a technological field covered by engineers and because these topics are part of the education of engineers these aspects are not covered in this section.

Process Control in Chemical Manufacturing

Dieter Fischer, Stefan Stieler, and Stephan Küppers

37.1

Introduction to Chemical Manufacturing Processes

Typical process industries such as the petrochemical industry, monomer production, and polymerization reaction and polymer processing often work with dedicated equipment and continuous or semicontinuous production processes. This means a process with a feed of raw materials that goes into the process and an outcome of product(s) from the process that needs to be controlled. On one hand, the measurement of mass flow is a key to control these processes but because the raw materials are not pure or have an inherent variability, some kind of method for the determination of the concentration of the valuable components is needed to correct the masses going into the process/coming out of the process. For example, in many cases, natural materials contain varying amount of water or, to give another example, natural oils have a varying composition in aliphatic components, aromatics, and impurities such as sulfur-containing components. The process may consist of one conversion step or even a number of steps that are combined. Examples for one-step conversions are waste incineration or the generation of biogas, whereas most processes in manufacturing consist of a number of steps. In many cases, not all of the steps of a conversion process are controlled by process controls. The typical reasons for deciding on an analytical control step are not only cost and quality but also time, where speeding up a process typically also means that costs of the overall process are decreased.

In these industrial processes, first a large number of sensors are installed for measuring, for example:

- feed of raw materials, flow rates of components, weight (balance);
- pressure, temperature, and power consumption.

While the first set of sensors measures the pure quantities, the second type, in many cases, already gives information on the process status that allows the control of parts of the process. In some cases, such information is also combined with the so-called soft-sensors. In addition, specific sensors are installed depending on the industry, from pH-measurement, via density, viscosity to conductivity. Mostly,

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

there is a linear correlation between the sensor signal and a step/part of the process. Therefore, the direct control to a specific need can be related.

Finally, in some cases, molecular information or element concentration is needed for tasks such as:

- the determination of the amount of additives that have to be used (e.g., the concentration of the desired metal in the ore);
- the end point of a chemical reaction;
- the conversion of an individual substance, that is, a monomer, and so on.

In these cases, sophisticated analytical techniques, which are often spectroscopic techniques, are implemented. The following examples will give a general overview of some of these implementations. The discussion will follow the supply chain of chemical industry from typical examples for starting or raw materials to the end-point/conversion control in later production steps and will move on to environmental control and close with some discussions on costs. Typically, in many industries in chemical manufacturing there is both an analytical chemical laboratory and a process control responsibility. While the laboratory is typically involved in the control of the starting material before use, for example, for release of the purchased material and the quality control of the final products, the process control is allocated in all of the intermediate steps. Depending on the size of the company and the industry, sometimes both responsibilities are found in one common organizational unit, but at least for large organizations there are two independent departments or groups. Figure 37.1 summarizes this discussion.

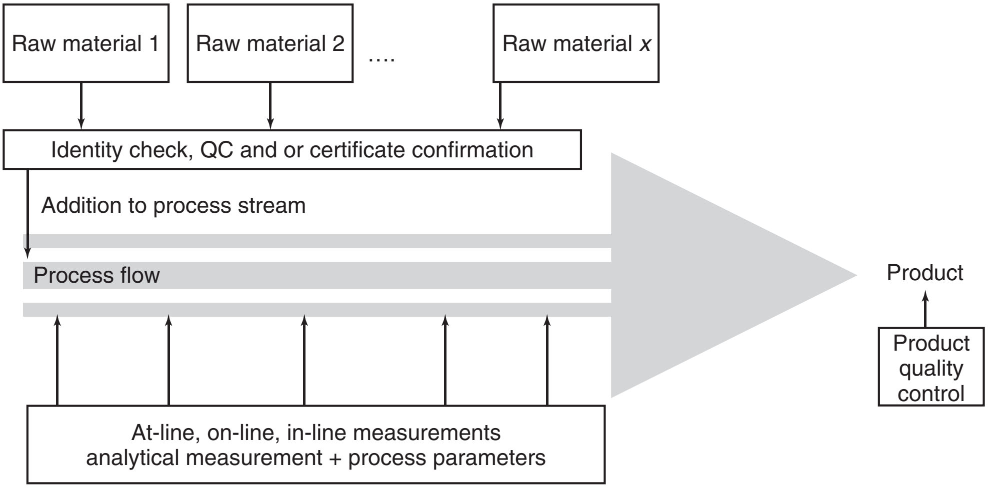

Figure 37.1 Typical workflow in process industries. QC, quality control.

37.2
Chemical Reaction Process Monitoring and Optimization

37.2.1
Monitoring of Pseudocontinuous Batch Processing

In classical industrial production processes such as steel or cement production, or similar processes, a number of process analytical techniques are currently applied. Among these techniques are a large number of spectroscopic techniques [1]. For organic production processes such as many dye productions, the optical spectroscopic techniques, as described later in this chapter, are typically applied, whereas in many inorganic production processes the amount, concentration, or weight of elements has to be determined. In many of these cases X-ray fluorescence (XRF) is a typical process spectroscopic method. Typically, in addition to a number of inorganic components such as nitrate, sulfate, or carbonate are determined by flow injection analysis (FIA), ion chromatography, or capillary electrophoresis, off-line or at-line in a laboratory. In many processes, gases such as carbon dioxide and carbon monoxide, for example, in iron and steel production, are also an important parameter. These gases are typically determined by commercially available gas sensors with a different working principle, some of them based on the infrared (IR) absorption principle.

For example, in cement production, XRF is used to control the raw material flow into the production process. The raw materials are transported via a continuous belt. Here, a weighing step is also included. After weighing, the components are mixed and directly behind the mixing point the implementation of a commercially available XRF spectrometer determines the element composition of the mixture. Here, the elements Ca, Si, Al, and Fe, which are critical for the process, are direct input variables for the process control system that controls the speed of the raw material feed belts. XRF has for a long time been used as an in-line sensor, using the same general instrumental setup as is known in laboratory instrumentation [2].

In a similar way, many floating processes are controlled by XRF. Typically, process flows or the addition of a feed to a process stream can be controlled with cycle times in the range of a few 10 s, and process flows or belt speed can be kept to optimum conditions. The important difference when compared to laboratory application of XRF is that reproducibility and or even precision of the results depends on the grain size distribution and the mineralogical composition of the raw material. The calibration of the measurements therefore needs to be performed on samples that are similar to the samples of interest with respect to type, degree of grinding, and so on. Still, techniques such as XRF are easy to implement in these cases because commercially available portable XRF instruments can be used. The in-line measuring is easy to implement directly in a production plant because the feed belts are typically at ambient conditions and the concentration range of interest is typically in the 0.1–50% range, which is easily stable calibrated by XRF. In cases where a different concentration range and/or a measurement at nonambient conditions is needed, other (typical laboratory) techniques are also implemented in the process.

Products such as steel are typically used as a starting material for the following production step, for example, for the manufacturing of vehicles. In such cases, the structure of the material may have an enormous importance in the stability/usability in the next step, as in the example of steel the corrosion stability, the mechanical plastic deformation stability, and so on. Therefore, X-ray diffraction (XRD) is a typical process control spectroscopy for grid structure of the produced steel. XRD, in this case, can also be applied as a continuous process in a similar way as XRF. Here again, the controls are typically applied on-line under ambient conditions for the measurement instrument.

Also, in other industries such as semiconductor or solar panel manufacturing, XRF and XRD are applied as control technologies on-line or at-line to determine the crystal structure or the content of a component. For example, in semiconductor manufacturing, the thickness of a wafer-coating process is typically determined by XRF. In this case, the analytics with XRF is used to determine the total amount of material coated onto the wafer. If the process is stable and the density of the material is determined once, this procedure allows the calculation of the thickness of the layer even in the nanometer range. In solar technology, in some cases the crystallinity of the material has to be determined. This can be applied on-line by Raman spectroscopy. All different types of Si crystallinity from noncrystalline (amorphous) – via polycrystalline – to monocrystalline – Si are used in production processes. Therefore, Raman or XRD can be used for the control of in-line, on-line, or at-line, depending on the question and or the industry. In the semiconductor industry, these techniques are typically installed as in-line process control instruments because only the in-line implementation inside a clean room and/or even directly connected to a high vacuum process do these tools allow the control of the process without contamination of the samples. Depending on the question, Raman spectroscopy can be applied in a transmission or a reflection configuration using standard commercial laboratory equipment with fiber optic coupling. For details, see subsequent text in this chapter.

In the semiconductor industry, in many cases extremely pure starting materials are needed. Therefore, a number of element and trace element techniques from total reflection XRF, atomic absorption spectrometry (AAS), inductively coupled plasma optical emission spectroscopy (ICP-OES), and inductively coupled plasma mass spectrometry (ICP-MS) are applied as laboratory control or at-line. In some cases, a direct transfer of the sample from the process to the laboratory has also been implemented; for example, in steel manufacturing, sampling processes that lead to a sample that is directly transferred to the laboratory have been implemented because any other sampling process would lead to contaminations of the liquid steel by the environment. In principle, in all the cases mentioned up to now, standard laboratory equipment for process analysis is still used, but a dedicated sampling and sample transfer system has to be established. Details of many of the analytical process controls including the detailed description of the processes themselves can be found in [1].

37.2.2
Monitoring of Continuous Processes

The heart of the chemical industry is chemical conversion. Important chemical conversions that are, in many cases, performed in continuous processes and therefore are measured and controlled by process analytics and control are reactions for monomer production and polymerization reactions.

A number of these chemical reactions are performed at high temperature in the gas phase. Typical examples are found in the petrochemical industry where both distillation and chemical conversions are performed at high temperature; chemical reactions in synthesis for various intermediates of chemical reactions; and the generation of basic chemicals, metathesis reactions, or other high-temperature gas-phase processes, for example, waste combustion or distillation processes for purification of chemicals and solvents. For these processes, gas chromatography (GC) [3] and mass spectrometry (MS) [4] are typical monitoring and control technologies; sometimes, the combination of GC with MS is also applied, but in many cases both technologies are direct competitors with each other and the application depends on which method is implemented. Mostly, the details of such implementations are not published because the manufacturing technology in many cases is one of the competitive advantages of the organizations. Although only a few examples are published, some information can be found in literature [5]. One example is the reaction of acidic acid to ketene. The reaction mechanism of the ketene process is given in Figure 37.2. The important point is that all components of the reaction are in equilibrium. Therefore, for process control a large number of components have always to be monitored.

The reaction is endothermic ($\Delta H = 140\,\mathrm{kJ/mol}$) at a temperature of 700 °C and a pressure of 500 mbar. The product contains acidic acid, acidic acid anhydride, carbon dioxide, methane, propadiene, hydrogen, diketene, carbon monoxide, and ethylene as well as some minor by-products. After the reaction, the mixture is cooled down to split the product from the acid that is transferred back into the reactor. The analytical challenge, as reported in the literature, can be monitored by process MS [5].

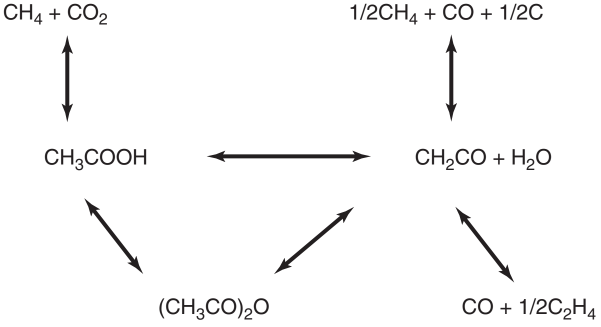

Figure 37.2 Schematic of the ketene reaction.

For better understanding of the system, the whole process from the reaction including distillation and hydrolysis was described by a model. The data for this model was received from on-line analysis. Measurements were performed in the reactor entrance and the reactor outlet. The reason for using process MS was the high reaction speed of the product, ketene. To receive data that is representative of the process, a high-speed process analysis was needed. The results of the on-line MS analysis and the optimization using the process model allowed the improvement of the process output of 13%. One of the key issues in the process analysis in this case was the sampling at high temperature with the need for fast analysis times.

The major advantages of process MS in this case are

- fast analysis times, up to 1 s per analysis;
- sensitivity to many components, parts per million to parts per billion, lower for special applications;
- a wide dynamic range, which allows to determine minor and major components in one analysis;
- because of the high speed, multiplexing is possible to analyze different processes and/or the same process at different stages/times in the process;
- because mostly full mass spectra are recorded, MS has the capability to detect unknowns in the process.

However, there are also disadvantages:

- Because process MS always works under high vacuum and at ambient temperature, the sample needs to be transferred to these conditions.
- The instrumentation is expensive compared to some other analytical techniques.
- The installment needs to be relatively close to the process.

The hardware used in process analytical applications is mostly based on laboratory equipment. Often, in process MS, quadrupole, sector field, or time-of-flight (ToF) instrumentation is used [6]. In contrast, in special cases, as in the above-mentioned example, special process mass spectrometers are developed for on-line applications. Other examples for the use of dedicated process mass spectrometers, for instance, can be found in steel manufacturing and in petrochemistry. The choice of the analyzer depends on the application. The mainly used analyzer is the quadrupole mass spectrometer because of price and speed, as also in the above-mentioned case. Sector field analyzers have the advantage of highest stability, which is sometimes needed for process applications, whereas the advantages of the ToF analyzers are the high mass resolution combined with a small analyzer size, which might be relevant for portable applications.

Typically, electron ionization is used. The sample inlet has to be adapted to the process. In case of MS, on-line configurations are always applied and the modifications of the inlet are less complex compared to optical spectrometry. In an ideal case, a direct capillary inlet can be used. Depending on the sample, this transfer line needs to be heated. In case of the sampling of liquids or components that are dissolved, membrane interfaces are applied [7] and in more special cases a GC is used as the interface to the process. The calibration of the mass spectrometer needs to be automated for process control. This can be achieved by sampling loops, sometimes also by direct adaption of a calibration gas bottle into the MS system.

Another typical example for mass-produced chemicals is polymers. The polymerization reactions are often continuous processes that are controlled by in-line and/or on-line methods. Temperature and pressure for polymerization reactions cover a wide range from low temperature to melting polymerizations and also sometimes accelerated pressure. Oxygen typically has to be kept out of the process, which means that coupling to the process and sampling is typically a challenge for the implementation of the analytical technique. Various techniques are used to control polymerization reactions. Besides the ‘‘classical techniques’’ from temperature, pressure, pH, density, viscosity, turbidity, and others, sometimes optical spectroscopy techniques are applied to receive molecular information on the process. For polymerization reaction monitoring techniques such as IR, NIR, and Raman spectroscopy are highly suitable. The advantage of spectroscopic techniques here is that they can be used on-line or in-line and time constants are short. The typical chemical conversion in polymeric reactions is the change in C=C double bonds, COH, NH, C=O bonds. In cases of, for example, NH and OH, hydrogen bonds can lead to shifts in the spectra, so especially for NIR with strongly overlapping bands and shifts caused by temperature, pH and, for example, the already-mentioned hydrogen bonds must be evaluated carefully [8]. Anyhow, multivariate methods are necessary for quantitative information in monitoring processes such as, for example, copolymerizations. Using Raman spectroscopy, the C=C double bond can be very sensitively monitored. This gives access to monitoring most of the typical vinyl- and acryl-based polymerization reactions on-line [9]. The laser excitation wavelength always is a compromise between prevention of fluorescence caused by impurities and by-products and efficiency. As reported in [8] for polymerization reactions monitoring the C=C double bond, a wavelength of 800 nm has been proved to be a good compromise. For safety reasons, the power of the laser radiation brought into the system has to be kept low, for example, below 30 mW [8].

The instrumentation used in the coupling of optical spectrometry to the process is typically laboratory equipment. The principle setup of the instrumentation, the detection systems, and so on are described elsewhere in this handbook. For the coupling of these instruments to the process, a number of strategies, depending on the process, are described in the same section.

Besides the polymerization reaction, the processing of polymers is also monitored by process control using spectroscopic tools. A typical example is the monitoring of extrusions. Extrusion is one of the most applied technologies for mixing and modifying of polymers in polymer processing. The example presented here is taken from the extrusion to create innovative multifunctional polymer materials such as polymer blends and nanocomposites, as presented elsewhere [10].

Off-line analytics does not display the current state of the material during the extrusion process. For an adequate characterization of the material, it is necessary to make real-time measurements at the extruder. Spectroscopic methods are outstanding for in-line monitoring [11–13]. In the example given, the opportunities of NIR and ultraviolet–visible (UV–vis) measurements as methods for in-line monitoring to characterize polymeric nanocomposites in the extrusion process are shown. Furthermore, the combination of in-line methods with off-line spectroscopic measurements, transmission electron microscopy (TEM), and atomic force microscopy (AFM) are demonstrated.

Measurements for the example described were performed on a twin screw extruder as shown. The sensors for ultrasonic, NIR, Raman, and light scattering (particle monitoring) are directly coupled to the extruder, as visible in the image (Figure 37.5), where the sensors can be seen lined up, along the outer wallet of the extruder.

The polymers used were polyamide 6 (PA6) and polypropylene (PP) modified with 5% maleic anhydride (PB 3200). Both polymers were mixed with different nanofillers (montmorillonite, sepiolite, and boehemite) in the concentration range from 1 to 12%.

Figures 37.3 and 37.4 show as an example the NIR spectra and the results of a chemometric analysis by partial least squares (PLS) for the nanocomposite PA6/montmorillonite. The NIR spectra of the PA6 series, with different montmorillonite concentrations in the wavelength range from 1 to 1.7 µm, are shown in Figure 37.3. The calculated concentrations by PLS analysis are in shown in Figure 37.4. The results of the in-line measurements show a good correlation between the predicted nanofiller concentrations in the polymer matrix and the NIR spectra.

The TEM and AFM investigations of the extruded samples show the state of intercalation and exfoliation and also the dispersion of the nanofillers in the polymer matrix.

A similar approach to characterize current polymer blends under research can be performed with ultrasonic measurements as technique for in-process monitoring of polymer nanocomposites in the melt [14–16]. An in-line process application was built up with a measuring adapter for the ultrasonic probes at the end of the

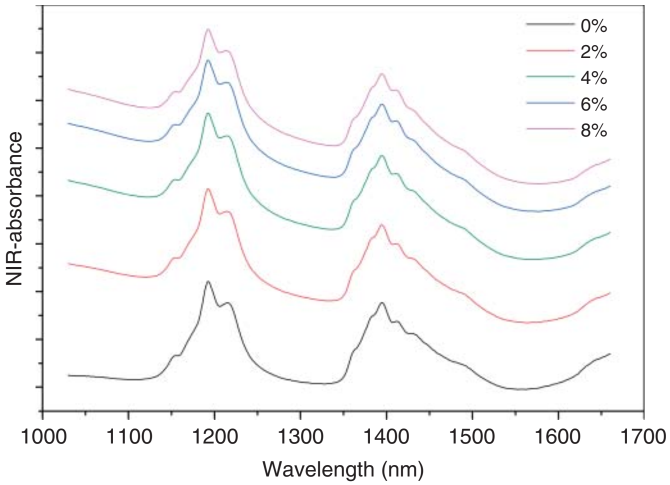

Figure 37.3 In-line NIR spectra of the nanocomposite PA6/montmorillonite.

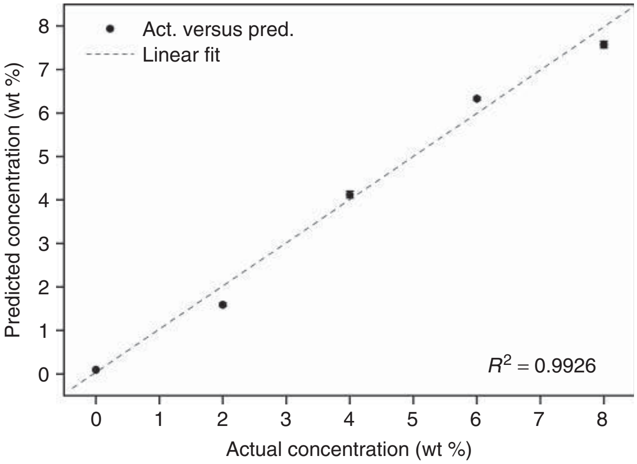

Figure 37.4 PLS results of the concentrations of the filler montmorillonite in the nanocomposite PA6/montmorillonite (2 PC) using NIR spectra.

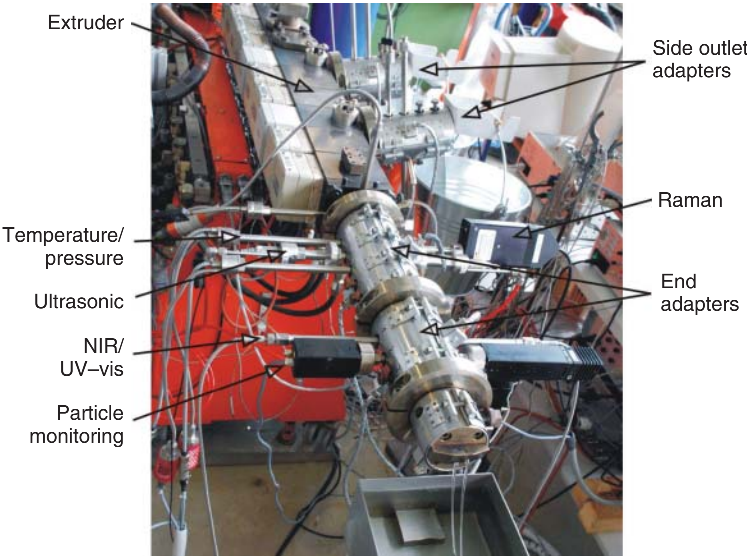

Figure 37.5 Laboratory setup of a twin screw extruder with an ultrasonic probe, a Raman probe, and an NIR probe.

same extruder shown in Figure 37.5. Different polymer/nanofiller mixtures were investigated during extrusion by ultrasonic velocity measurements and ultrasonic attenuation spectroscopy.

The data obtained show a decreasing sound velocity with an increasing content of the nanofiller and changes in the ultrasonic attenuation spectra. A frequency-dependent ultrasonic attenuation in the range from 3 to 12 MHz was measured, as shown in Figure 37.6. To find a correlation between the measured ultrasonic

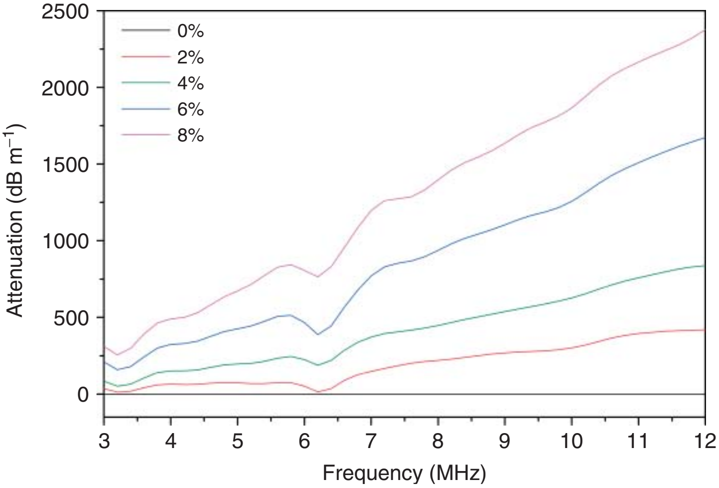

Figure 37.6 Ultrasonic attenuation spectra of the nanocomposite PA6/montmorillonite (2–8% content of montmorillonite).

spectra and the contents of nanofillers, a chemometric analysis was performed using the PLS method. The predicted concentrations, calculated from the ultrasonic attenuation spectra, show a very good correlation to the actual concentrations for all nanocomposites, as seen in Figure 37.7.

The difference between these examples and those given in the beginning is that, in this case, no commercial solutions were available and therefore the process analytical solution had to be developed especially for process control reasons. Other

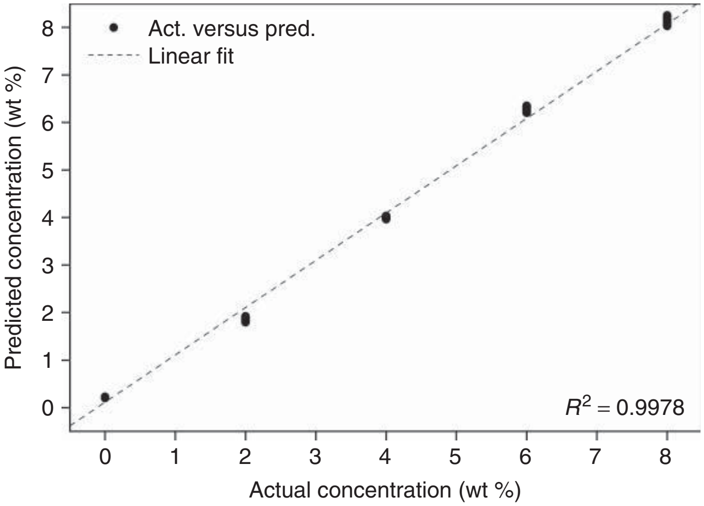

Figure 37.7 PLS results of the concentrations of the filler montmorillonite in the nanocomposite PA6/montmorillonite (2 PC) using US attenuation spectra.

techniques are currently evaluated for similar approaches as, for example, terahertz (THz)-spectroscopy for in-line monitoring of polymeric compounding processes [17]. A current overview of the techniques where the development is ongoing is given later in this section.

In many industrial manufacturing processes, the downstream processing is relevant for either quality of the product or even costs and therefore often is controlled by process control tools. The highest requirements for quality process control in downstream processing are found in biotechnology and pharmaceutical products. Many of the technologies already implemented in the chemical and food industry are under investigation in the pharmaceutical industry [18]. Examples for process control in downstream processing are therefore given in the subsequent text.

37.2.3

Monitoring of the Process Environment

Another key issue for many chemical production environments is the extreme corrosivity of the mechanical components of a plant. Typical chemical conversions that lead to high corrosion are reactions with acids at high temperature or, for example, reactions using halogen from fluorine to iodine, which are used in many chemical processes from polymers to pharmaceutical products. An example of a production process monitoring of a chlorine production plant was presented by Welmink [19]. Here, water was monitored in the plant, to ensure a safe, uninterrupted, and smooth operation because the water together with chlorine gives the extremely corrosive mixture. To keep the plant producing continuously, it is vital to prevent corrosion of piping and other production equipment and therefore keep the water content low. Besides routine checks of leakage of the pipelines in a plant, the monitoring of corrosive media is an opportunity to ensure a smooth, continuous operation of a plant. The continuous monitoring of the water vapor concentration in chlorine gas in several stages of chlorine production is an example of the use of process control with spectroscopic tools that can help predict corrosive situations at an early stage.

The moisture measurement in chlorine gas in-line or on-line is therefore an example of process analytics in chemical production, but in this case the infrastructure is secured by process analytical tools. Because tunable diode laser absorption spectroscopy (TDLAS) is not a widely known technology, this example is also an opportunity to describe a technique that is typically used only in process control or some special applications but not in the laboratory environment.

TDLAS relies on well-known spectroscopic principles and sensitive detection techniques, coupled with advanced diode lasers and optical fibers developed by the telecommunications industry. The principles are straightforward: gas molecules absorb energy at specific wavelengths in the electromagnetic spectrum. At wavelengths slightly different from these absorption lines, there is essentially no absorption. By transmitting a beam of light through a gas mixture sample containing a (usually trace) quantity of the target gas, and tuning the beam's wavelength to one of the absorption lines of the target gas, and accurately measuring the absorption of that beam, one can deduce the concentration of the target gas molecules integrated over the beam's path length. This measurement is usually in the parts per million concentration range.

In most TDLAS instruments, the laser's fast tuning capability is exploited to rapidly and repeatedly scan the wavelength across the selected gas absorption line [20–23]. While this scanning occurs, the fraction of emitted laser power that is transmitted through the gas mixture is monitored with a photodetector. When the wavelength is tuned to be off of the absorption line, the transmitted power is higher than when it is on the line. Measurement of the relative amplitudes of off-line to on-line transmission yields a precise and highly sensitive measure of the target gas concentration along the path transited by the laser beam. Furthermore, techniques known as *frequency* or *wavelength modulation spectroscopy* (WMS) and balanced ratiometric detection (BRD) are frequently employed in TDLAS instruments to make them exquisitely sensitive to even very weak absorption of the laser power. Thus, TDLAS instruments offer a combination of high sensitivity to trace concentrations of many gases, freedom from cross-species and external interference, and fast response. Examples of gases that can be sensed with TDLAS, and typical minimum detectable path-integrated concentrations, are listed in Table 37.1.

In many current implementations of TDLAS, the diode laser beam is coupled to optical fibers. This enables separating the laser, associated electronics, and microprocessor from the measurement head. This capability has led to the evolution of the TDLAS system architecture, utilized by many of today's practitioners for monitoring and controlling various chemical, combustion, or manufacturing processes, that has made the technology attractive for use in harsh, hazardous, or difficult-to-access industrial environments. The instrument is separated into two distinct, yet interconnected, components called the *system console* and the *measurement path*, illustrated in Figure 37.8. The laser beam originates within the

Table 37.1 Some gases measured by TDLAS (according to *http://www.tdlas.com/*).

Gas	Detection limit (ppm)
HF	0.2
H_2S	20
NH_3	5.0
H_2O	1.0
CH_4	1.0
HCl	0.15
HCN	1.0
CO	40
CO_2	40
NO	30.0
NO_2	0.2
O_2	50

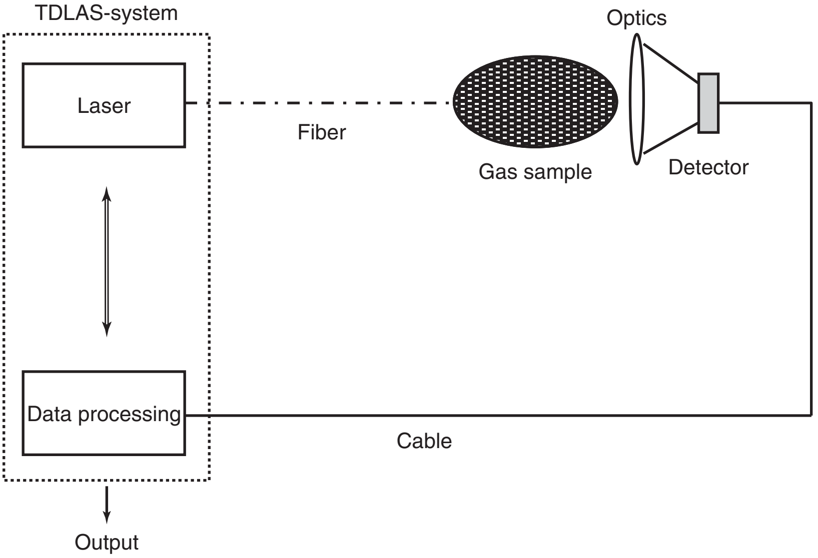

Figure 37.8 TDLAS gas detector system, according to *http://www.tdlas.com/theory.shtml*.

system console, which is usually installed in a general-purpose environment. An optical fiber conducts the beam to the measurement path, which is built to withstand the harsh installation environment. At the beginning of the measurement path, the laser beam exits the fiber and is transmitted into the gas sample. At the opposite end of the measurement path, the laser beam impinges on the photodetector, which converts the beam, and the information it carries, into an electrical signal that is returned to the system console via an electrical cable. At the console, the signal is processed and the path-integrated target gas concentration is reported. Noise reduction in sensitive BRD and WMS detection techniques is accomplished by use of an optical or electronic reference signal that connects directly from the laser transmitter module to the signal processor module.

Since a few years, such TDLAS systems are marketed as in-line process analytical equipment to measure various components in gases in various process environments [24]. TDLAS equipment is already in use for the measurement of oxygen and experiences are good until now. The TDLAS measuring principle can also be used in the measurement of moisture in chlorine gas at parts per million levels. If the TDLAS equipment can be used for moisture measurement, less maintenance effort can be expected. However, measuring moisture at parts per million levels is a totally different challenge from measuring oxygen at percentage levels. When the sample matrix contains corrosive gases such as chlorine or hydrochloric acid, additional issues are to be dealt with. Till now in most chlorine plants, the moisture content of chlorine is measured with instruments based on the coulometric phosphorus pentoxide (P_2O_5) principle (also named "Keidel"cell).

If the moisture content of the chlorine gas rises above certain limits, the protective ferric chloride ($FeCl3 \times aq$) coating on the inside of the plant piping will liquefy, resulting in severe corrosion. Therefore, a comparison between TDLAS equipment and the P_2O_5 cell in laboratory and field tests and by cost of ownership by TDLAS was performed and it was demonstrated that the TDLAS could be successfully applied. Because corrosion prediction is a typical challenge for process analytics in chemical manufacturing, it can be expected that such implementations will be routinely seen in coming years [19]. Besides corrosive gases, other extreme reactive materials, such as, for example, the halogen iodine, are used in chemical manufacturing, and other techniques are therefore used in the monitoring corrosive substances in production.

37.2.4
Environmental Monitoring in Industrial Processes by Process Analytics

A large number of process controls in industrial manufacturing are also related to control of emissions into the environment caused by manufacturing itself, recycling processes but also by waste incineration. This area of process controls is regulated by law, for example, by European and national law.

For example, in Germany the seventeenth BImSchV (''Bundes-Immissionsschutz-Verordnung'') sets limits for emissions into the environment. Therefore, for example, the continuous monitoring of waste incinerations is a typical field for process analytics and control and, depending on the waste, sometimes a challenging application (Table 37.2). The following table shows an overview of important components to be measured as well as typical devices applied for that, representing the current status of German law at the time of writing this contribution.

In some of these cases, for multicomponent analyzers, Fourier transform infrared (FTIR) spectrometers are applied. In case of only one component of interest, often nondispersive IR systems are used. Details of the implementation of such instruments are discussed in subsequent text. An overview of UV–vis applications in environmental applications is given elsewhere [25].

For a number of gases, the European guideline gives limits and requirements that have to be measured on a routine basis if emissions occur (European Directive 2000/76/EC and 2003/87/EC). The list contains a similar list of gases, as given,

Table 37.2 Emission and typical control according to German national law.

	Components to be measured	**Typical analytical system**
Gas	HCl, CO, NO, SO_2, O_2, TOC, Hg, if applicable: HF, dioxin/furan	Multicomponent analyzer (e.g., FTIR)Mercury measuring device Multicomponent analyzer (FTIR)
Dust	Dust concentration	*In situ* dust measuring device, extractive dust measuring device
Others	Temperature, flow, pressure humidity	Combined measuring devices multicomponent analyzer (e.g., FTIR)

from German national law but also a number of metals—Cd/Tl, Sb, As, Pb,Cr, Co, Cu, Mn, Ni, V, and Sn. The regulated limits are on a daily average or half hour average values. Especially, if more than one element has to be determined, spectroscopic analytical techniques are a powerful tool.

There are two major points with respect to the recent revisions of regulations and guidelines. On the one hand, a new demand is set on the availability of the plant and, on the other, quality requirements on the measuring equipment and its continuous operation are sharpened.

The measurement of gas emissions in a clean gas is normally performed by extraction and classical laboratory analysis. A representative measuring gas sample is continuously extracted by means of a heated gas sampling probe and led to the analyzer via a heated measuring gas line. Gas conditioning with a multicomponent analyzer may be installed directly in the analysis cabinet. The dust measurement can be performed either *in situ* or extractively using commercial solutions provided by various suppliers. The continuous measurement of the gas, for example, by the IR technique, needs a combination with a gas flow measurement to determine the overall emission. The elemental analysis of, for example, dust is normally performed in a classical laboratory environment by various spectroscopy techniques, often ICP-OES or XRF because of their multielement capability. The implementation of a solution strongly depends on company size and the products to be produced. Very large companies sometimes establish homemade solutions based on separation techniques or hyphenated approaches [26]. The reason, therefore, is the complexity of the samples that cannot be handled even byhighly sophisticated spectroscopic methods. One major advantage in these cases is also the longer time scale, because in case of ''normal'' emission the concentrations are so low that samples for each half hour or up to once per day are requested by authorities. For the optimization of waste incineration plants also, a number highly sophisticated techniques such as on-line, real-time MS combined with FTIR have been applied [27].

37.2.5
Investment, Return on Investment, Cost of Ownership

For the chemical industry in a global competitive situation, the most important motivation for implementing process analytical tools is the possibility of cost reduction. Therefore, the calculation of investment in process analytical instrumentation, the determination of the return for this investment, and the cost of ownership are important issues. Here, the industrial point of view is described for better understanding. In this context, a more general starting point has also to be applied because spectroscopy in many cases competes with other techniques; besides, the comparison between laboratory and process implementation often means comparinga spectroscopic with a nonspectroscopic method, if only costs and quality matter.

Starting with a general view of analytical chemistry in production, up to 4% of production costs are spent on analytical work. A major part of this work is done in the classical way – off-line by laboratory analysis. This is the case although most analyzers used in the laboratory are available as on-line working process analyzer versions. The decision to move from laboratory analysis to process analytical equipment in the chemical industry has three major reasons:

- Increase the safety of a production facility
- Improve the quality or yield of a product
- Reduce the costs of a product.

Typically, in production an overall cost balance has to be made. The costs of a product are determined by the cost of the raw materials, energy, workforce, the quality of the product, and the cost of equipment.

The costs of analytics in many cases are part of the costs of workforce and equipment. So, the benefits of an improvement of analytics by on-line or in-line in process control can be found in the workforce costs, equipment costs and also in the quality of the product and sometimes in raw materials costs. The balance of these factors, as listed here, has to give a positive benefit.

- Costs
  - Instrumentation
  - Implementation
  - Training of personnel
  - Calibration, maintenance, repair, and supplies.
- Benefits
  - Reduced cycle time
  - Higher quality of the product
  - Less usage of raw material
  - Documentation of testing
  - Higher process control stability, planning becomes easier
  - Transferability of processes to various plants.

Typically, the investment in instrumentation and implementation of process analytical equipment is low compared to the costs of the production equipment ($\ll$10%), but typically two to five times higher compared to similar laboratory equipment. This difference including the company's internal capital costs has to be justified by a turnover within typically 6 months to about 2 years.

The question is therefore which investment in process analyzers is profitable regarding a certain production process and the requirements for quality of measuring values. Such data would be valuable for the planning of new and optimization of existing production plants.

In the following, some guidelines for different measuring principles on the basis of long-term experience in process analyzer technology are given.

The examples of some standard analytical measurements in chemical and pharmaceutical processes are given in Table 37.3; see column 1.

Methods commonly used for process control are shown in column 2 process analytical technology (PAT), whereas the competing laboratory method is given in column 3.

Table 37.3 Measuring tasks and methods used for evaluation of process analytics versus laboratory analytics.

Measuring tasks regarded

Measuring task	**PAT method**	**Laboratory method**
pH-measurement	Potentiometric	Potentiometric
Nitrate in chemical wastewater	Titrator/automatic analyzer with a specific reagent	Titrator/automatic analyzer with a specific reagent or *photometer*
DOC + VOC in chemical wastewater	Thermic TOC with VOC-channel and dilution + filtering	Thermic or UV decomposition TOC with VOC channel
Gas analysis of five components	Filter photometer or *GC*	GC
Liquid analysis of five components	NIR spectrometer	GC
Gas analysis of one component	NDIR photometer	GC
DOC of ultrapure water (ppb-range)	Ultrapure water DOC (UV-decomposition + conductometry)	Ultrapure water DOC (UV-decomposition + conductometry)

NDIR (non-dispersive infrared) photometer.

Cost of ownership was determined on the basis of manifold experience with such measurements. Because investment and running costs vary within a wide range depending on the application, average values were taken. Assuming a lifetime of 15 years, the following costs have been taken into consideration:

1) Interests and depreciation of
   a. engineering, application, installation of measurement;
   b. fraction of analyzer room (it has been assumed, that an analyzer room contains 8–10 process analyzers).
2) Operating costs for
   a. maintenance (including functional tests and calibrations);
   b. repairs;
   c. expendable items (gases, buffers, and so on) and repair materials.

For the laboratory analysis methods, the following expenses were taken into account:

- Sampling
- Sample transport from the sampling point to the laboratory
- Laboratory hours/analyzing costs
- Enter results into plant data system (data sampling)
- Disposal of samples.

To give a more general estimate for this cost balance in a survey, a number of chemical and pharmaceutical companies were asked for quotations of such laboratory analysis services. In addition, prices from commercial analytical laboratories were collected. Finally, the results were averaged.

For two of the seven measuring tasks, two alternative solutions (indicated underlined) were investigated. An important finding was that – for the investigated applications – 45–75% of process analyzer ownership costs were caused by maintenance, inspection, and repair (Figure 37.9). The contribution of investment costs is relatively small. Therefore, in planning or applying a process analyzer, the focus should be more on maintenance and not too much on investment costs because cost optimization is achieved mainly in maintenance, which means that the decision between different analyzers with similar specifications is performed simply on maintenance effort or costs. For example, self-diagnosis and maintenance request status signals require higher investment but may help to reduce maintenance costs by switching from periodic to condition-oriented maintenance.

As a second result, it turned out that on-line analysis is often less costly than laboratory analysis (Figure 37.10). The breakeven point is about 1–2 analysis per day (nitrate in wastewater, multicomponent gas, and liquid analysis, dissolved organic carbon (DOC) plus volatile organic compound (VOC) of wastewater) and even less than 0.5 analysis per day for some measurements (pH, one-component gas analysis, DOC in ultrapure water).

The application of PAT can save a lot of money in chemical and pharmaceutical production processes. Examples with amortization times of 1–2 years are as follows:

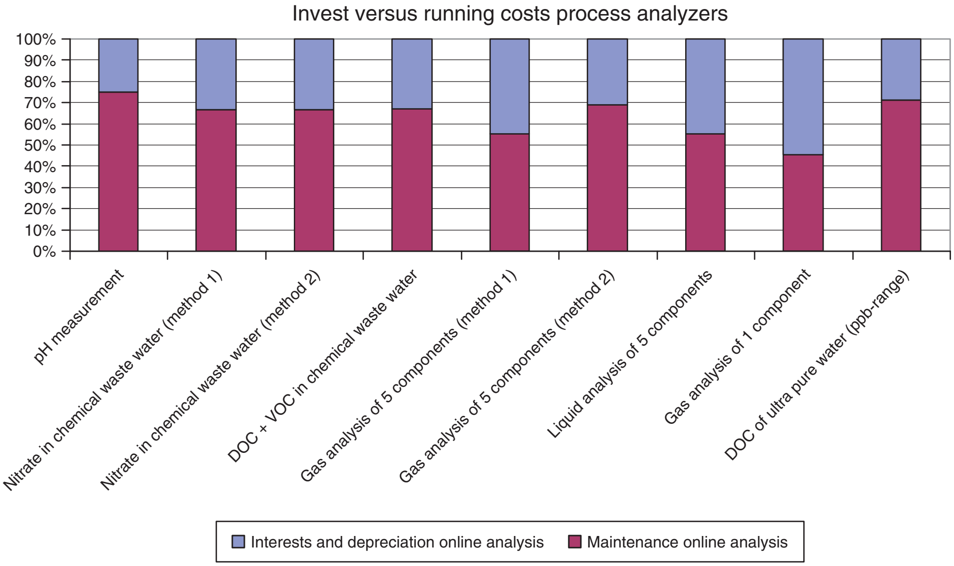

Figure 37.9 Ratio of investment and operation costs for the various process analyzer systems evaluated.

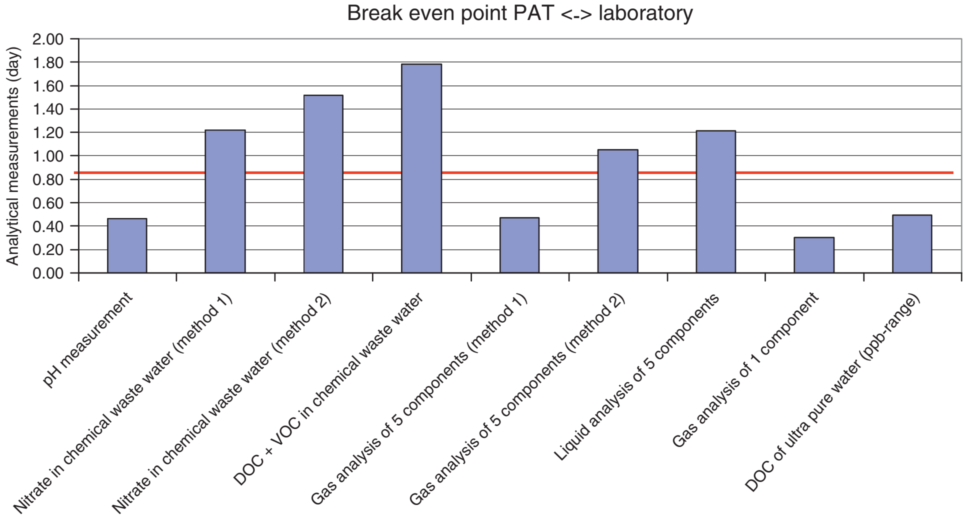

Figure 37.10 Results of the evaluation with mean value of measurements per day and the individual results for each technique.

- Supervision of distillation columns with an NIR-spectrometer
- Analysis of fractions after a preparative chromatography with on-line high performance liquid chromatography (HPLC)
- Supervision of boiler feed water.

As a rule of a thumb, it can be summarized that approximately for one analysis per day the costs of process analyzers are comparable with the costs of laboratory analysis. The main task for on-line analyzer specialists will be to optimize consulting, planning, and maintenance to reduce the breakeven point to laboratory analysis and to increase the benefits of the plant managers. Smart engineering, the introduction of diagnosis tools, and new analytical methods will help achieve this.

Process Control Using Spectroscopic Tools in Pharmaceutical Industry and Biotechnology

Michael Brudel, Uwe Schmidt, Holger Mueller, and Stephan Küppers

38.1

Introduction to Pharmaceutical Industry

The company structure in the pharmaceutical industry typically is divided into a drug substance (active pharmaceutical ingredient (API)) production and a drug product production. The drug substance is either produced in a chemical or sometimes in a biotechnological process, as already mentioned. Typically, at least the drug substance – but in most cases also the drug product – is produced in multipurpose equipment using a batch production process. A chemical production plant produces between a few and up to 20 different products, which means also that quite often each chemical synthesis is only produced once a year. Very often, the drug substance is produced within a low number of batches, <3 to 10 batches per year. Afterwards the equipment is cleaned and used for the next product. The typical equipment of the chemical or biotechnological production process is the stirred tank reactor. A typical API synthesis has between 5 and 15 chemical or biotechnological steps. The typical processing time of a chemical conversion is hours and the process from preparation of equipment to the isolation of the product has a time scale from 1 day to a few days. This is different from the biotechnological processes, which typically need at least a few days/1 week to a few weeks.

Because of the strong batch and multipurpose orientation of chemical manufacturing in the pharmaceutical industry, special technologies, such as process analytical instrumentation, is used only if it can be applied to a large number of chemical synthesis steps.

In addition, a typical chemical manufacturing plant in the pharmaceutical industry has a large infrastructure of special process and/or downstream processing instrumentation, starting from distillation, wastewater plant to process chromatography, and so on. In this infrastructure part of the plant, typically different products are processed, but the various support processes are always the same. For example, in distillation different solvents are distilled but the distillation process stays the same and, therefore, in the infrastructure part of a chemical manufacturing plant much more process control instrumentation is applied, than in the chemical part of the pharmaceutical core facility. In solvent recovery (a distillation plant), in many

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

cases, a process control instrumentation such as process GC (gas chromatography), process MS (mass spectrometry), or near infrared (NIR) is applied to receive the specified quality at lowest costs. Here, a point of view similar to chemical manufacturing is taken, and implementations are comparable to the examples described.

The pharmaceutical production process, starting from the API to produce the drug product, is also typically a batch-type process. Here, the equipment and processes slightly differ for solid, semisolid (ointments, crèmes), and liquid products. In addition, there are some special products such as suspensions, band-aid/plasters, and others. The key quality issues depend on the product. For example, for solid products, homogeneity of mixing of the API with the additives is the key issue; for semisolid products, this is only sometimes an issue; but, typically, the homogeneity is no issue at all for liquid products. This also means the process control and, therefore, the process control instrumentation is strongly dependent on the type of product.

Biotechnological manufacturing, in principle, is just another way of manufacturing the API. Sometimes, even some of the steps of the conversion from starting material to API are produced using biotechnological conversions. But there are some important differences compared to chemistry with respect to the importance of process controls. The most important differences are as follows:

- the biotechnological processes are much more complex on the molecular level;
- a biotechnological conversion takes much longer and therefore the control of the process is also possible with slower analytical tools;
- sampling is often much easier than in chemical conversions because the samples are water based and the processes are typically at ambient pressure and moderate temperatures.

Especially because of the second reason, process analytics has a much longer tradition in biotechnology. Because of this tradition, the modern (and often fast) spectroscopic analytical tools often have first been implemented in biotechnology and implementation in chemistry has been following slowly. In this chapter, therefore, much more examples from biotechnology are shown compared to the current importance of biotechnology in the pharmaceutical industry.

The overall workflow for pharmaceutical industry is given in Figure 38.1.

38.2
Regulatory Aspects

In the pharmaceutical industry, quality is still the key issue for a product. In development, a product is therefore tested by a toxicological study with healthy humans and then with patients. At the date of submission, the pharmaceutical company submits a ‘‘contract,’’ with a promise to produce the same quality with the same impurity profile to the regulatory agencies. This general procedure leads in combination with the fact that the pharmaceutical industry is interested in the shortest possible

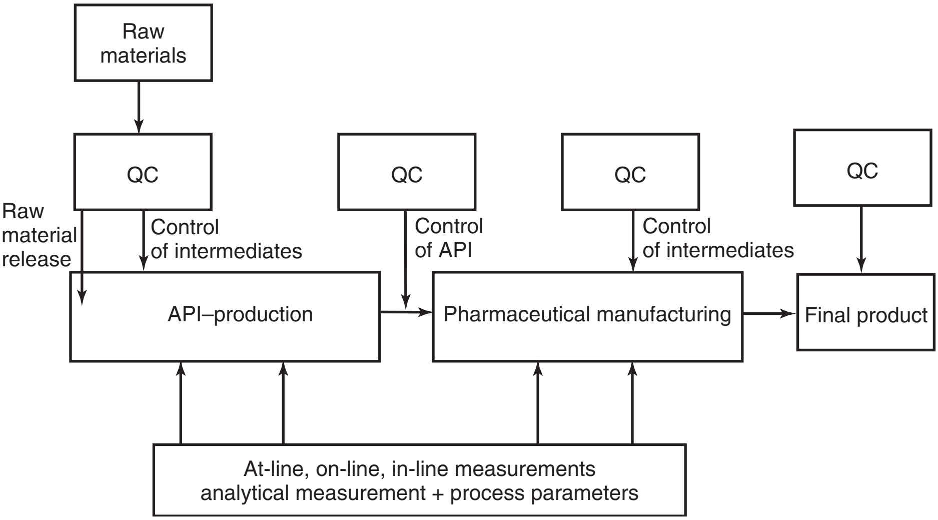

Figure 38.1 Typical workflow for the pharmaceutical industry.

time to market to a situation that the production processes are typically fixed before they are fully optimized. Every change (also an optimization) in the production process has to be accepted by the regulatory agencies. If the impurity profile is changed, a new study showing the comparability of the new product in clinics has to be applied and a new stability test is needed. Both tests typically take years and the costs are extremely high. Therefore, typically, in chemical and pharmaceutical manufacturing, only a few sophisticated process controls are implemented because they are not available at the time of the submission of a new product.

The situation slightly changes because of the FDA's (Food and Drug Administration) so-called Process Analytical Technology (PAT)-initiative. The PAT-initiative was initiated at the beginning of the century and is intended to present a new risk-based approach of the FDA for the twenty-first century. It is an interdisciplinary and process-oriented approach to the quality in production in the pharmaceutical industry. Because of the complexity of the approach, a number of scientific and business organizations are involved in the PAT-initiative.

The definition of PAT is

> A system for designing, analyzing, and controlling manufacturing through timely measurements (i.e., during processing) of critical quality and performance attributes of raw and in-process materials and processes with the goal of ensuring final product quality.

In a later part of the definition, the innovation orientation of the approach is clarified:

> Using this approach of building quality into products, this guidance highlights the necessity for process understanding and opportunities for

> improving manufacturing efficiencies through innovation and enhanced scientific communication between manufacturers and the Agency [1].

This approach is already changing the way the pharmaceutical industry thinks about process control. Process control is becoming more integrated into process development, as first examples show [2], and critical parameters in the production process are controlled to ensure product quality. An interesting part of the FDA definition is also:

> It is important to note that the term analytical in PAT is viewed broadly to include chemical, physical, microbiological, mathematical, and risk analysis conducted in an integrated manner.

Here, the widening of the scope of process control to include mathematical tools such as chemometrics will be important for further developments. A general introduction on the process initiated by the FDA's PAT-initiative can be found elsewhere [3, 4].

The new approach is oriented toward other industries such as the semiconductor industry, where also a very strict quality orientation is performed but the quality is produced by the following:

- a strict quality control (QC) system including statistical process control in each process step, between process steps;
- on-line and in-line controls are essential and an integral part of every process technology [5].

The PAT-initiative is currently changing the production in the pharmaceutical industry, which leads to a continuous increase in process analytical tools in manufacturing, especially in pharmaceutical production. Spectroscopic techniques are mainly used here. Therefore, the number of publications dealing with applications as well as reviews [4, 6–9] and on special aspects of the production process in this special field is growing strongly. In general, the interaction between regulatory agencies and industry leads to a strong integration of new technologies and evaluation processes. In this respect, a strong growth of integration of chemometric tools in industrial applications has been observed recently. One current aspect in the transformation process in the pharmaceutical industry is the definition of design spaces that describe a parameter space for the production of a product. Within this parameter space, the product reaches the necessary quality. The control of the parameters of the design space might be performed either by analytical measurement, as shown for the vaccine example later, or by settings of the optimized process parameters, as shown in the fluid bed granulation example [9]. The following discussion will therefore never be up to date. We more or less try to describe the process and give a few examples for a more general understanding.

38.3
Applications in Pharmaceutical Industry

As regulatory aspects play an extremely important role in the pharmaceutical industry, this aspect and its influences are explained in the following discussion. As shown in the workflow for the pharmaceutical industry, there are two major parts of manufacturing. As many chemical reactions in API production are similar to production processes in the chemical industry, only one example for the monitoring of a chemical reaction is given. In addition to chemical manufacturing, biotechnology as a manufacturing process is of increasing importance in the pharmaceutical industry for API production and also in food production, as discussed earlier. The monitoring of these types of products is therefore discussed in this chapter. As also visible from the workflow, the pharmaceutical part of manufacturing is an important part of the production process; this part is also discussed. The downstream processing is monitored in the chemical as well as in the pharmaceutical industry. Because of the strong regulatory influences, the specs for downstream processes are much tighter in the pharmaceutical part compared to the chemical and therefore the monitoring of downstream processes is performed much more rigidly in this industry. Here, a few examples are discussed.

38.3.1
Raw Material Control

In the pharmaceutical industry, each raw material that is purchased is tested with respect to identity, assay, and purity before use. Depending on the type of raw material, the supplier and the stage in the synthesis where the material is used, the tests are more or less complex. For many raw materials, the current test procedures are still laboratory tests, which contain wet chemical and physical parameters and often also a chromatographic purity test. NIR spectroscopy has changed the field because it can be used for identity and purity tests. In the purity test, not only are the individual impurities identified but the impurity profile is also identified to be ‘‘in-spec.’’ One of the advantages of the pharmaceutical industry is the high degree of standardization in production and the high regulatory standards. This means that the chemometric calibration models only need to include a relatively limited number of raw materials and a relatively low number of different qualities for the raw materials. The interface for the application of NIR in this field is typically an attenuated total reflectance (ATR) probe as described in the subsequent text, and both the NIR technique and the chemometric model are described in detail elsewhere [10].

38.3.2
API Production

Chemical reactions often lead to more than one product. In case of chemical products, often the by-products are recycled or used in a separate product. In API production, typically, a synthesis from 5 to 15 chemical, biological, microbiological, or their combinations lead to a single product that must have a purity of higher than 95%, often higher than 98%. This means on each step of such a synthesis, the control of the purity and the assay are essential to receive a high yield of the final product with the necessary quality. Therefore, the individual synthesis steps can be purified (which sometimes has to be performed in addition to process control) and or the chemical reactions can be controlled to lead to the optimum quality. In addition to the control of the chemical process, the endpoint detection of chemical reactions is useful to keep the desired product instead of forming degradation products. Endpoint detection also may save other resources such as energy, equipment time, solvents, and other resources. For a growing number of chemical synthesis steps, process controls, the so-called PAT-solutions, are under establishment. Historically, process control implementations only have been established if necessary because of the relatively high costs in a batch process environment with low annual batch numbers.

A chemical reaction that is widely investigated with respect to start and endpoint determination is the Grignard reaction. One of the major reasons is the safety control of this reaction in a production plant environment [11, 12]. The principle of the reaction is the reaction of an organic halide with solid magnesium in tetrahydrofuran (THF) to Grignard reagents R-Mg-X, which then is *in situ* used by the reaction. This first reaction is a spontaneous and extremely exothermic reaction. Therefore, it is vital to control the start of the reaction und extremely useful to monitor the whole reaction till the end. Although various approaches have been tested, Fourier transform infrared spectroscopy (FTIR) monitoring has been proved to be the most useful method [11–13]. In some cases, NIR has been used [14].

The implementation of a mid-IR (infrared) spectrometer in a plant environment is more complex compared to NIR because, typically, the coupling has to be direct to the process, whereas NIR can be coupled with a fiber optic to the process. The mid-IR spectrometer is coupled to the process using an ATR-type interface. The spectrometer itself has to be installed in an Ex-proven box directly connected to the reaction flask where the monitoring is performed. In case of defined chemical conversions, the advantage of mid-IR is that in some cases a single wavelength is characteristic for the conversion. Therefore, the evaluation is much easier compared to the complex mathematical evaluation typically performed in NIR monitoring, as shown in Figure 38.2. Here, the reaction monitoring for the Grignard reaction at three different wavelengths versus time is shown K. Lovis, unpublished, 2000.

Another field where process control applications are being implemented for a number of years is the final step of the chemical process that leads to the API itself, in case this step is a crystallization step under salt formation. The reason for using process control here is that different polymorphs could be generated and typically only one of the different polymorphs leads to the correct pharmaceutical formulation. Very few examples of pharmaceutical process monitoring for this final synthesis step have been published. A published process monitoring example is the formation of an HCl salt from a free base. In this reaction, the free base, the

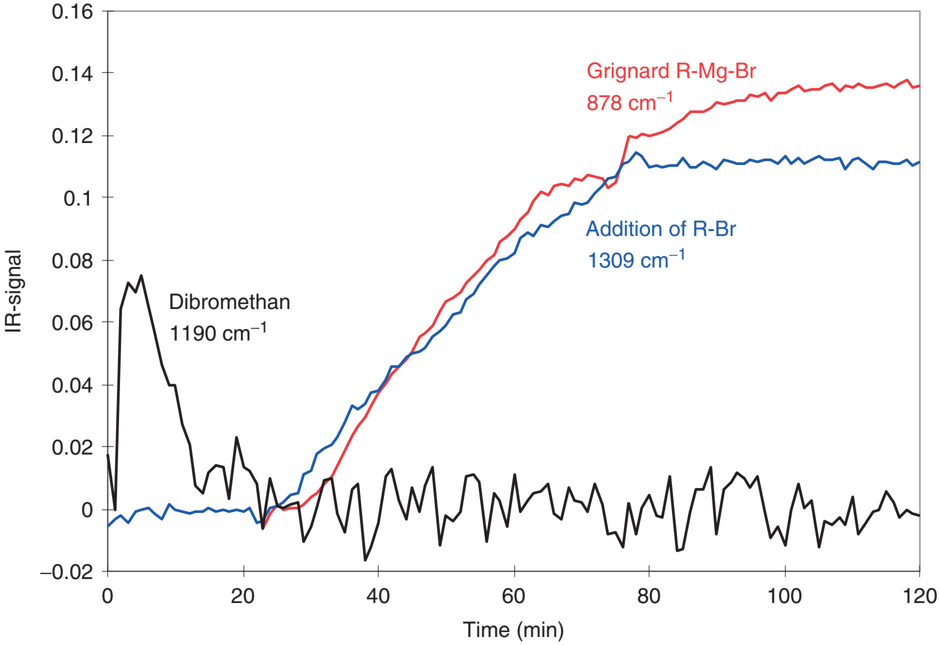

Figure 38.2 Mid-IR monitoring of a Grignard reaction.

mono- and the bis-HCl salt are found, where the free base and the bis-HCl salt can be monitored by IR. The mono-HCl salt is the desired product, whereas the bis-HCl salt is an impurity. The optimum of the reaction, where the salt formation/addition of HCl is stopped, is found at the flat point of the concentration profile of the free base. At this time, the concentration profile of the bis-salt starts increasing. The paper shows that the endpoint determination of a salt-formation process using mid-IR is possible; for details, see [15]. Another example of a combined process control for crystallization, where also the particle size control is discussed, is given later in this chapter.

38.3.3
Biotechnology

Biotechnology has been used for about 8000 years [16] for beer manufacturing and still has an extremely broad use in food manufacturing from wine, acetic acid, leaven, to various milk products. In general, the so-called classical biotechnology is understood as the use of microorganisms in technological processes besides food; fermentations including composting and waste water plants are also covered by this definition.

Currently, biotechnology has a much wider range and is structured in four fields of application:

- green biotechnology is the use of any kinds of plants including genetically modified plants;
- red biotechnology is the area of any kind of biotechnology for the manufacturing of drug substances;
- blue biotechnology has its focus in the marine area;
- white biotechnology is the industrial manufacturing and use of biotechnology for any kind of products from chemicals via textiles to food products.

The field of biotechnological products ranges from enzymes, vitamins, amino acids, antibiotics, aroma substances, vaccines, fine chemicals, monomers, and many others products. New areas such as energy conversion play an increasing role in the application area of biotechnological processes. The importance of biotechnological processes for the pharmaceutical industry is both changing in the area of chemical entities and growing for the area of biopharmaceuticals.

An overview of the products of the white biotechnology, where process control is typically applied, is given in subsequent text [17] (Table 38.1).

38.3.4
Technological Aspects of Biotechnology

For the discussion of process control in biotechnology, a few explanations on the technology itself have to be given as introduction. In biotechnology, reactions are preformed at room temperature and normal pressure. The control process has to take into account two major points. On one hand, the microorganisms themselves have to grow and produce biomass and, on the other hand, the concentration

Table 38.1 Important products of white biotechnology.

Product	World annual production in tons
Riboflavin (vitamin B2)	30 000
Vitamin C	80 000
L-Glutamic acid	1 500 000
L-Lysine	700 000
L-Threonine	30 000
Citric acid	1 000 000
Acryl amide	100 000
Polylactide	140 000
Bio-ethanol	>18 500 000
Beer/wine	165 766 000
Antibiotics	<80 000
Glucose	20 000 000
Iso-glucose (HFCS)	8 000 000

high fructose corn syrup (HFCS)

of the desired product should increase to the optimum. First, process control has to care about biomass. Typically, cells replicate within hours or days; that is, *Escherichia coli* (*E. coli*) under optimum conditions replicate every 20 min. For monitoring the biomass generation, a measurement cycle of one point per hour is typically sufficient and typically the input into a reactor is well known in the form of air (oxygen), additional sugar, additives, and so on. For monitoring the biomass growth, therefore, the output can be measured, which means measuring the gases CO_2, H_2, CH_4, pH, and acetate. In many cases, the monitoring of the gaseous compounds is routinely performed by gas sensors on the basis of IR sensors, commercially available for many years. In the past decade, in addition the monitoring of the target compounds has become state of the art. In the beginning, these analyses have been performed within the day-shifts off-line, whereas currently on-line- or in-line-analytical-systems are being implemented or are already state of the art. A detailed example is given in subsequent text.

Central to the concept of bioprocess monitoring are the sensors with which measurements are made. Nature has developed very efficient, highly precise methods of controlling biological processes. The challenge is to transfer these principles into technically applicable and precise analytical systems that can be used for many applications. Although this goal has not yet been met, it is nonetheless true that an impressive range of sensing devices has been developed over the years for measurement of chemical, biological, and physical parameters of both up and downstream bioprocesses. These devices are conveniently categorized as biosensors, chemosensors, or optical sensors, depending on their detection principle.

In addition to the measurement of traditional bioprocess parameters such as substrate, product and biomass concentrations, there will be an increasing need for new measurements. For example, as our design of therapeutic proteins becomes more sophisticated, it will be important to have measurements of particular glycosylation patterns. A drug with multiple chiral centers is another case of a complex analyte. Other motivations for sensors will come from systems biology: although sensors for some compounds of the metabolome have been described or even commercialized, these usually cover only some of the extracellular metabolome and only a small fraction of the range of intracellular compounds. On-line sensors of the transcriptome and proteome may also be needed in the future. Regardless of the sensor type, the target analyte, or application, sensors are expected to be sensitive, selective, and specific. Continuous signals and rapid responses to analyte changes are desirable, especially for process control purposes. An additional requirement, less recognized but perhaps more important, is for robustness and the ability to function in real bioprocess environments for extended periods. This includes the need for aseptic measurements, either by sterilization of the sensor or by incorporation of a sterile sampling device. Although perceived as less glamorous than the invention of a new sensing technique, creative ideas are also needed to solve practical problems so that new sensors can be commercialized and implemented [18].

38.3.5
Overview of Analytical Technologies Used in Biotechnology

38.3.5.1 Off-line/At-line

In biotechnological processes, a wide range of classical analytical techniques are applied; especially if the analysis is not time critical, the analysis is still often performed in a laboratory [19]. The techniques typically applied in the laboratory are high-performance liquid chromatography (HPLC), GC, nuclear magnetic resonance (NMR), and others depending on the process. For determination of the biomass concentration, often ultraviolet–visible (UV–vis) (optical light absorption) or gravimetric dry biomass is determined at-line. In addition, a number of analytical measurements such as density, titrations of acid concentration in the medium, and a large number of enzyme tests are performed off-line or at-line. As an example, for a spectrometric test typically performed close to the process in biotechnology, the glucose determination by the generation of glucose-6-phosphate may be mentioned. In this determination, the glucose-6-phosphate reacts with its dehydrogenase to the corresponding lactone. In this reaction, NADP+ is converted to NADPH (nicotinamide adenine dinucleotide phosphate), which is detected at 334 nm in a UV–vis spectrometer. Alternative tests are also commercially available on the basis of amperiometric detection [19].

38.3.5.2 On-Line

As already mentioned, a number of gas sensors based on IR detection are used in on-line biotechnology process control to monitor the gas flows of CO_2, O_2, N_2, and Ar through the fermentation [20]. The fermentation brow itself depending on the question is monitored on-line by many optical spectroscopic techniques from refractive index measurements, to UV–vis to IR and NIR spectroscopy [21]. The reason these techniques are applied on-line instead of in-line often is that the biomass in this case does not interfere with the optical path. In process development also, combined techniques consisting of HPLC and MS [22] are used to generate process understanding by structure elucidation of metabolites. MS has an additional advantage compared to other spectroscopic techniques such as NIR in case of unknown contaminations. While an NIR model typically can give only the information that there is something wrong, the MS is capable of structure elucidation of unknown components. In a process MS, the mass of the unknown component would become available and could give a first hint to the impurity or contamination.

38.3.5.3 In-Line

If the transparency of the fermentation brow allows use of optical techniques also in-line, in many cases UV–vis spectrometry and NIR are used directly in the process to determine mass growth, the concentrations of feed, the compounds of interest and also by-products such as acetate. The typical challenge for using in-line process control in biotechnology is that the sensor has to be sterilized. For NIR, in addition, the calibration is much more complex than in many other cases because of the very complex mixtures.

38.4
Examples of Applications of Process Control in Biotechnological Processes

As mentioned, the gas analysis of the reactor outlet is an important indicator for the growth of the cells in the fermentation process. The gases of interest are, for example, O_2, CO_2, or also ethanol. Because ethanol is difficult to measure, in the fermentation brow, the in-line measurement in the gas phase above the fermentation by IR sensors can be used alternatively. This measurement can either be performed by MS [23] or by IR sensors [24]. In the outlet pipe of the fermentation reactor, the on-line application of MS is also possible. The advantages of MS are the high analysis speed (within seconds) and the sensitivity down to the parts per million range. The disadvantage is the higher investment cost of a process mass spectrometer. This is partially compensated for by the quite low costs of maintenance [25].

The IR example described in detail in [24] shows an example of yeast fermentation. In this fermentation, first the increase in biomass is desired. Although the feed contains enough carbon source (e.g., sugar) the production of ethanol starts. Because the ethanol decreases the biomass production speed, this so-called Crabtree effect usually is unlikely. Therefore, for the control of all gases, CO_2 for the overall turnover in the process and ethanol for the type of turnover are used to control the fed-addition, that is, for example, the glucose, and by this way to minimize the effect of the Crabtree effect (Figure 38.3 and Figure 38.4).

The three sensors in the waste gas line are directly coupled to the control system of the fermentation. The sensors can in many cases be used to estimate

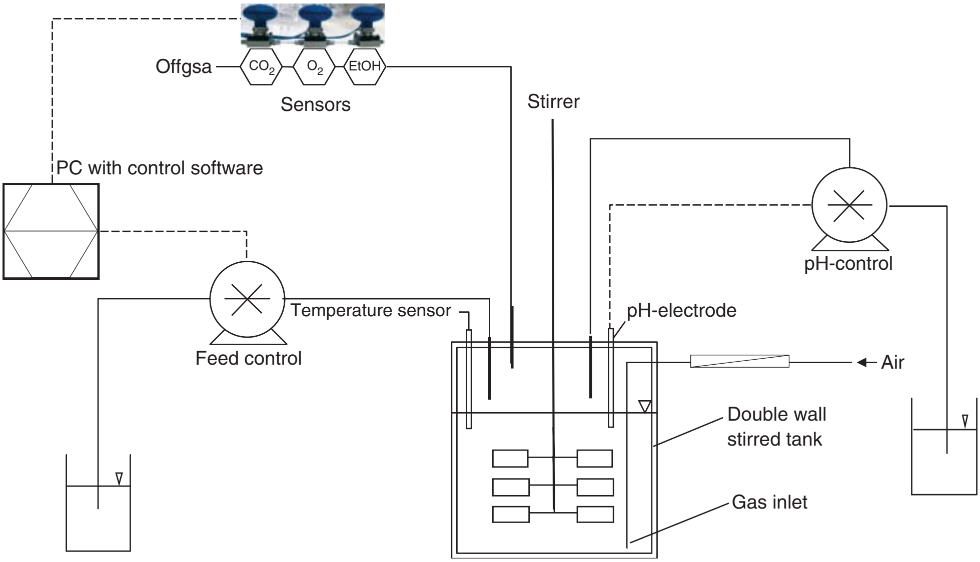

Figure 38.3 The experimental setup with the three gas sensors in the waste gas line.

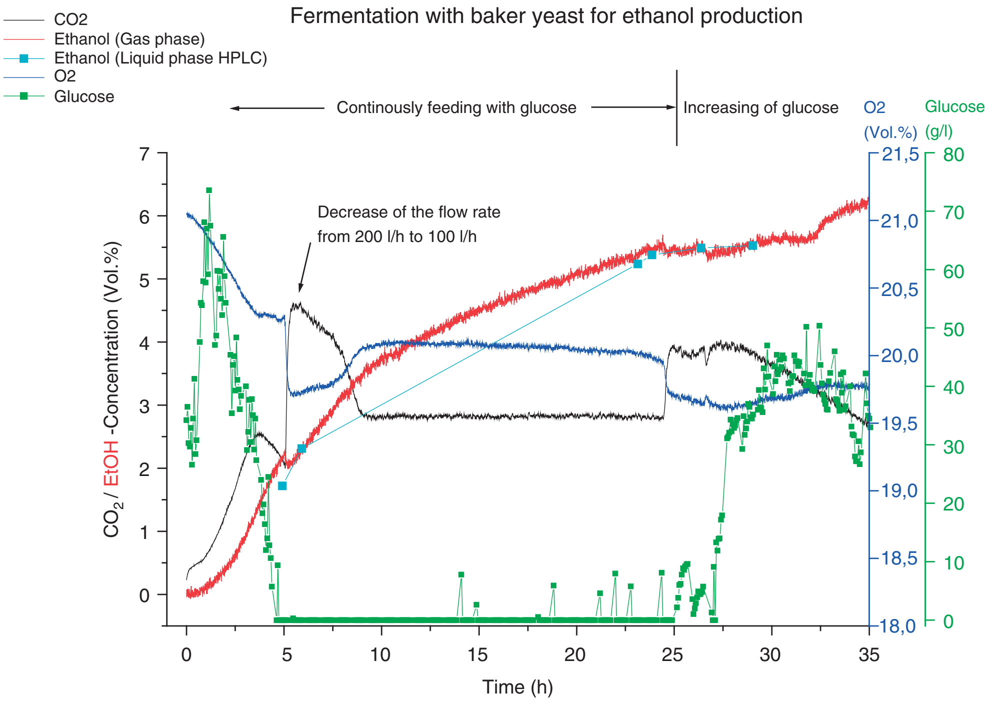

Figure 38.4 Typical results of a fermentation with the received sensor signals for CO_2, ethanol, and O_2. In addition, the added glucose and the determined ethanol concentration in the liquid phase (determined by HPLC) is shown.

the biomass generation by the carbon dioxide sensor, whereas the oxygen sensor shows the limitations of the process. In Figure 38.4, a typical curve of fermentation without process control is shown. This leads to a continuous increase in the ethanol concentration, which leads to the limitation of the fermentation. In Figure 38.5,a controlled fermentation is shown. Here, the ethanol concentration controlled by the sensors is nearly kept constant. For details, see [23].

Optical sensors have become more and more important for bioprocess monitoring. The term *optical sensors* is used here to encompass all analytical methods that are based on interactions of light with matter. Optical sensors offer the advantages of noninvasive, nondestructive, continuous, and simultaneous multianalyte monitoring. A major advantage is that no contamination is introduced into the process if on-line or in-line monitoring can be performed. Optical systems do not interfere with metabolism and thus *in vivo* measurements are possible. This can yield intracellular information that is difficult to obtain with other methods. As modern bioprocesses are extremely complex and differ greatly from process to process (e.g., fungal antibiotic production vs mammalian cell cultivation), appropriate analytical systems must be set up for each biotechnological process, designed to meet the special demands of the particular process.

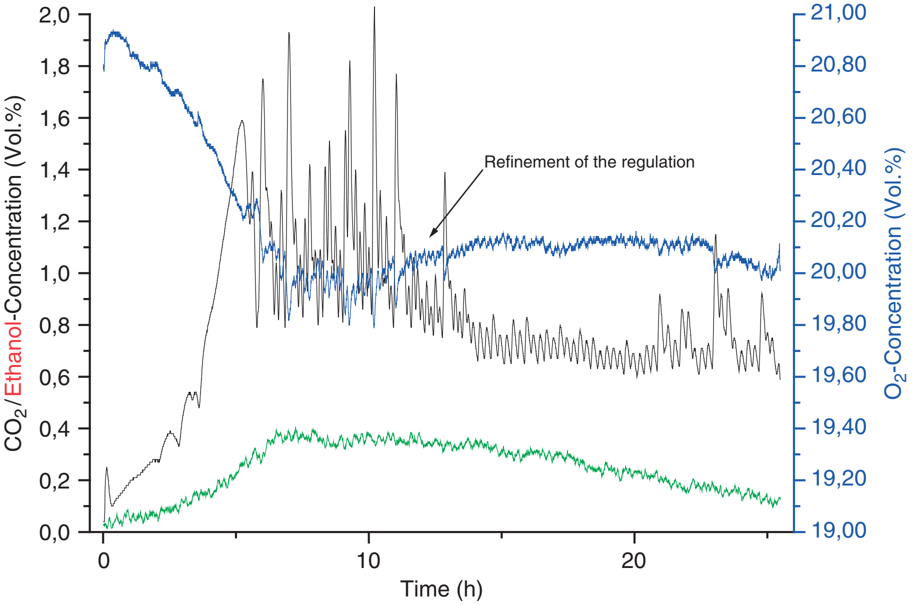

Figure 38.5 The resulting curves of a process-controlled fermentation. Here, the production of ethanol is limited to the desired range.

In most cases, the sensors are based on a few analytical principles, namely, ultraviolet (UV) spectroscopy, IR spectroscopy (NIR and FTIR), Raman spectroscopy, fluorescence spectroscopy, and pulsed terahertz spectroscopy (PTS).

Some current applications of these sensor types in biotechnology are described in subsequent text.

38.4.1
Application of UV Spectroscopy

UV spectrophotometers with high resolution are suitable for use in on-line monitoring of fermentation and downstream processes. New UV spectrometers have been developed in the past years [26] capitalizing on recent advances in electronics and especially in the development of new light detectors. One main advantage of these new devices is the use of charge-coupled devices (CCDs) or photodiode arrays to replace photomultipliers in conventional spectrometers. Because of lower costs combined with robustness, optical spectroscopy detectors are increasingly applied in industrial processes. The development of a high-resolution UV spectrometer that is suitable for the on-line monitoring of different kinds of bioprocesses is described by Noui *et al.* [26]. In this application, a deuterium light source was used to produce a light beam with an effective spectral radiation range of 185–400 nm. With this instrument, one is able to measure a continuous spectrum and this technique allows the simultaneous detection of several analytes. Another approach to sensing focuses not on detection of specific target analytes but rather on integrated parameters. This is especially useful in complex media, including classical culture media, as well as in domestic and/or industrial wastewater treated by biological processes.

Pons *et al*. [27] described more global methods based on UV spectroscopy that can be used to rapidly detect ‘‘accidents’’ such as the appearance of an undesirable by-product in a fermentation broth or of a toxic substance in wastewater. These methods combine a ‘‘hard’’ part, for sensing, and a ‘‘soft’’ part, for data treatment. In addition to the direct measurement of compounds of interest, increasingly chemometric tools are used [26, 28, 29].

38.4.2
Application of NIR and FTIR Spectroscopy

NIR spectroscopy enables detailed monitoring of substrates and products in many important types of industrial and food bioprocesses in order to document progress, ensure comparable end-product quality, and process control. Examples include the report by Jorgenson *et al*. [30], who described a newly developed modification of multivariate statistical process control charts based on on-line NIR. This enabled simple, efficient identification of abnormal fermentation runs, even at an early stage of the fermentation, which is critical for industrial production monitoring. Sorensen [31] has developed prediction models for determination of lactic acid, acetic acid, pH, NH_3, and ethanol in grass and corn silages by *in situ* NIR spectroscopy. The application of on-line NIR spectroscopy to measure simultaneously the concentration of substrates and products of acetic fermentation (ethanol, acetic acid, and biomass concentrations) was reported by Garrido-Vidal *et al*. [32].

Other examples of the application of in-line NIR monitoring in food biotechnology include fermentation of *Lactobacillus casei* [33], wine [34], and yogurt [35] fermentation. The application of NIR in-line to monitor and control an industrial fermentation process was investigated by Tosi *et al*. [36]. The determination of biomass, glucose, and lactic and acetic acids during fermentations of *Staphylococcus xylosus* was performed by an interactance fiber-optic probe immersed in the culture broth and connected to an NIR instrument. Thus, NIR seems to be one of the most promising spectroscopic techniques for the future of bioprocess control and modeling [37]. In addition to NIR-based technologies, FTIR has also been applied to bioprocess monitoring. For an example, a novel attenuated total-reflection-FTIR sensor was used for continuous on-line monitoring of chlorinated aliphatic hydrocarbons in a fixed-bed bioreactor. The sensor was based on an ATR internal reflection element coated with an extracting hydrophobic polymer, which prevented water molecules from interacting with the IR radiation [38].

FTIR spectroscopy, coupled to sequential injection analysis (SIA) was employed by Kansiz *et al*. [39] for the on-line monitoring of an acetone–butanol fermentation by simultaneously determining acetone, acetate, butanol, butyrate, and glucose from the mid-IR spectra of the samples.

38.4.3
Application of Raman Spectroscopy

Raman spectroscopy is based on the phenomenon of shifted wavelength scattering of molecules excited with monochromatic light due to inelastic collisions of photons with the molecule. The application of Raman spectroscopy to bioprocess analysis was made possible by the development of adjustable lasers. In principle, it is suitable for multianalyte monitoring of complex industrial bioprocesses on-line [40, 41] as well as for performing differentiated measurements of certain parameters, as demonstrated by Shaw *et al.* [42] and Lee [43]. The simultaneous estimation of glucose, acetate, formate, lactate, and phenylalanine concentrations in *E. coli* cultivations using *in situ* Raman spectroscopy was recently reported [44].

Challenges to the application of Raman spectroscopy to bioprocess monitoring lie in the strong fluorescence activity of many biological molecules that often overlies the Raman signal. One solution to this is ‘‘shifted subtracted Raman spectroscopy’’; using this approach, the resulting spectra have much lower apparent noise and fluorescence owing to the cancellation of irregularities in the detector response [44].

38.4.4
Application of Fluorescence Spectroscopy

Because many important biomolecules fluoresce, it is not surprising that fluorescence spectroscopy has been applied to bioprocess monitoring for several decades. A promising new version of the classic technique is two-dimensional (2D) fluorescence spectroscopy, in which a range of excitation and emission wavelengths are scanned. In comparison to traditional NAD(P)H fluorescence techniques, this method provides much more analytical information with a single measurement. With 2D fluorescence, all fluorophores present in a sample can be monitored simultaneously. Recently, a noninvasive 2D fluorescence sensor was developed for the measurement of the whole cell biotransformation of L-serine and indole to tryptophan [45] and for industrial downstream processing of sugar beet molasses [46].

Fermentation processes can be monitored using various spectroscopic techniques for growth and metabolic activity monitoring, as mentioned in detail earlier. The group of Scheper and Hitzmann [47, 48] demonstrated the use of 2D fluorescence spectroscopy for monitoring fermentations used for protein production. In this case, the excitation and emission wavelength in fluorescence spectroscopy are used in the range of 250–550 nm for excitation and 260–600 nm for emission. The evaluation is performed using the 2D plots of excitation versus emission. Some known fluorophores are used as markers for the quantitative evaluation of the protein production.

38.4.5
Pulsed Terahertz Spectroscopy

The ongoing developments in PTS may lead to new analytical applications for bioprocess monitoring. The potential for applications in chemical and biological identification [49] has already been shown and first examples of PTS to examine low-frequency collective vibrational modes of biomolecules have already been reported [50, 51]. Those results demonstrate that PTS is a viable technique for time-resolved measurements of protein folding.

One of the most important fermentation processes in health care is vaccine production. Here, safety and quality of the product are of extreme concern and this why a number of technological developments have been performed in this area. An example of vaccine production is therefore used to show the current status of PAT in the pharmaceutical industry.

38.5
Example Vaccine Production for the Control of a Biotechnological Process

The upstream part of a vaccine manufacturing line is a typical biotechnological fermentation process. Typically, measurements such as temperature, pH, dissolved oxygen, and flow rates are measured in this process, but the product is also monitored. This is either possible by on-line coupling of HPLC or high-performance liquid chromatography–mass spectrometry (HPLC-MS) [52, 53], but direct measurements using NIR have also been demonstrated [54, 55].

For a few years, PAT-approaches have been implemented in this field. A promising example has been developed by Streefland and colleagues from the Dutch National Vaccine Institute (NCI). For vaccines, the process can stay constant but the vaccine that is produced changes typically each year. Therefore, the process was described by a design space that was evaluated by systematic process variations and process controls. The result of the systematic approach is a controlled process. The major process control tool is NIR, and as a result of process control the product testing effort can be reduced, which in the case of vaccine production is an important issue because it saves time for the product to come to the market, an especially important issue for vaccines [56, 57]. The key parameter for QC of the vaccines consists of on-line monitoring of the nutrient concentration by NIR spectroscopy.

38.5.1
Downstream Processing

As already shown in the previous example, the production of a drug substance consists of the chemical and/or biotechnological step but this step is always followed by some kind of downstream processing to isolate, purify, or modify the product to bring it into an appropriate form for the next process step. In the case of vaccines, the downstream processing is closely related to the fermentation and both processes are nearly integrated currently, which can also be seen in the above-cited literature. In addition, in this case, downstream processing only consists of heat inactivation and concentration to yield the bulk product. This process step has only very low impact on quality. In chemical API manufacturing, the different chemical steps typically show a much larger change from one step to the next. Therefore, downstream processing may have an enormous impact on quality by the purity of the received intermediate. This importance of the purity of the material is therefore much higher and it gets an increasing importance the closer the chemical step comes to the final product. An important downstream processing technology is crystallization, which is often controlled by process analytics, now increasingly using a PAT-approach. After the purified product has been received, often a drying follows as the next process step. Here, the temperature could lead to the destruction of the product and therefore drying is the second important downstream processing in pharmaceutical industry, which is often controlled by process analytics, again with an increasing trend toward PAT-approaches. Examples for crystallization, drying, and mixing are discussed subsequently, as typical process control steps. During downstream processing, other changes might also appear, as, for example, polymorphic transformation. Many of these processes are currently observed offline, but might be also controlled on-line as the same technologies are used as shown elsewhere [58].

38.5.1.1 **Crystallization**

Crystallizations are a typical purification in the synthesis of organic products in API or fine chemical manufacturing. In many cases, besides elimination of by-products, the crystallization is also used to receive a desired polymorph of a product (in case of the final step of the synthesis). For further processing, the particle size (distribution) is adjusted to the desired range, to make washing, filtration, and drying as easy and robust as possible. In pharmaceutical manufacturing, the particle size/particle size distribution of the API may be also essential for the formulation. The monitoring of crystallizations therefore has received high attention since the FDA has started the PAT-initiative [1]. In this initiative, a regulatory agency for the first time has requested that the quality should be demonstrated within the process.

As already mentioned, the key issues in process design and scale-up of crystallization processes are

- robustness
- particle size/distribution
- polymorphic form.

To receive these goals, process control for critical crystallizations is necessary to control the thermodynamics of the process in a reproducible manner. Up till now very often in process development, the crystallization is investigated and in production a procedure based on the process knowledge is used to receive the needed quality. With respect to the PAT-view, this procedure does not demonstrate the quality of the process; here, a continuous process monitoring would allow the demonstration of the quality, and the product could be directly forwarded to micronizing, for example, without offline testing.

Therefore, the following paragraphs will describe the crystallization process and the techniques focused beam reflectance measurement (FBRM) and ATR–FTIR as tools to understand and control the crystallization in pharmaceutical production from process development via scale-up to process monitoring in manufacturing. For details, see also [59–62].

For any optimization in crystallization, first the solubility of the compound of interest in various solvents needs to be known. The solubility is a thermodynamic parameter and therefore is valid also for scale-up and other variations of other parts of the process. Unfortunately, the solubility may strongly depend on variations in impurities. The solubility data typically is achieved in laboratory experiments by either gravimetric or chromatographic (HPLC) methods. For some time, the use of ATR–FTIR measurements have been growing in importance [53]. Besides the solubility area (below the solubility curve (Figure 38.6)), there is a metastable area above the solubility curve where the system can exist as an oversaturated solution without spontaneous crystallization. The automatic determination of the solubility curve and the metastable area can be performed be in-line measurements with IR sensors (ATR–FTIR) and the solid product, in this case, is characterized, for example, by FBRM with respect to particle size and distribution. The crystallization its self is than optimized by changing the environmental parameters (temperature (cooling)), addition of seed or a so-called antisolvent, stirrer speed, and so on.

38.5.1.1.1 **Crystallization – Monitoring** FBRM [63] is one of the techniques that have been widely used for in-line crystallization monitoring for a few years. The probe is directly introduced into the reactor. The technique works even with a

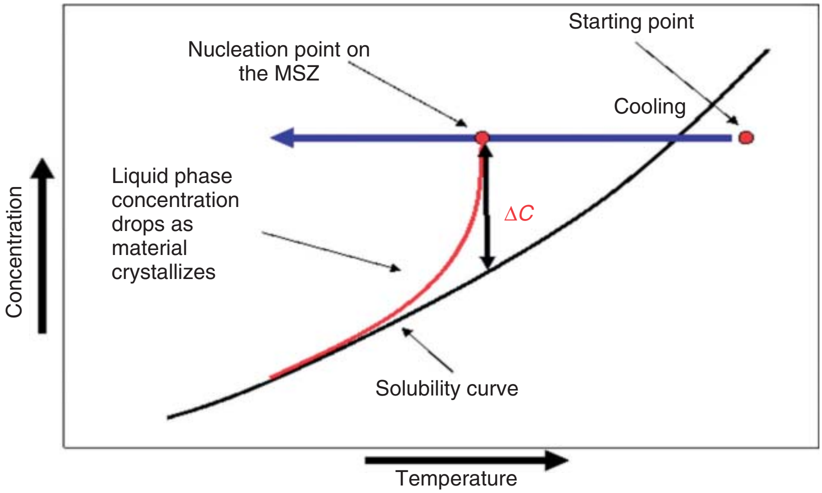

Figure 38.6 Schematic diagram of the cooling crystallization process (MSZ = metastable zone).

relatively high concentration of solid material in solution. In principle, FBRM is based on a focused, rotating laser beam. This laser beam is reflected by particles in solution. This reflected part of the light beam is analyzed and a so-called chord length distribution – CLD versus particle diagram is received in real time. This distribution is directly correlated to number, size, and form of the analyzed particles (Figure 38.6). The conclusion from the CLD/particle diagram provides information on the status of the crystallization, that is, if the process leads to growth of crystals or if the number of new crystals increases. The optimization by variation of parameters such as temperature (i.e., cooling) can be monitored in real time (Figure 38.7).

Figure 38.8 shows the typical change in the concentration of the compound of interest in solution during a cooling crystallization, as, for example, measured by IR. The concentration first increases because of the decreasing temperature. The concentration crosses the solubility curve into the metastable area and finally the crystallization starts, which leads to a decrease in concentration. This curve can be used both for process optimization and later on in manufacturing as a characteristic for process reproducibility. Figure 38.8, therefore, might be one parameter in a PAT-concept for a parametric release of the product.

Monitoring of a complex, real-world crystallization is shown in Figure 38.9. The crystallization is initiated by seeing and is then controlled by cooling. The figure shows the CLD plot of three different particle sizes (front) and in the background the temperature profile. In the beginning of the crystallization (A), the temperature is kept constant with a clear solution without particles. At B, the seed is added, which is seen in the FBRM signal. After the number of particles has become constant, the cooling starts. At this time (C), the particle size increases. This becomes visible because the number of larger particles increases dominantly. This also means that in C the generation of new particles is a process of low importance.

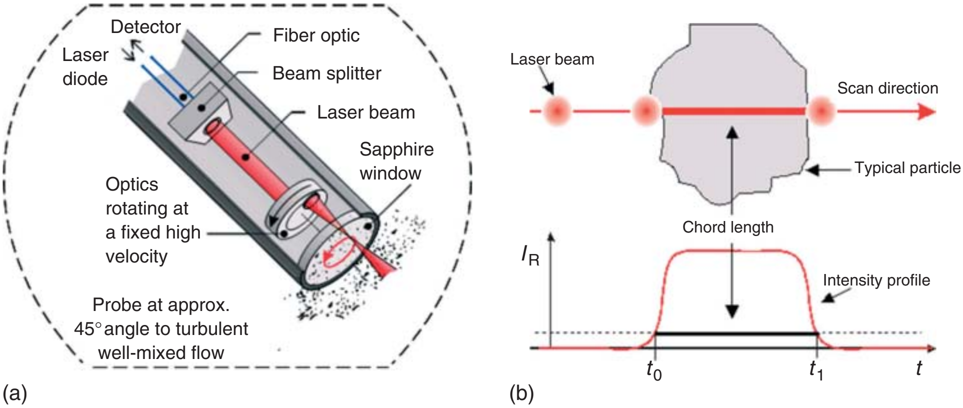

Figure 38.7 FBRM probe head (a) and the general measurement principle (b).

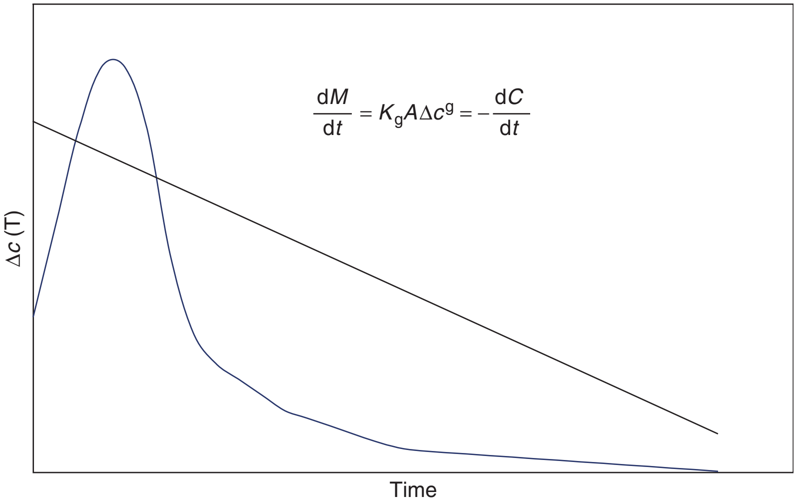

Figure 38.8 Schematic representation of the concentration profile of the component of interest during crystallization.

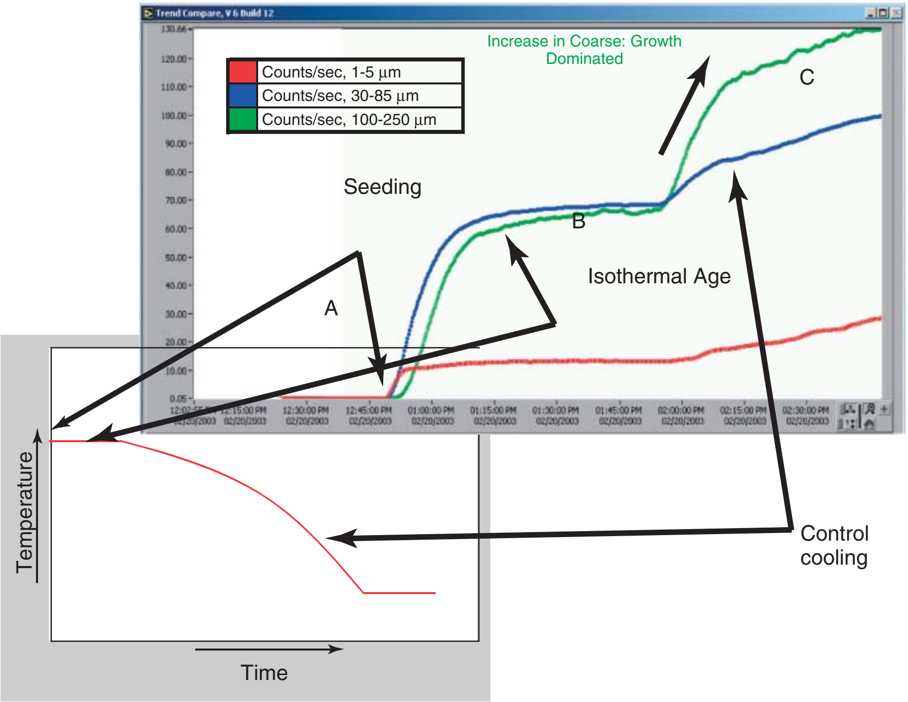

Figure 38.9 Evaluation of the FBRM measurement during cooling crystallization (for details, see text).

The knowledge of particle generation and growth kinetics allow the generation of a protocol for a robust process. The process stability is in addition supported by the independent optical techniques [62, 64].

Process control as described here as a tool improvement of quality is typical in the pharmaceutical industry. Up to now, most of these technologies were mainly used in process development, but since the PAT-initiative the number of implementations that allow real-time quality monitoring is increasing.

The product received so far either is transferred directly to the next process step or is isolated in a dry form, which typically is much more stable and can be stored for further processing, can be analyzed, may be released as a drug substance, and may then be also transferred to another site. But, typically, this drying process is also a process step with a high impact for the quality of the product and is therefore monitored by process analytical tools.

The current interest in many large scale batch processes is not only to control the process on the macroscopic scale but also to understand the process in different scales to molecular dimension during scale-up. This is of course of extremely high importance if phase changes are part of the process as in crystallization. Some attempts have been made in process tomography [65] and the combinations of spectroscopic tools with other techniques. A promising example is given by Simon *et al*. [66].

38.5.1.2 **Drying**

The partial or complete removal of solvents is an important process step in manufacturing pharmaceutical intermediate and final products. These drying processes extract water and other solvents from the substrate up to a precisely defined residual value. The extraction of solvents from a given batch is often accomplished considering substance- and plant-specific regimes of heating and evacuation cycles. In addition, many of these drying cycles use make-up or inert gas to support the drying process and protect product quality.

Batch production processes are dominant in the pharmaceutical industry and various drying apparatus types are used. The drying endpoint is reached at different times depending on the substance and solvent in the batch. The drying endpoint is the point where the residual content of solvent decreases to the required level. The current method to determine the solvent content of the batch is usually accomplished via manual sampling from the drying apparatus and offline analysis in the company laboratory. The repeated iterations on drying determinations are labor and time intensive using discrete sampling especially in the case of the vacuum drying processes, which often results in interruptions of the process vacuum and thus the drying processes.

On-line measuring methods offer a better alternative. The primary purpose is to draw conclusions about the progress of the drying process, to document the drying process as completely as possible and to reduce the number of manual samplings considerably or completely. The on-line measurements may be used advantageously for developing and optimizing a specific temperature and pressure behavior inside the drying apparatus with regard to reduced drying times.

The increased introduction of continuous process analytical technologies in the production schemes resulting from the PAT-initiative of the FDA may thus be supported effectively. Two spectroscopic techniques that are typically used are NIR for drying of water based drying, which are very often applied in the API step, or MS as a more general technique that can nearly detect every solvent. Applications for both types of drying procedures are presented. Besides these two spectroscopic techniques, the drying process often is monitored by IR-heating-based drying balances. These balances are used as a screening tool at-line in the plant. They are quite fast, do not need a calibration but because the heater is an IR lamp the balance does not work with all kinds of materials and all kinds of solvents. In some cases, these type of balances lack seriously in accuracy. The Karl Fischer (KF) titration is used in QC laboratories because of the high precision but currently it is no longer used in a plant environment. The drying of organic solvents in control laboratories is also monitored by GC, typically coupled to a headspace sampler. The analysis times are typically too long and data evaluation typically too complex for at-line analysis.

38.5.1.2.1 **Drying Monitoring by NIR** As known, NIR is very sensitive to water and therefore in the pharmaceutical industry, drying monitoring is very often monitored with this technique. NIR nearly has replaced the classical monitoring techniques such as KF-water-titration, which also has been used widely also in plants as an at-line process control by experienced technicians. One of the major problems of this technique is that the humidity in production plants is typically kept very high for explosion prevention. Therefore, for very hygroscopic products taking a sample and transferring it to the plant laboratory may be a major reason for wrong results.

In contrast, NIR can be coupled directly to various drying processes, also for the often used vacuum drying process. Especially again for later steps in a chemical/biotechnological synthesis, where the product value is high, and sometimes the product is temperature labile, vacuum drying is applied. In this case, there is a slow drying gas flow pumped through the system. The outlet line of the vacuum dryer can by directly coupled in-line to an NIR instrument.

But the NIR sensor can also be directly coupled to the various dryers where the NIR sensor directly measures the water content on the surface, which is proportional to the water content of the water in the bulk sample. There are various types of dryers. Very often, in the pharmaceutical industry static dryers are used, were the product is typically placed on a plate of about $50 \times 50\,\text{cm}^2$ and then the product is dried. In these dryers, the problem is that the sample drying kinetics is also part of the NIR calibration model because NIR only can analyze the first few nanometers of the material, whereas the material is lying in a layer of a few centimeter thickness on the plate. In these dryers also, for each product a separate calibration model is needed. Depending of the crystallization, there still might be deviations from the calibration model because the particles have slightly different sizes and this changes the drying kinetics. Later, an example of a high-shear fluid bed mixer and dryer for the granulation in pharmaceutical manufacturing is presented. In this case and in other examples where continuous mixing of the drying material is applied, the calibration of NIR [67] is much more stable and it has even been shown that the calibration may be widely independent of the drying material [68]. Also, NIR drying monitoring in a paddle dryer works extremely well [69]. A very special type of drying, freeze drying, was also monitored by the PAT-tools Raman and NIR. The authors compare and evaluate the strengths of the techniques during the process [70].

38.5.1.2.2 **Drying Monitoring by On-Line Process Mass Spectrometry** Similar to many biotechnological approaches, in drying also the analysis of the gas stream leaving the drying chamber can be used for the control of drying processes. In this case, for the complete drying process, the gas atmosphere inside the drying apparatus may be monitored and documented continuously with a process gas mass spectrometer. The interesting point for MS is that a wide range of solvents can be analyzed with one instrumental set up and one calibration strategy. Therefore, this approach is typically advantageous in multipurpose chemical production processes.

The continuous sampling of gas samples can be taken at the drying apparatus outlet, in the outlet gas stream, or in the vacuum suction line. When the drying is to be monitored both in the vacuum area and when working with carrier gas, the mass spectrometer will be equipped with a two-stage, pressure-controlled gas inlet to adjust constant pressure conditions for the mass spectrometer. The pressure control at the gas inlet is done independent of the gas type and for an inlet pressure range of 1–1200 mbar (absolute). The sampling lines and the gas inlet can be heated to measure solvents with low vapor pressures. Multiple drying apparatuses (up to 16) may be connected via a multiport valve unit and measured consecutively with one mass spectrometer.

Typically, quadrupole mass spectrometers are used for various reasons:

- Mass spectrometers allow for continuous measuring of the solvent concentration in the gas phase without interruption of the drying process. Measurement may be done inside the drying apparatus at various pressure ranges.
- Mass spectrometers have a high sensitivity (detection limit <0.1 ppm) and a wide dynamic measuring range (0.1 ppm to 100%), allowing for continuous monitoring of the drying process up to very low ‘‘loss-on-drying’’ (LOD) values.
- The measuring principle of MS has a high selectivity for the individual solvents. Partial pressure curves for all solvents may be determined and evaluated individually.
- In addition to the solvent concentrations in the gas phase, it is possible to measure further components such as, for example, nitrogen, oxygen, or argon and thus detect possible malfunctions or leakages of the drying apparatus at an early point of time.
- Solvent analysis can be accomplished fully automatically with measuring parameters [mass numbers (MNs)], selected for given solvents (Table 38.2).

38.5.1.2.3 **Vacuum Drying in a Blade Dryer as an Application Example**

Because many chemical intermediates of final products are temperature labile, on one hand, different types of dryers are used; sometimes, only the sophistication of the dryer alone will not guarantee the quality of the product. Therefore, in some cases process control is also implemented. In the example presented here, a quadrupole mass spectrometer was connected via a pressure-controlled gas inlet to the vacuum suction line of a blade dryer. During the drying process, the air constituents and the two solvents, water and isopropanol, were measured in the residual gas from the suction line of the drying apparatus.

Figure 38.10 shows the concentration curve for water, isopropanol, and nitrogen during the final phase of the drying process. For comparison, the results of five manual samplings with subsequent determination of the LOD are also stated in the figure. In the example, the target nominal value for the LOD is 6%.

The blade dryer was bathed with nitrogen. The sample lock chamber is flushed with nitrogen, resulting in considerable N_2 concentration increases during sampling.

Table 38.2 A selection of various solvents with mass numbers (MN 1–4) of the most important mass spectrometric fragment ions.

Solvent	MN 1	MN 2	MN 3	MN 4
Commonly used solvents				
Water	18	—	—	—
Methyl alcohol	31	32	29	—
Ethyl alcohol	31	45	29	46
Acetone	43	58	—	—
Isopropyl alcohol	45	—	—	—
Cyclohexane	56	84	41	—
N,*N*-Dimethylacetamide (DMA)	44	87	72	—
Methyl-*tert*-butylether (MTBE)	73	57	41	—
Toluene	91	92	—	—
Butylacetate	43	56	61	—
Some other solvents

T: temperature in the drying apparatus

p: total pressure in the drying apparatus

LOD:Loss-on-drying

Figure 38.10 Example of a concentration curve of water (H_2O), isopropanol (i-Prop), and nitrogen (N_2) in the suction line of a blade dryer. (By courtesy of Boehringer-Ingelheim Pharma GmbH & Co. KG, Ingelheim.)

As shown in Figure 38.10, at the start of the drying apparatus evacuation, isopropanol is volatized first from the substance. After 50 min, the drying rate for isopropanol drops to <1% of the stationary value.

In this example, the necessary drying time is mainly determined by slower water vaporization. In the drying phase from 2:35 p.m. to 3:25 p.m., the concentration value for water remains nearly constant. The transition of water from the surface of the substance particles into the gas phase is the limiting effect on drying in this example. From about 3:25 p.m., the measured water concentration in the suction line starts to drop and may be related to the degree of dryness. If this correlation is once determined, it is no longer necessary to take samples for repeated determination of the LOD and the drying process can be controlled via parameters that are measured on-line.

The concentrations or partial pressures of the solvents measured with the mass spectrometer may be used directly or after calculation with further process quantities such as temperature or absolute pressure in the dryer. Calculation of the process variables may be done directly with the control software of the mass spectrometer.

The mass spectrometric determination of solvent concentrations or solvent partial pressures in the gas atmosphere of a drying apparatus results in data sets that are suitable for optimization of drying processes.

The drying curve may be tracked and documented on-line with the mass spectrometer. As soon as the correlation to the LOD values has been determined once, the end of the drying process can be inferred from the mass spectrometric data without delay. The time saving that results from this allows for an improved plant utilization and reduces energy costs. The avoidance of unnecessary offline analyses also contributes to cost reduction.

The mass spectrometric data gives important information for optimization of the temperature, pressure, and carrier gas parameters in process development, particularly with regard to influencing the sequence of individual drying steps if there are several solvents. It is also easy to detect critical dryer conditions (leakages, starting disintegration of the product, etc.).

38.6
Pharmaceutical Manufacturing

The API is the end-product of the chemical (biotechnological, and so on) process and also the starting point of the pharmaceutical process. In many cases, the API manufacturer and the pharmaceutical manufacturer are two different companies. The process therefore typically starts with the identification of the starting materials for this new process. Besides the API depending on the dosage form, different materials have to be identified, for example, microcrystalline cellulose, cellulose ethers, starch, additives, urea, fats, and so on. Currently, this is often performed by NIR identification. The NIR is used as a qualitative tool and sometimes also as a quantitative tool [71] in these cases. With a number of test substances, a chemometric model that allows discrimination of the product in the specified quality from other products and other qualities is established. Applications in detail can be found elsewhere; for example, see [9]. Some quality parameters may not be checked by process control tools; therefore, depending on material and specification, classical laboratory analysis is also performed at this stage of the process. An overview on the application of process control in pharmaceutical manufacturing is given elsewhere [72–74].

After all starting materials are released, the pharmaceutical manufacturing process consists of a formulation where typically the API and the other excipients have to be mixed to a homogeneous mixture. Often, this mixing and blending process is also monitored by process control currently, in many cases with optical spectroscopy such as NIR or IR. For the manufacturing of tablets, this mixture often undergoes a granulation process. This is a physical process of agglomeration of smaller particles to larger conglomerates. This step is necessary for the tablet compression process. In the granulation process, water is added to the mixture followed by drying. Here again, the homogeneity of the mixture, with respect to the distribution of the API, the water content, and the particle size distribution, have to be controlled. In addition, the drying process is critical for many pharmaceutical products because of possible degradation. Therefore, the water content is monitored – which is a typical NIR application. Current trends show that the blending, mixing, granulation, and drying are under way for integration. An example of such an application is discussed in detail in subsequent text.

38.7
Granulation

In-line NIR spectroscopy is already a common tool for the measurement of moisture in granulation and drying processes in fluid bed equipment [6, 75, 76]. Reliable and robust in-line measurements are a key factor for applying the PAT-philosophy in a production process. Many authors have proved the successful use of NIR spectroscopy for in-line moisture detection. The drawback of the NIR spectra is a high amount of influencing factors, which are all physical or chemical properties of products. These lead to a high amount of samples that are necessary to reach a high prediction accuracy of the methods. These circumstance hamper the application of the NIR in-line measurement in the daily production. An example o such a process is described in subsequent text. Alternatives to NIR are also reported in the literature, using microwave resonance technology [77], which is at least currently only a niche technique with only very few applications.

Relying on the high influence of the water content on the NIR spectra at selected wave length, the current scope is to establish moisture detection using several products and two different processes by employing the same calibration curve. This would allow considerable reduction of the calibration samples needed for each product and thus lead to higher acceptance of in-line IR spectroscopy in production.

The example shown uses an NIR spectrometer model Xone made by NIR-Online GmbH, Waldorf, Germany, including a software implementation based on a PLS (partial least squares) algorithm. Two different types of processes were evaluated in the fluid bed. In the first, the fluid bed was used as a dryer in a full closed in-line process subsequently after the high-shear granulator. In the second type of process, the fluid bed was used as a spray granulator where the whole granulation process was carried out in the fluid bed. The fluid bed system consists of different types of fluid bed mixers of Hüttlin GmbH (now a subsidiary of Bosch). Two different fluid beds (HKC 200 and one high-shear mixer HMG 600) were used to evaluate the influence of the equipment. Table 38.3 depicts the process equipment used to manufacture the different products.

The reference method for the moisture analysis was a thermogravimetric moisture meter type MA 100 (Sartorius AG, Göttingen Germany). The drying temperature was 130 °C and the endpoint was reached, when the changes were <1 mg during 5 min. The wide difference between the NIR spectra of the 16 products is shown in Figure 38.11.

In Figure 38.12 and Figure 38.13, the calibration curves of products 1 and 10 are presented. The standard error of prediction for the cross validation for these products was 0.22 and 0.24% relative humidity, respectively.

Figure 38.14 contains calibration curves of the 16 different products. The standard error of the prediction for the cross validation sums up to 0.33% relative humidity. Thus, it is only slightly higher when compared to the single product curves.

The application of only one calibration curve for the product moisture detection of 16 different products was successful. The standard error of prediction was only 0.22% relative humidity, which is acceptable in many production processes. Even

Table 38.3 Process equipment used for production.

Product	Batch size (kg)	Process equipment	Composition
Product 1	131	HKC 200[a]	94% Lactose; 6% PVP K25
Product 2	131	HKC 200[a]	76% Lactose; 19% starch; 5% PVP K25
Product 3	136	HKC 200[a]	88% Lactose; 9% HPC; 2% starch
Product 4	100	HKC 200[a]	85% Magnesium-carbonate; 9% HPC; 9% lactose
Product 5	100	HMG 600 + HKC 200[a]	46% MCC; 38% calcium-carbonate; 10% lactose, 5% croscarmellose (additive)
Product 6	125	HKC 200[a]	Blend of API and additives
Product 7	125	HKC 200[a]	95% Lactose; 5% PVP K25
Product 8	125	HMG 600 + HKC 200[a]	87% Lactose, 10% starch, 3% PVP K 25
Product 9	125	HMG 600 + HKC 200[a]	67% Lactose, 10% starch; 20% MCC, 3% PVP K 25
Product 10	100	HMG 600 + HKC 200[b]	Blend of API and additives
Product 11	200	HMG 600 + HKC 200[b]	46% Lactose; 30% MCC, 16% HPMC; 5% crosspovidone; 3% cellulose
Product 12	200	HMG 600 + HKC 200[b]	Blend of a mixture of different APIs with additives
Product 13	125	HMG 600 + HKC 200[b]	Blend of a mixture of different APIs with additives
Product 14	200	HKC 200[b]	Blend of a mixture of different APIs with additives
Product 15	200	HKC 200[b]	Blend of a mixture of different APIs with additives

many *ex situ* measurement systems in the daily production have a lower accuracy. A further decrease in the standard error of correlation and prediction should also be achievable by applying a reference method with a higher accuracy such as KF titration instead of a drying balance [68, 78]. Also, the measurement of particle size is under establishment, which will introduce another spectroscopic method as an in-line process control into this process.

Typically, in the pharmaceutical industry, the mixing and granulation is performed in batches. For batch mixers, it is important to know how long the components have to be mixed. The reason is not only saving time and therefore money but also the risk of overmixing, as some bulk materials have the tendency to segregate after the mixing quality has passed through an optimum. The determination of the

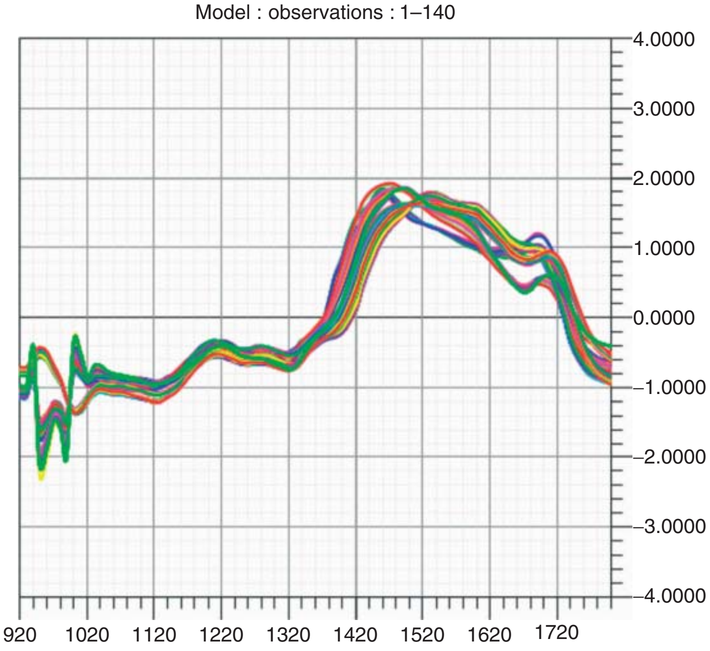

Figure 38.11 Near infrared spectra of 16 products.

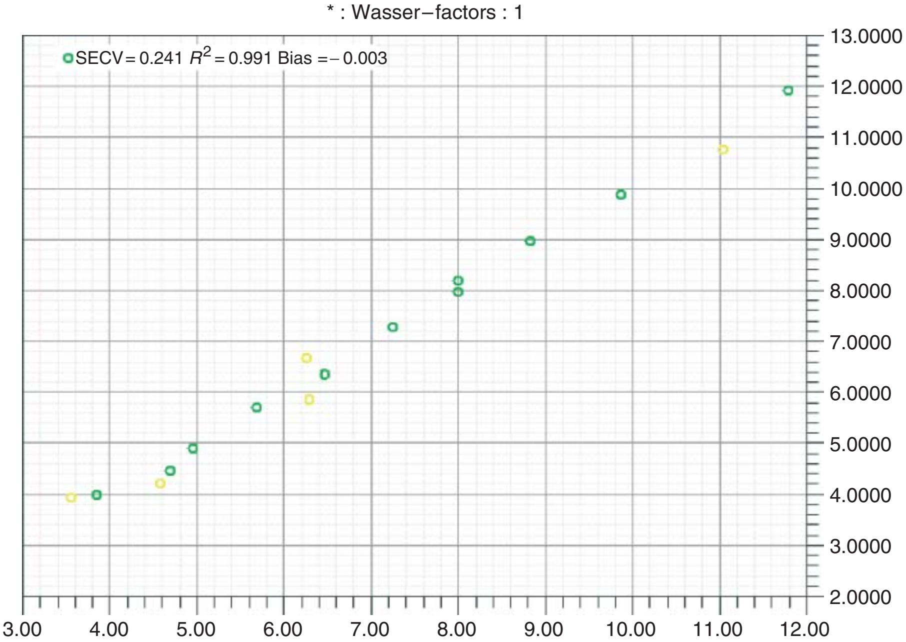

Figure 38.13 Calibration curve of product 10.

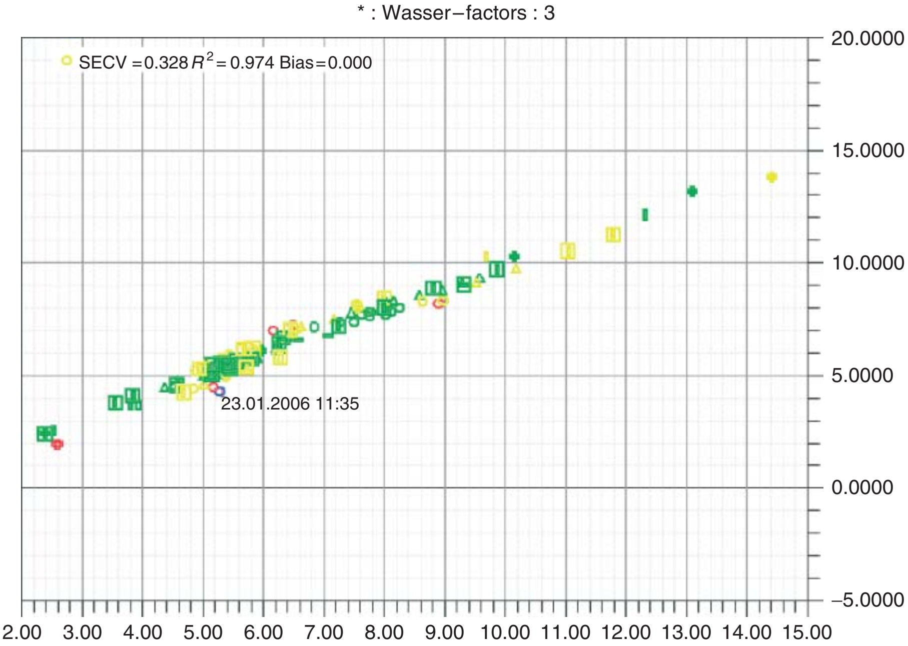

Figure 38.14 Calibration curve containing all 16 different products.

optimum mixing time is performed using the above-mentioned approach. In very few cases only in the pharmaceutical production of extremely large products is the currently continuous mixing used, whereas the process of continuous mixing and drying is also, for example, used in food processing. Here, it is a very import unit operation. In continuous mixing, there is a different reason for applying process control. Although the dimension of continuous mixers is relatively small, their throughput can be very high. In order to reduce or even avoid wastage, it is important to react as fast as possible to deviations of the product composition from the specification. An example for the control of a batch mixer has already been shown. Similar approaches can be found for instrumentation from various manufacturers, with different implementations of the sampling system [79]. The monitoring of a continuous mixing process in polymer manufacturing has also been shown in Chapter 2 of this section. Other authors [80] have developed an approach for applying NIR spectroscopy to receive a fast feedback process control of continuous mixing of powders for various industrial applications.

38.8
Final Product Control

After mixing and homogenizing of the product in the pharmaceutical industry, the product is filled into tubes, pressed to tablets, or filled into vials (liquid products). Further on, there is also some process control using NIR, typically for identification reasons. In many cases NIR is applied, but in some cases other techniques have also been described. An interesting application is the identification of tablets by Raman spectroscopy [81]. The interesting point here is that the peak-rich Raman spectra combined with chemometrics even allow the determination of the source of a tablet, for example, if a tablet is an original product or a generic product [82]. In recent years, counterfeited products are becoming a serious problem in the pharmaceutical industry. This has led to a number of investigations where spectroscopic techniques from NIR via IR to Raman have been used to identify the manufacturers' own products via profile intermediates, impurities, or, for example, by polymorphism [83]. A wide range of techniques has been applied to the characterization of the final product, mainly in research projects. Another interesting example with the potential to routine control is the nondestructive determination of film thickness of tablet coatings by optical spectroscopy [84] or terahertz spectroscopy [85]. Other examples describe the use of Raman spectroscopy to investigate multiple layers [86], which might also be relevant for the process control of tablet manufacturing.

38.9
Packaging

A very young application of spectroscopic tools in the pharmaceutical field is the filling control of vials, capsules, and injection solutions. In some drug cases, this is relevant because the amount of drug per dose is controlled by the filling level. A number of different techniques have been used for different cases from optical spectroscopy, via X-ray and time-domain nuclear magnetic resonance (TD-NMR) [87]. Some of these applications such as the fill level inspection via X-ray are already used in routine manufacturing, whereas others such as the TD-NMR techniques are still under evaluation.

Applications of Optical Spectroscopy to Process Environments

Stephan Küppers

39.1
Optical Techniques Applied in Process Control

Optical spectroscopy covers the interactions of matter with the electromagnetic waves in the range between UV to far IR [1]. Details of the optical spectrum can be found above [2]. Nearly the whole wavelength range is used for spectroscopic applications. The way of interactions with matter may vary from adsorption via reflection of light to more complex processes such as scattering, fluorescence, or chemiluminescence. There are a number of different physical processes underlying these spectroscopic processes that are discussed in various textbooks of spectroscopy and also above [2]. All of these spectroscopic techniques with the underlying physical processes are used in process control, some of them in very few and even very special applications. Some applications are also mentioned in other chapters of this section.

In the mid-IR-region two fields of applications for process control are found. On one hand, the interaction with the IR range is used for the selective detection of individual components by a single characteristic wavelength that has no (or nearly no) interference with other component spectra in nondispersive infrared (NDIR) and the use of more than one characteristic wavelength, typically in complex reaction monitoring using Fourier transform infrared (FT-IR) spectrometry.

The NDIR instruments are used in many gas-analytical applications, for example, in safety monitoring. The general principle of NDIR is the use of one light source that is split into two separate beams and both beams are filtered through a fixed wavelength filter. The filter wavelength is chosen for the sample of interest and only the wavelength that leads to an adsorption of the sample goes through the filter. Typically, the reference beam goes directly to the detector, whereas the sample beam interacts with the sample in a flow cell. The difference between the two signals at the detector should be proportional to the sample concentration of the component of interest. NDIR instrumentation has been used for decades in the same way. Commercially available instruments currently show a number of different instrumental designs following the same principle with one or two beams, with one or multiple wavelengths. Typical applications are the gas

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

monitoring devices, for example, for carbon dioxide, carbon monoxide, ethylene, nitrogen oxides, sulfur oxides, and so on. For details, see elsewhere [3].

For about a decade the use of near-infrared spectroscopy increases dramatically [4]. The reason is the use of chemometrics for the evaluation of NIR spectra. The difference between mid-IR and NIR mainly is that in the NIR area, overtones and combinations of various vibrations are summarized in one spectrum. In addition to the number of bands and the mixture of overtones and combined vibrations, the NIR bands are broad. All this made NIR spectra difficult to interpret for many years. This has changed with chemometric models that allow the fast evaluation of NIR data. Another important advantage of NIR versus mid-IR is the possibility of using fiber optics for the transmission of the light to the sample and NIR signals back to the spectrometer. Therefore, a standard NIR spectrometer can be installed outside the so-called Ex-area, whereas the fibers (up to 100 m) can transport the signal from the Ex-areas of a plant directly to the spectrometer. In cases of permanent installations, multiplexing capabilities of NIR can also be used to monitor a process stream at various places (i.e., stages of the process) or even different processes can be monitored. NIR is very sensitive to water and changes of water in various forms. Typical examples for applications of NIR therefore show a high correlation with the change in the water content, for example, drying process monitoring, granulation, and so on. Also, many food manufacturing processes are correlated with the change in the content of water or the bonding of water to other components of the product. Therefore, NIR has a large number of applications in food processing.

UV–vis spectrometry, instead, is a classical process control technique. Traditionally, UV–vis spectroscopy is/was used at-line. In some configurations, on-line or in-line implementations are used. The reasons for using UV–vis spectra is, on one hand, that color is an important specification in many products and, on the other hand, that the conversion of aromatic ring structures in many chemical processes can be used to monitor the rate of conversion or determine the endpoint of a chemical reaction. UV–vis spectroscopy in process control is comparable to the use in the laboratory; the instrumentation is also comparable. Typically, the low price of instrumentation for UV–vis instruments and the importance of color, besides the ease of use, are the reasons for using UV–vis spectroscopy. Often, process control still uses filter instruments, which means that a filter is used to select the wavelength at which quantitative information is gathered. These are used because they are cheap and robust. The instruments are built in the same general way as described for dispersive IR. Details on instrumentation in optical spectroscopy are also given above [2].

Raman spectroscopy has been a niche technique for a very long time owing to limited availability of laser sources and because for many years the so-called ‘‘notch filters’’ have not been available for nonmilitary use. The interest in Raman spectroscopy has for some time been growing strongly in laboratory and process control use. The Raman effect is a scattering effect, which means that a small number of molecules scatter light elastically. This scattering leads to a slight wavelength shift. The shift contains information on the molecule that has interfered with the light. Raman spectra show sharp bands and are information rich; this means that for process control selective information on the state or conversion of the molecules of interest can be extracted. In addition, this information is complementary to IR, which means that in some cases where IR does not give the desired selectivity Raman may be an interesting alternative. Water is a very weak Raman scattering molecule. This means that in contrast to NIR, Raman spectroscopy is especially of interest when the water content in a process is high but concentration changes of water do not correlate with the ongoing process.

Because the Raman effect is very small, most of the light collected from the sample has the same wavelength. This light has to be eliminated with the notch filter before the information can be extracted in a spectrometer. All this makes Raman spectrometry complex and expensive, but there are also some advantages for Raman spectroscopy for process control. Because nearly no mechanical parts are involved in a Raman spectrometer, the technique is robust and the excitation as well as the emission light can be transferred by fiber optics, which gives the same advantages for process control using Raman spectroscopy as for NIR spectroscopy with respect to explosion zones.

Laser diode techniques have been developed especially for process control. An application for the monitoring of gases using a tunable diode laser absorption (TDLAS) in chemical manufacturing has been described in detail before. The laser diode techniques are suitable and applied in various gas analytical tasks; see also further applications in this field in the literature [5]. One advantage of laser diode techniques is their usability at high temperatures. So, monitoring of gas components in harsh environmental conditions is possible. Although some of the examples are very interesting, laser diode techniques are currently expected to be niche solutions for the time being.

Another interesting niche technique in optical spectroscopy is fluorescence spectroscopy. The principle and the best-known application of fluorescence is the same as in the laboratory, the detection and determination of polycyclic aromatic hydrocarbons (PAHs). With fluorescence, this can be done in combination with high performance liquid chromatography (HPLC) in the laboratory but also in or on water in the environment. Similar applications are the determination of the film thickness of oil on water, which is described in detail elsewhere [6]. The advantages are the low sensitivity and the robustness of the systems.

39.2
Instrument Design for Process Control

In many cases, as described earlier, in process control, the same or similar basic instrumentation is used as in the laboratory environment. The software and the interfaces to the various process systems, depending on industry and product type, are always different from the laboratory instrumentation. In special cases, as in laser diodes or fluorescence, the whole setup is designed for the process application.

In many cases, the interface to the process is specially designed and adapted to the process. This is always necessary for in-line or on-line applications of optical spectroscopy. Besides the instrument manufacturers, there are some companies that have specialized in the field of interfacing the optical spectrometers to the process.

39.3
Coupling of Optical Techniques to the Process

Optical spectroscopy in measuring process control situations is applied in four different configurations:

- the transmission,
- reflexion,
- "transflection," and
- the ATR (attenuated total reflection)-mode.

Accordingly the geometries of the probes have to be different.

39.3.1
Transmission

Figure 39.1 displays the classical geometry of transmission measuring cells, suitable for most applications involving clear liquids. Measuring cells are available for measuring the concentration of transparent liquids directly in the pipe (production or bypass line). The transmission path length can often be set as variable or fixed. The so-called fixed settings are easy to change, with different distance bolts or base discs. The functionality is similar to that of a traditional cuvette setup. The light arrives from the transmitting fiber through an optic, passes the medium present in the pipe, and then is coupled to a second optic in the receiving fiber.

Depending on the application and installation points, transmission measuring cells (Figure 39.2) and transmission immersion probes are available.

The importance of crystallization has already been discussed. Besides the abovementioned approach other approaches are also used. One option is the monitoring

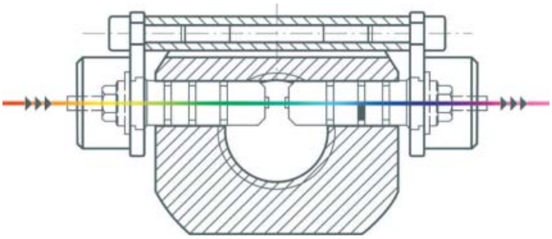

Figure 39.1 Transmission measuring cell schematic (courtesy of Solvias AG Basel).

Figure 39.2 Transmission measuring cell (courtesy of Solvias AG Basel).

using NIR. A typical way is that a pharmaceutically active ingredient (API) is crystallized from a solvent mixture containing two main components and one side component. The composition of the precrystallization solution is not accurately known. Efficient seeding is thus impossible and the product suffers from significant fluctuations in particle size and yield. The out-of-specification batches are either lost or need reprocessing, which is expensive and does not conform to cGMP. With NIR process spectroscopy, concentrations of all components (100% analysis) can be determined simultaneously. Such an application requires a process control, for example, by NIR spectrometer (in an Ex-free area) and an NIR transmission probe mounted in a bypass of the crystallizer and connected by fibers to the spectrometer. Application of NIR process spectroscopy has been shown to have a number of benefits: constant and increased yield; full control of polymorphs; reduced cycle time; uniform particle size distribution throughout all batches; elimination of expensive reprocessing steps; and savings in laboratory costs by fully automated determination of concentration.

Besides the examples discussed in previous chapters, further standard procedures for transmission measurements are

- color number determination according to American Public Health Association (APHA), Hazen, Lovibond, and Saybolt;
- reaction monitoring in chemical synthesis from UV to NIR range;
- control of process chromatography;
- solvent blending.

For gas measurements it is important to have a measuring cell with a long optical path length (OPL): ranging from 50 mm to over a meter; this is due to the low density of the molecules in the gas phase. For such special applications, there are fiber-optic transmission flow cells on the market, which allow measurement with such a long OPL. Examples are the measurement of UV–vis-absorbing gases (e.g., F_2, CL_2, Br_2, NO_x, SO_2, and ozone) and the measurement of UV–vis-absorbing substances in the gas phase (e.g., benzene, chlorobenzene, and phosgene). These measuring cells can also be used to monitor liquids used in cleaning validation programs for API production.

39.3.2
Transflection

In transflection mode – a combination of transmission and reflection – the sample is measured as in the transmission mode, only that the beam is reflected on a mirror; the OPL is thus doubled. Measurement in reflection mode is also possible with this type of probe (Figure 39.3).

Transflection probes have a multitude of applications – in multipurpose plants, in fermentation, or in organic-chemical process development – and thereby provide the user with a high degree of flexibility. For reaction monitoring in transmission mode, the OPL is in most cases easily and quickly adjustable to rapidly respond to changing concentration conditions. Typical are the examples for endpoint determination, where a pharmaceutical product is manufactured in a multistep chemical synthesis. One example where a successful implementation is possible is a condensation reaction, where an optimum product purity and yield is obtained only if the reaction is stopped as soon as the concentration of a certain reagent drops below 0.3%. This point is reached within roughly 4 h after the start of the reaction. Traditional laboratory analysis is slow and can therefore not be used for an accurate endpoint determination. For the real-time determination of concentrations of both the reagent and the product, an NIR spectrometer and an NIR transflection probe can be used. The probe is mounted in a reactor bypass and connected by fiber-optic cables to the spectrometer (in an Ex-free area). The bypass system allows easy cleaning of the transflection probe. The benefits are shorter cycle times, higher yield, avoidance of purification steps as the reaction is stopped before side products start to develop, and an optimized process due to ideal dosing profiles established on the basis of real-time reaction monitoring.

Besides the examples discussed in previous chapters, further standard procedures for transmission measurements are

- color number determination according APHA, Hazen, Lovibond, and Saybolt;
- reaction monitoring in chemical synthesis from UV to NIR range;
- control of process chromatography;
- concentration development monitoring in biotechnological fermentation processes.

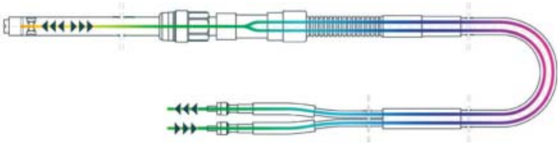

Figure 39.3 Transflection probe schematic (courtesy of Solvias AG Basel).

39.3.3
Diffuse Reflection

Diffuse reflection probes are particularly useful for heterogeneous reaction masses such as slurries, emulsions, or solids. Many processes involve transformation between or separations of liquid/liquid or liquid/solid phases. Optimal control of reaction steps can often be achieved with simple turbidity measurements. However, substantially greater quantities of information may be gained via the acquisition of diffuse reflection spectra throughout the course of the process. In diffuse reflection probes, light enters the medium through a window or fiber so that no light reflection is generated – which would otherwise lead to an unwanted offset. The measurement signal is produced through backscattering in the medium and is essentially proportional to the concentration (Figure 39.4).

Typical applications include the identity control, for example, of raw materials or the API used in a pharmaceutical formulation. Often, various APIs are delivered to a central storage facility. Before final processing, identities of all the ingredients must be checked. Conventionally, samples would be taken to the off-line QC lab for analysis, where the identification procedure takes up to a few days – a period far too long for efficient control of the process. On-site NIR analysis allows direct identification at the storage site within seconds and can easily be carried out by the stock-keeper through the polyethylene bags containing the APIs.

The identity control system consists of an NIR spectrometer and an NIR diffuse reflection probe connected via a fiber-optic bundle to the spectrometer. The benefits are redundancy of expensive laboratory analysis; time-saving, and more efficient storage due to on-site identification; improved work-place hygiene by avoiding sampling and analyzing through the PE bags; and elimination of potential error sources by simplifying the identity control procedure.

Besides the examples discussed in previous chapters, further standard procedures for transmission measurements are

- reaction monitoring in heterogeneous systems in NIR range;
- analysis of solids compositions directly in mixers;
- determination of residual solvents concentrations on solids directly in driers;
- noninvasive determination of residual solvents or water concentrations on lyophilisates directly in vials.

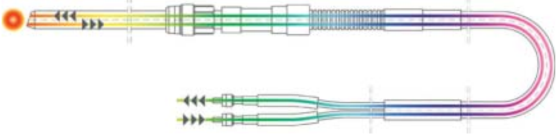

Figure 39.4 Diffuse reflection probe schematic (courtesy of Solvias AG Basel).

39.3.3.1 Raman and Fluorescence Probes

Raman scattering can also be utilized in rapid and efficient material characterization. In pharmaceutical manufacturing, *in situ* Raman spectroscopy has proved effective in monitoring crystallization processes in real time. Another widespread use of Raman spectroscopy can be found in the manufacturing of paint, where Raman immersion probes are used to monitor color during the mixing process. Similarly, *in situ* fluorescence spectroscopy is employed in the analysis of turbid and biologically active masses. Raman and fluorescence probes are very similar to turbidity probes, although Raman probes contain another in/out light coupling ratio as laser light is used to stimulate the sample, and well-selected filters are used to reject unwanted light.

39.3.4
Attenuated Total Reflection (ATR)

With ATR it is possible to take advantage of the total reflection of light transmitted from an optically dense medium to a less dense medium. The light at the boundary layer (e.g., sapphire/liquid) penetrates approximately a quarter of the wavelength into the less optically dense medium, where it can be absorbed. This method is applied mainly in the whole UV region and also in the analysis of dyestuffs in the visible region. Solid particles (e.g., catalysts) or bubbles do not interfere with the measurement. However, the path length is too small to acquire acceptable NIR spectra (Figure 39.5).

A typical example implemented was the hydrogenation of hydrazone, which is an important process in a fungicide production [7]. The reaction endpoint is critical because overhydrogenation produces unwanted by-products. Sample extraction under hydrogenation conditions is technically complex and does not yield representative process data. Immediate reaction monitoring with ATR spectroscopy offers two clear advantages: it allows for a direct and undiluted measurement of samples despite high absorbance in the UV range; and heterogeneous constituents such as catalysts have no influence on the spectrum, unlike in transmission measurements.

ATR probes are also used in heterogeneous catalysis (e.g., hydrogenations [8]) and where highly concentrated dyestuff is processed. Besides the examples discussed in previous chapters, further standard procedures for transmission measurements are

- reaction monitoring in heterogeneous catalyzed processes;
- on-line determination of concentrations in active ingredient- or color concentrates; and
- control of process chromatography.

Figure 39.5 ATR probe schematic (courtesy of Solvias AG Basel).

39.3.5
Fiber Optics

For the transmission of light from the probe to the photometer, different types of optical fibers are available. Generally, there are two transmission regions: the UV–vis region (200–900 nm) and the vis/NIR region (400–2200 nm); measurement with the same glass fiber in both UV and NIR regions are not possible from a physically technical viewpoint. For every region there is a high quality glass fiber, with small absorption in the whole spectral region. There are many attractively priced glass fibers for the visible region, as for other spectral regions. These can be used as extension fibers in specialized applications where the whole spectrum is not needed. Transmission lengths up to 50 m are possible without problems for wavelengths above 270 nm; in the vis/NIR region, distances of over 100 m have been successfully realized.

The application and potential of fiber-optic probes for the NIR and ultraviolet–visible (UV–vis) spectral region is described here. Application examples are illustrated for the different spectroscopic techniques: transmission, reflection, transflection, and ATR. These are only a few examples of many successful applications in chemical and pharmaceutical plants.

In addition, in order to enable the in-line use of spectroscopy in various processes where samples could clog the window or the tip of the spectrometer, for example, with powder mixers [9] or chemical reactions [10] installations have been developed to clean the probe tip of the spectrometer with air or solvents.

39.4
Additional Application of Optical Spectroscopy

A few interesting new applications are very reviewed in short to demonstrate the enormous range of optical spectroscopy in process analytics and control applications.

For future applications of process control, small productions and privately used productions sites, such as the decentralized generation of electricity, are becoming higher in importance because in many small and medium-sized production units there is still high potential for optimizations. An interesting new application is the process monitoring and control in biogas plants, shown by Baumgarten and Busche [11], recently. The production of renewable energy by biogas plants is the focus of interest owing to amendments in German law. The efficiency of biogas plants is highly dependant on maximized exploitation of the substrates for fermentation. Nowadays, modern biogas plants are not running on the maximum of efficiency. A reduced yield of biogas, among others, caused by a lack in measurement technology, is directly resulting in a waste of biomass and a loss of money for the plant owner. A quantitatively and qualitatively constant production of biogas is needed for an economic operation of the plant. Therefore, the requirements on reliable and precise process monitoring and control become more and more important [12, 13].

The optimization of the biogas production by continuous analysis of the fermentation process and the monitoring of the status of the plant is one of the interesting technological approaches to improve the production of ''clean'' energy. The advantages that can be achieved are

- balancing of the parameters of the mass fluxes;
- control and optimization of the feeding of the plant with dry matter and nutrients with respect to the gas yield;
- control of the stability of the process within the fermentation reactor;
- modeling and trend analysis for the regulation of the biogas production.

NIR spectroscopy can be applied to obtain relevant parameters of the fermentation process. The plant is monitored by a fiber-coupled NIR spectrometer equipped with a multiplexer. Parameters, such as dry matter, acidity, and pH value, are monitored on representative locations within the plant and quantitative results are available in the control room and for remote maintenance.

A scheme of a biogas plant with integrated measuring and control technology with the different measurement points using only one spectrometer is shown in Figure 39.6. The contribution of NIR spectroscopy is found in the increase in efficiency of energy production [11, 12]. One of the interesting points is that all parameters needed for the control of the plant can be achieved by one NIR spectrometer using a combination of chemometric data models, fibers for coupling to the processes and a multiplexing device. Such approaches open the door for a wide range of applications in various fields on optimization of ''microplants.'' This is of special interest for commercial reasons as also for environmental reasons, because in large-scale production processes often are already optimized, whereas in many small production facilities there is still an enormous potential for optimization.

The control of bioprocesses, as already described in the previous example, is discussed in the next short summary of an application. Because of its wide

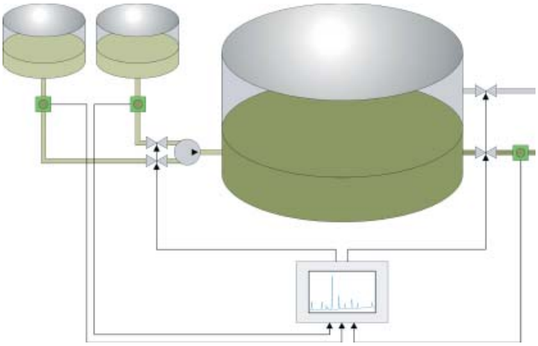

Figure 39.6 Scheme of a biogas plant with measurement and control system. The measurement points are the input lines of the substrate and the cosubstrate as also the gas phase and the liquid phase of the biogas reactor. The controlled units are the mass flow regulators of the substrate flows and the outlet of the reactor.

applicability, the monitoring of a bioprocess is described, in this case in order to ensure optimal biomass and product formation [13].

Till date, for product control in biotechnology off-line techniques such as HPLC or mostly HPLC-MS are often applied for nonvolatile components because the complexity of the sample mixtures typically does not allow to determine nutrients and products by NIR, even using chemometric modeling. The disadvantage of the off-line methods in general is that these measurements are performed with a time delay. To allow the determination of a number of different components of interest in a complex mixture, the information-rich mid-IR spectroscopy (FT-IR) was combined with data evaluation using PLS (partial least square) in an example presented by Hopf *et al.* [14].

Typically, FT-IR-spectroscopic methods are used for chemical process monitoring if the sample is not to complex and a direct correlation between one wavelength and the process is possible, whereas FT-IR-methods are not commonly applied for monitoring of biotechnological processes. For such a process, the ATR technique has been evolved as a suitable method for quantitative determination of components in bioprocesses in combination with FT-IR spectroscopy.

The advantages of IR spectroscopy in this case are

- the measurements are rapid,
- nondestructive,
- require minor sample preparation,
- provide the possibility of simultaneous constituent determination.

In their work, the authors presented an FT-IR spectroscopic method for monitoring the so-called dark fermentation, an anaerobic process for H_2 production. Special microorganisms are applied, converting different sugars to hydrogen and organic acids, such as acetic and lactic acid. Real substrates are conventionally hydrolyzed before their conversion. Considering the obtained sugar patterns, lignocellulosic material is mainly degraded to glucose and xylose, whereas fruit residues are composed of glucose and fructose. Therefore, it was aimed at generating a method to determine three monosaccharides and two organic acids simultaneously. A set of calibration (88) and test samples (47) was prepared according to a statistical plan. The measurements were performed using a standard FT-IR instrument with horizontal ATR with ZnSe-crystal with six reflections. Commercial Bruker OPUS Quant 2 Software was used for the PLS regression.

The results of calibration and validation are summarized in Table 39.1. The calibration yielded excellent data and regression coefficients close to one for several components. Similarly, the error of cross validation was very small, indicating promising applicability of this method. The validation with real samples and reference analysis by HPLC is in progress.

These few examples are intended to demonstrate the range of applications currently under development. In this field, a continuous process to more and more applications is under way, so that optical spectroscopy will go on dominating the field of process control.

Table 39.1 Calibration and validation results of the IR method for determination of glucose, fructose, xylose, acetate, and lactate in the range of 0–30 $g\,l^{-1}$.

Component	R^2	RMSECV	Used PCs
Glucose	0.9998	0.106	10
Fructose	0.9997	0.139	10
Xylose	0.9999	0.0838	8
Acetate	0.9999	0.0644	9
Lactate	0.9999	0.0862	10

Spectral Imaging in Quality and Process Control

Rudolf W. Kessler and Waltraud Kessler

40.1
Introduction

Applications in chemical imaging have only a short history compared to the widespread and well-known field of machine vision [1]. Especially, the use of chemical imaging in quality and process control is still a young subject but with no doubt of growing importance [2–4].

Spectral imaging is the combination of three possibilities, to characterize a sample, that are integrated into one single system: the chemical characterization; the physical, morphological, or texture characterization; and the lateral visualization of the above-mentioned, which then gives the image of the sample. The term *hyperspectral imaging* is used when images of more than 10 wavelength regions are recorded simultaneously. Which spectral wavelength range is chosen to build the image is decided on the basis of the application. It is the objective of this short introduction to outline the present technological alternatives, the setup of a sound instrumentation and calibration, and also the handling of the huge amounts of data that are obtained with each image. The data reduction is commonly done by multivariate image analysis (MIA).

Applications of ''chemical imaging'' in process control are interested in visualizing the distribution of different chemical components within a sample. This can be the protein content in fish or the distribution of an active pharmaceutical ingredient (API) in a tablet [5] or the distribution of binder and strands in oriented strand boards (OSBs) [6], only to name a few. These examples demonstrate that distribution of a compound or the particle sizes and their distribution and sometimes also the layer thicknesses of the coating or other structural details might be of interest.

40.2
Instrumentation for Chemical Imaging

The techniques in chemical imaging are generally classified into mapping and imaging techniques and depend on the used wavelength range [7]. The common

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

meaning of mapping is to measure a full spectrum of i wavelengths (λ_i) at one local point of spatial x_k- and y_l-coordinate of the sample. The complete image is obtained by adding the local information point by point to form a spatial image. The term imaging is used when the spatial image for several x_k- and y_l-coordinates is obtained simultaneously by measuring with a camera at different wavelengths (λ_i) sequentially. In addition, line scans are possible, which measure a full spectrum along a spatial line x in one go. In remote sensing, the different applied imaging technologies are labeled as [1]

- whiskbroom (''spot light'') imaging
- staring (''staredown'') imaging
- pushbroom imaging.

Figure 40.1 visualizes the different techniques. As mentioned, all techniques can be used in the wavelength ranges from UV to IR as well as with Raman and fluorescence spectroscopy.

A pushbroom imager is a line scanning system and acquires the full spectral information for all lateral x_l-coordinates in a single line, mostly called *x-pixels*, simultaneously. The system is a direct light imaging spectrograph that can be quickly combined with a broad range of matrix detectors to form a spectral imaging device. For process control, which is often applied to moving samples and therefore should be as fast as possible, the pushbroom acquisition mode is the best suited one. The sample is moved, for example, on a conveyor belt, in the y-direction and the imaging spectrograph measures a full spectrum (λ_i) for all x_l-pixels along the x-direction. A detailed description of the staring and whiskbroom imaging is given by Griffiths in [7].

Owing to cost efficiency and availability of technology, the focus for process control is emphasized to imaging in the spectral range of UV–vis, NIR, and also to IR and Raman spectroscopy [8] and to a certain extent even to fluorescence spectroscopy. They are reasonably inexpensive, readily available, and ideally suited and proved for in-line and on-line control. Using molecular or optical spectroscopy, several chemical components can be determined simultaneously.

When measuring opaque or scattering samples, special care has to be taken to the instrumental setup and the calibration procedures as well as the measurement procedures. This is described in detail by Boldrini *et al.* [9].

40.3
Chemometrics and Data Analysis in Chemical Imaging

The evaluation of hyperspectral image data for quality and process control is very much related to normal quality and process control in the way that the final decision parameters, which determine the quality of the product, can be qualitative as in ''pass'' or ''fail'' or quantitative such as the concentration of an analyte. The most obvious difference between hyperspectral image data and classical spectroscopic data is the sheer amount of data collected with each collected image. Another

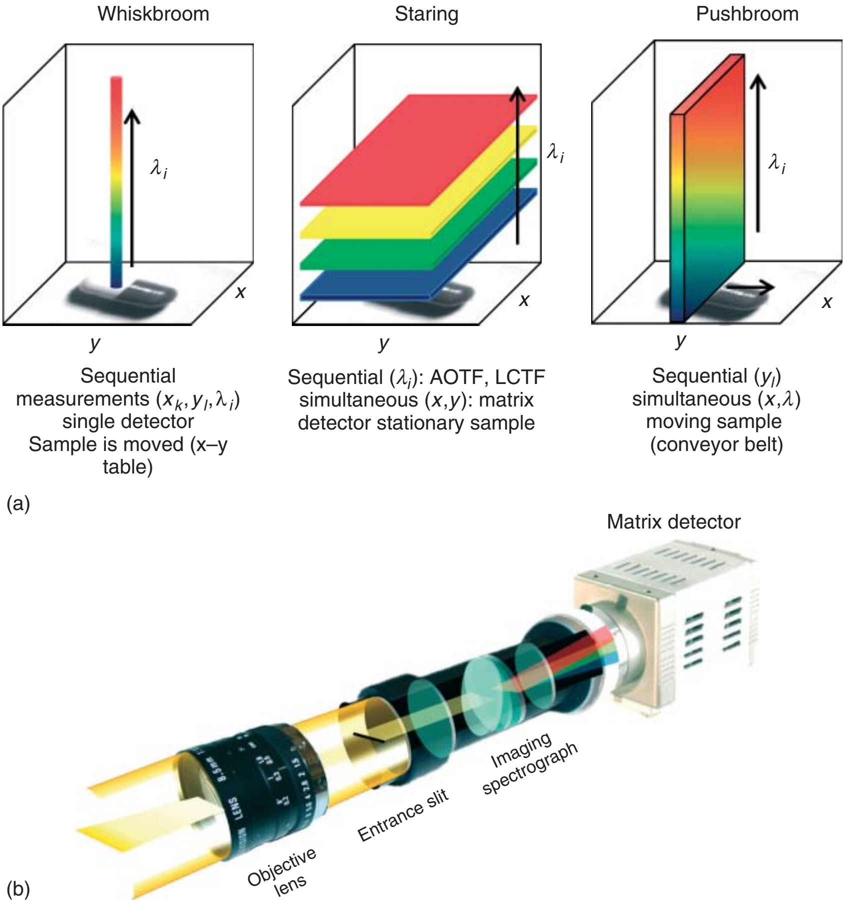

Figure 40.1 (a) Visualization of the different imaging technologies: whiskbroom imaging, staring imaging, pushbroom imaging and (b) a pushbroom imaging spectrograph. (Courtesy of Specim, *http://www.specim.fi*.)

important difference is the combination of spatial and chemical information in the hyperspectral image. By reducing the huge amount of data to the relevant information, chemometrics offers the possibility of using the full spectral information instead of extracting single-wavelength channels only. When chemometrics is applied, the relevant information is reduced to one or a few quality-defining so-called latent variables. Each spectrum is then represented by its score values, which are calculated from the latent variables. These scores are used to build either multivariate classification or regression models with the hyperspectral data. For images it is called *multivariate image analysis* and for qualitative analysis it is very often linked to principal component analysis (PCA). If a quantitative quality or process parameter is required, it is called *multivariate image regression* and is mostly related to partial least squares (PLSs) algorithms [10–12].

There has been constant development in chemometrics on the image analysis field and a number of good reviews and useful tutorials have been published [13, 14]. Multivariate curve resolution(MCR) methods belong to those chemometric tools that have been incorporated into the field of image analysis only recently and they have already revealed many successful applications [15–18].

Before a multivariate image analysis or regression is calculated, the data should be checked for obvious abnormal spectra due to instrumental artifacts such as bad pixels. A detailed description is given in [9, 19].

A very easy way to compress the original image is to bind two or more pixels together to form only one measurement. This can be done in the spatial and spectral dimension, but it is not advisable if a high resolution of the spectra is desired. In this case, data reduction by PCA is preferable in the spectral dimension. Often, three to five principal components (PCs) capture most of the relevant information of several hundreds of spectral pixels. The image is composed of the scores and can be looked at separately for the different scores or combining three scores to an RGB (red-green-blue) image. Figure 40.2 gives an example of the information contained in the different PCs (PC1 to PC3) of a hyperspectral image. The letters RRI (Reutlingen Research Institute) were written with a UF (urea formaldehyde) resin binder, which is commonly used in the production of OSBs. The image was recorded in the NIR wavelength range (900–1700 nm) with a pushbroom technique by moving the sample below the line scanning spectrograph. A PCA is calculated for the gathered spectra. Figure 40.2a shows the distribution maps of the scores for PC1. This score captures most of the binder information (dark blue letters), PC2 (Figure 40.2b) gives information on the morphology of the wood chip, and PC3 contains surface effects due to inhomogeneous illumination (Figure 40.2c).

The aim of PCA is more explorative but it is also possible to build regression models with the PCA scores, which are then regressed on target values as, for example, binder concentration as shown in the above-mentioned example. This is called *principal component regression* (PCR). But, as in traditional spectroscopy, the most commonly used algorithm for multivariate regression is PLSs regression (PLS regression, sometimes also called *projection to latent structures*) [11–13, 20].

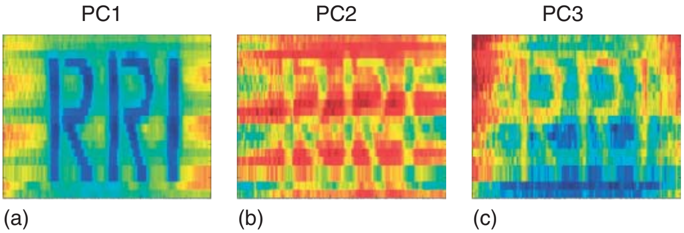

Figure 40.2 Example of data reduction by PCA: Three letters written with urea formaldehyde resin binder on a wood chip. Shown are the PCA scores of the measured spectra (a) PC1, which is the binder information; (b) PC2, which is the information of the morphology of the wood chip; and (c) PC3, which are surface effects due to inhomogeneous illumination.

When building calibration models for hyperspectral image data, the same problems of under- or overfitting arise and the same caution has to be taken when selecting the number of latent variables. The agreed procedure for building multivariate calibration models is first to divide the data set into a calibration and an internal validation data set, which is often referred to as a *cross validation data set*. The model size (number of latent variables) is determined by the internal validation data set by a cross validation and should be checked for correctness with an external data set [21]. The main difference between calibration models in classical spectroscopy and in image spectroscopy is that in classical spectroscopy for each spectrum a reference y value is available, whereas for images a reference value accounts for hundreds or thousands of pixel spectra. Most often, a bulk property is given as reference value, but the spectra can be very different from pixel to pixel. One possibility is to use a mean or median spectrum of all pixels of that sample and relate this mean or median spectrum to the bulk concentration. Another possibility is to find a region of interest on the sample that can be attributed to the reference value [22].

The combination of spectral image acquisition and multivariate data analysis has led to many successful applications. The objective of the following chapter is to give an overview on recent publication in the field of process industry.

40.4
Selected Applications

The majority of papers on spectral imaging are published in the field of food, feed, and pharmaceutical industries. And most of them use spectroscopy in the NIR range, which is still the workhorse in spectral imaging.

40.4.1
Food and Feed

Food and feed safety control as well as quality control are often carried out by human vision, especially for sorting out bad looking products. But by human vision it is often not possible to see chemical changes in the product. Combining NIR hyperspectral imaging spectroscopic techniques with chemometrics can greatly improve food and feed safety and improve quality control. An overview of several applications is given in [23, 24]. Chemical imaging is used for sorting apples [25–27] and tomatoes [28]. Furthermore, there are applications that determine the composition of food and feed [29, 30]. Even for safety reasons, to determine undesirable substances such as bacteria in food and feed chemical imaging has proved to be applicable [31, 32].

Daugaard *et al*. [33] showed that hyperspectral imaging has the potential for quality control in a continuous frying process. They used canonical discriminant analysis of the multispectral images of samples of fried minced meat and diced turkey to visualize the effect of different heat treatments. It was even possible to detect slight increases in the agglutination of the fried minced meat during the process, which is difficult to measure otherwise. Chemical imaging was also used to measure the tenderness of fresh beef [34] and the water holding capacity of beef muscles [35], thus facilitating the identification and classification of beef meat in a simple and fast way. Similar applications for quality control are found in the fish industry [36] and in bread [37] or pasta [38] making.

40.4.2
Pharma

The growing interest of the pharmaceutical industry in NIR chemical imaging is a result of its high usefulness for quality control analyses of drugs throughout the entire production process [39]. Focus is given mainly to these different uses: blend uniformity of powders and tablets [40], content uniformity [41], composition and morphological features of coated tablets [42] and granules, and spatial changes during hydration and degradation [43].

Counterfeit pharmaceutical products are a real threat to the health of patients. NIR chemical imaging provides a rapid method for detecting and comparing suspected counterfeit products without sample preparation. The advantage of imaging is that the discrimination of the tablets is not only caused by changes in the chemical composition but also from its spatial distribution. This reflects the use of different raw materials as well as different processing conditions, which change the distribution of the components in the tablet. The advantage of NIR chemical imaging over classical NIR spectroscopy is the potential to determine not only the amount but also the spatial distribution of ingredients within a single tablet. Furthermore, the combined chemical and morphological information provides an individual measure for the characterization of tablets [44, 45].

40.4.3
Recycling and Sorting

NIR and Raman spectroscopy is widely used in laboratory and industrial applications for material classification. While standard spectrometers only allow measurements at one sampling point at a time, chemical imaging techniques can identify, in real-time, both the size and shape of an object as well as the material it is made from. Sorting of materials requires the determination of the correct material, size, and shape of the entire object for reliable separation.

There are applications of industrial in-line material sorting system for cellulose-based materials such as pulp, paper, and cardboard [46]. Recent papers report the development of a hyperspectral imaging system in the NIR range (1000–1700 nm) to classify polyolefin particles from complex waste streams in order to improve their recovery, producing high-purity polypropylene (PP) and polyethylene (PE) granulates, according to market requirements [47]. Gosselin and coworkers [48] report an NIR hyperspectral imaging sensor for predicting spatiotemporal variations of extruded wood/plastic composite materials. Pushbroom imaging technology is

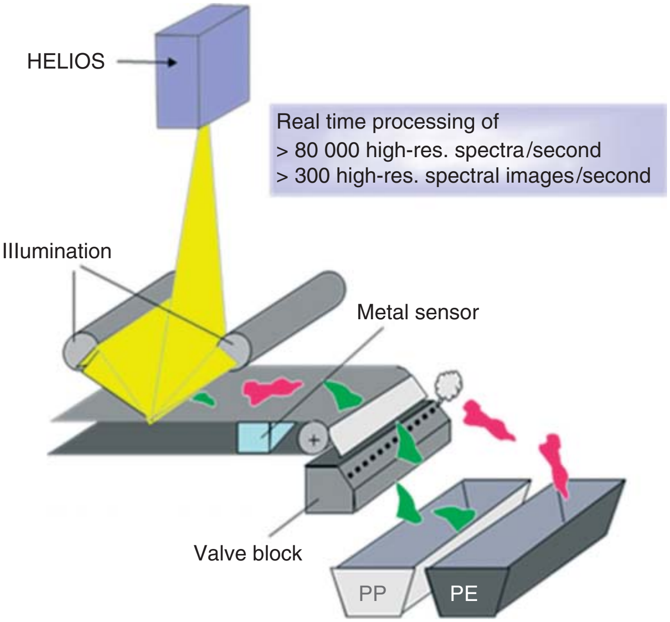

Figure 40.3 Real-time characterization of polymers in plastic waste separation. (Courtesy of EVK company, *http://www.evk.co.at*.)

also used to identify plastics in waste management systems [49, 50]. Figure 40.3 shows an example of a commercial application in separating the different polymers automatically on a conveyor belt.

Trends in Spectroscopic Techniques for Process Control

Michael Maiwald, Igor Gornushkin, and Markus Ostermann

41.1

Trends

As previously described, the science-based regulatory guidances such as the process analytical technology (PAT) guidance [1] and ICH Q8 [2] have recognized spectroscopic techniques as potentially useful tools on building quality into the product and manufacturing processes, as well as continuous process improvements [3]. The goal of PAT is to enhance understanding and thereby control the manufacturing process: quality cannot be tested into products; it should be built in or should be by design.

There is a considerable trend to recognize process analytical techniques as potentially useful tools for classical chemical production and manufacture in general [4–6]. A need to study complex multicomponent mixtures and gain insight into their behavior in the real process can be recognized. On-line spectroscopic methods can meet these demands when either flow probes are directly coupled to process equipment such as reactors for process monitoring – from laboratory size up to industrial scale. Likewise, commercial off-the-shelf offers for optrodes, light and radiation-guiding material (e.g., infrared (IR) transparent light fibers), as well as suited interfaces (e.g., flanges with spectroscopic windows) were significantly expanded on the market.

Besides the technical demands – and chances – of microanalytical sensors to become smaller and smaller (e.g., for analysis in microreactors or small amounts of samples), there is also need for precise local quantification in bulk materials or large-scale apparatuses (e.g., tomography, detection of hot spots).

41.2

Nuclear Magnetic Resonance Spectroscopy (NMR)

41.2.1

Process Analytical Applications of High-Resolution NMR Spectroscopy

Quantitative high-resolution on-line nuclear magnetic resonance (NMR) spectroscopy is the method of choice for the investigation of complex fluid mixtures

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

with analytically similar compounds, where other analytical methods (e.g., optical spectroscopy such as UV–vis, (near) infrared (IR, NIR), Raman, or fluorescence spectroscopy) suffer from insufficient differentiation of components. In addition, the high value of NMR in determining chemical structure and accurate quantitative measurements, more subtle features such as speciation (e.g., protonation) are clearly indicated. The development of on-line (flow) techniques has tremendously increased the value of NMR spectroscopy for process development applications and became very attractive as noninvasive methods.

One of the most attractive features of quantitative NMR spectroscopy [7, 8] is that the coefficients relating the peak area to the number of nuclei are essentially identical for all nuclei of the same species in a mixture. Provided that spin saturation is attained, NMR peak areas can be directly used for quantification without further calibration. A major advantage of NMR spectroscopy is that the method features a high linearity between absolute signal area and sample concentration, which makes it an absolute analytical method independent of the matrix (Figure 41.1).

The NMR effect subject to atomic nuclei possessing a nuclear spin (spin quantum number $I \neq 0$). Among the most important isotopes are the NMR active proton (^{1}H, $I = 1/2$) and deuterium (^{2}H, $I = 1$). Only the isotope carbon ^{13}C shows nuclear magnetic effects ($I = 1/2$). Its relatively low natural abundance of 1.108% and other effects result in a relatively low sensitivity and hence to longer acquisition times for NMR experiments. From all elements of the periodic table in most cases, there are some that have a nuclear spin with very individual sensitivities.

A magnetic spin momentum μ arises from the nucleus' spin momentum L owing to its moving charge. The magnetogyric ratio $\gamma = \mu/L$ describes the ratio between the magnetic property μ of the nucleus with respect to its mechanical spin momentum L. It is responsible for the sensitivity of detection and is listed in tables [9]. A strong, homogeneous, and timely constant magnetic field B_0 provided by

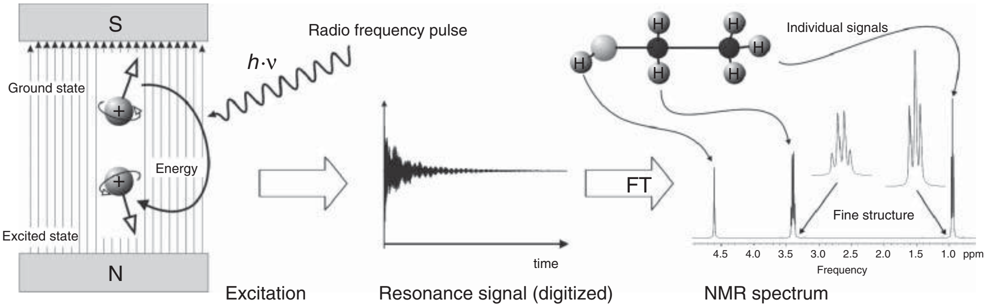

Figure 41.1 Schematic representation of an NMR experiment. A short radio frequency pulse leads to a temporal population difference between nuclei in its ground state and excited state, which affects the total magnetization of the system. This can be detected by the radio frequency receiver coil and is digitized. The NMR spectrum is derived by Fourier transform (FT). As individual atomic nuclei are magnetically shielded by individual electron currents, this leads to separate signals in the spectrum. A characteristic fine structure that allows for structural determination of the observed molecule (e.g., ethanol) is observed.

superconducting magnets leads to alignment of the magnetic spin moments into the direction of and contrary to B_0. Spins into the direction of B_0 are energetically preferred. Both states are indicated by an energy difference of

$$\Delta E = h\nu = 2\,\mu_z B_0 = \gamma\hbar\, B_0$$

This allows for spectroscopic excitation with radio frequency (RF) radiation (e.g., $B_0 = 9.4\,\mathrm{T}$ resulting in 400 MHz resonance frequency). As thermal energy counteracts with magnetic polarization, population differences are typically only several parts per million – in contrast to optical spectroscopy, for instance.

Excitation is typically achieved by using a high-energy short-time pulse of resonance frequency, which excites a broad frequency range of the resonant nuclei. The pulse changes the magnetization of the observed nuclei, which induce an alternating current into an RF detection coil. While the magnetization of the system relaxes back to its ground state, an impulse response is detected for several seconds [time domain (TD)] and digitized. A Fourier transform (FT) yields the NMR spectrum in the frequency domain [10]. Relaxation effects arise from various inter- and intramolecular effects and reflect molecular properties. Therefore, relaxation times grant access to molecular movements and segment movements.

On-line coupling of NMR spectrometers was first developed with high performance liquid chromatography (HPLC) and supercritical fluid chromatography SFC, using NMR as an analytical detector with high spectral dispersion [11–13]. Flow NMR probes were developed, and these have also been used for high-throughput NMR spectroscopy.

A major advantage of flow NMR probes is that they are less sensitive to changing magnetic properties of the sample because of the fixed fluid volume and the cell design. When used for on-line reaction monitoring, the pressure-handling capacity of the flow probe is an important design consideration. The shimming of deuterium-free samples can give excellent results when automated shim procedures based on pulsed magnetic field gradient experiments are used. These processes work reliably and without operator supervision, even for concentrated samples or solvent mixtures for which solvent peaks have the same order of magnitude as analyte peaks – and even under flow conditions. Shimming or tuning of the probe during an experiment is typically not necessary. The choice of a suitable solvent suppression pulse sequences of deuterium-free samples is possible but nontrivial.

Despite the high spectral resolution that follows from the use of a high-field magnet (about 500 MHz or better for ^{1}H), NMR signals may overlap because the interesting chemical species are structurally related. Solvent signals can, in most cases, only be reduced but not completely eliminated, so that the remaining signal may falsify quantitative results for close solute signals. In the worst case, the signal intensities can only be determined by peak deconvolution.

Various applications of chemical as well as pharmaceutical reaction and process monitoring of reactions and processes are described in the recent literature [14–16].

41.2.2
Time Domain NMR Spectroscopy

Since the mid-1990s medium resolution (MR) and TD NMR devices are commercially offered for laboratory quality control as well as process analytics, which typically work at field strengths under 1.41 T (60 MHz proton frequency). There are both desktop devices and process-suited devices available. Magnetic fields with small scattering fields are typically produced by a permanent magnet. Relaxation times, which are directly accessible from the measurements without accomplishment of a FT (decay of the free induction decay (FID) signal), represent the main valuable process variables.

In some cases, MR NMR spectra can be derived if a sufficient shim is provided [17]. Owing to the relatively low-field strengths of the magnets used in such instruments, the resulting spectral dispersions are clearly restricted. Usually for the interpretation of the spectrum or the pure TD information, chemometric methods are applied to allow for a multicomponent and/or a multiparameter correlation to the sample characteristics.

Desktop devices possess a modular design and can be supplemented for various options such as gradient units with bipolar rectangles and formed gradient pulses, excitation by shaped waveforms, 3D gradient experiments, and so forth. Various sample probes are offered, which are predominantly intended for the observation of ^{1}H, ^{19}F, and ^{31}P nuclei with acceptable sensitivity covering a wide temperature and pressure range. Likewise, custom-built sample probes can be integrated [18].

MR NMR process instruments are accordingly constructed for employment in direct proximity of production plants. They fulfill high safety standards and have internal control functions such as switching off functions or leakage control. Besides, a set of sample probes and components for observation of the above-mentioned nuclei are available, for example, for switching between different sample lines as well as for cleaning and rinsing. Likewise, standards can be brought into the spectrometer.

The uses of MR NMR spectrometers cover measurements of components and component conditions in technical process liquids with the need for direct transmission through the equipment using a bypass. Besides, measurements of physical and chemical parameters such as relaxation times, diffusion procedures, droplet size distributions, and so forth are possible. The devices are at present predominantly used for the investigation of process liquids from the refinery and chemical industry, for pharmaceutical products [19] and for food and dairy products [20, 21].

41.2.3
Process NMR Spectroscopy Outlook

Novel polarization transfer methods [22], spin–lattice relaxation time reduction techniques [23], and cryogenic NMR probes [24] have been utilized toward the improvement of NMR measurements. Because cryogenic magnets are not compatible with the industrial environment, the development of process capability of such instruments is highly appreciated, for example, by further developing MR NMR and microcoil capillary NMR techniques [25, 26]. The latter reduce the RF coil diameter [27] and allow application of suited tubing material.

Small, low-field NMR systems equipped with permanent magnet technology have already been developed and applied at-line and on-line [28–30].

41.3
Ion Mobility Spectroscopy (IMS)

Ion mobility spectroscopy (IMS) is an analytical technique with growing application in semiconductor, pharmaceutical, and medical device manufacturing, industrial monitoring, petrochemical and chemical plant security as well as for chemical agent detection, for example, in airports or military applications [31, 32]. Ion mobility has recently also been proved in the analysis of biological materials (proteomics and metabolomics [33, 34]) and for pharmaceutical applications, for example, cleaning validations.

In IMS, drift times under the influence of an electrostatic field of ionized species through a drift chamber are measured. The method is comparable to mass spectroscopy but works under ambient pressure, mostly with air as drift gas. The (diluted) sample enters the drift cell from a sampling system over a semipermeable membrane, which provides a degree of sample selectivity. Dopant materials can be added to enhance the ionization process and increase specificity. Purified air sweeps the membrane on the inside of the cell and delivers the sample to the ionizer. The molecules of the sample have to be ionized, usually by corona discharge, electrospray ionization (ESI), atmospheric pressure photoionization (APPI), or a radioactive source, for example, ^{63}Ni. An electrically biased shutter grid (gate) allows periodic introduction of the ions into a drift tube where they separate based on charge, mass, and shape while flowing counter to a drift gas flow, which is introduced at the end of the drift tube. The ions drift with constant velocity v_d in a homogeneous electric field E ranging from a few up to several hundreds of volts per centimeter.

$$v_\mathrm{d} = KE$$

Typical mobility coefficients K for swarms of ionized particles with atomic mass constants of 10–500 amu are on the order of 0.5–2.5 $\mathrm{cm^2\,V^{-1}\,s^{-1}}$ for an electric field of 150–300 $\mathrm{V\,cm^{-1}}$ and drift velocities of 1–10 $\mathrm{m\,s^{-1}}$. Typically, mobility coefficients K are normalized to standard pressure and standard temperature according to

$$K_0 = K\frac{p}{p^\ominus}\frac{T^\ominus}{T}$$

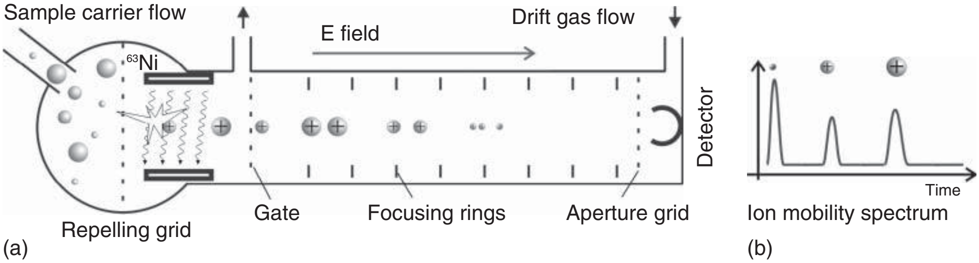

Figure 41.2 (a) Ion mobility spectrometer. The sample is delivered to the ionizer (here: radioactive ^{63}Ni) and periodically introduced into the drift tube with a homogeneous electric field while flowing counter to a drift gas flow. (b) Time-of-flight ion mobility spectrum with detector signals of the sample ions separated on the basis of charge, mass, and shape.

A Faraday plate located at the end of the tube serves as collector and detects the arrival of the ions, producing a current. This current is amplified to produce a time-of-flight spectrum (Figure 41.2).

IMS is a technique of growing interest for an expanding number of applications because of its versatility by properly selecting temperature, flow rates, membrane type, drift-tube polarity, and other parameters to specifically monitor selected compounds. Limits of detection are in the lower parts per billion level for many compounds. Real-time monitoring, sensitivity, selectivity, and speed of response (millisecond range) make this technique preferable to other monitoring methods.

IMS is applied in semiconductor manufacturing to detect bases such as ammonia, NMP (*n*-methylpyrrolidone), and other amines during photolithography processes. It is also employed to monitor acids in metal deposition, etch, and copper CMP processes. For accurate monitoring of HCl and HF at the parts per billion and parts per million levels, IMS is advantageous compared to other analytical techniques. In petrochemical production environments, IMS is used to analyze trace ammonia in ethylene and light hydrocarbon process streams, which causes catalyst poisoning in most production processes. Airport security and chemical agent detection are widely applied fields for IMS ownig to its sensitivity, selectivity, and speed of response.

41.4
Process Analytical Applications of Laser Spectroscopy

Extraordinary progress has been made in advancing the performance and manufacturability of quantum-cascade laser (QCL) materials. Proposals concerning the development of intraband lasers on quantum wells were formulated already in the 1970s, but such lasers only appeared several decades later. In a structure with quantum wells, or in a super lattice, emission of electromagnetic radiation can be influenced by a bias voltage, the spatial position of the conductance band, the energy levels in the wells, and populations of these levels. Transition between the wells can be induced by tunneling or phonons and by electromagnetic radiation [35]. The combination of quantum-cascade media with external-cavity lasers produces mid-IR radiation with narrowband output, broadband single-mode tuning abilities [36, 37]. The high optical power output, tuning range, and room temperature operation make QCLs useful for spectroscopic applications such as remote sensing of gases [38].

41.4.1
Cavity Ring-Down Spectroscopy (CRDS)

Cavity ring-down spectroscopy (CRDS) is a direct absorption technique that is normally used in a wide spectral region from the UV (200 nm) to the IR (10 μm). The technique is also known as cavity ring-down laser absorption spectroscopy (CRLAS). Pulsed or continuous light sources can be used. A broad variety of atoms and molecules have been studied with significantly higher sensitivity to trace amounts of substance or very weak absorbing species than obtainable in conventional absorption spectroscopy, including radicals, ions, clusters, and solids [39].

The experiment is based on detection of the rate of absorption rather than the magnitude of absorption of a light pulse, which is restricted to an optical cavity with a high Q factor. A short laser pulse is coupled to the optical cavity and reflected between the mirrors. With every reflection, a small fraction leaks out of the cavity. Instead of measuring the total intensity of the light exiting the cavity, one determines the decay time by measuring the time dependence of the light leaking out of the cavity. As the sample absorption increases the decay, the rate of absorption reflects the sample contribution. The resulting intrinsic insensitivity to light source intensity fluctuations and extremely long optical pathways in stable optical cavities (some 1000 m) are advantegous over normal absorption spectroscopy. Multimode excitations of the ring-down cavity were typically reported in the range of 10^{-6} to $10^{-10}\,\text{cm}^{-1}$, single-mode excitations between 10^{-9} and $10^{-12}\,\text{cm}^{-1}$. The difficult calibration is a disadvantage of this method, when used as an absolute detection method (Figure 41.3).

41.4.2
Tunable Diode Laser Absorption Spectroscopy (TDLAS)

Tunable diode laser absorption spectroscopy (TDLAS) is a technique for quantitative detection of certain species, for example, methane or water in a gaseous mixture using tunable diode lasers in combination with laser absorption spectroscopy. TDLAS achieves very low detection limits in the order of parts per billion. In addition, determination of temperature, pressure, velocity, or mass flux is possible. The method is the most common quantitative laser-based absorption technique for gases [40].

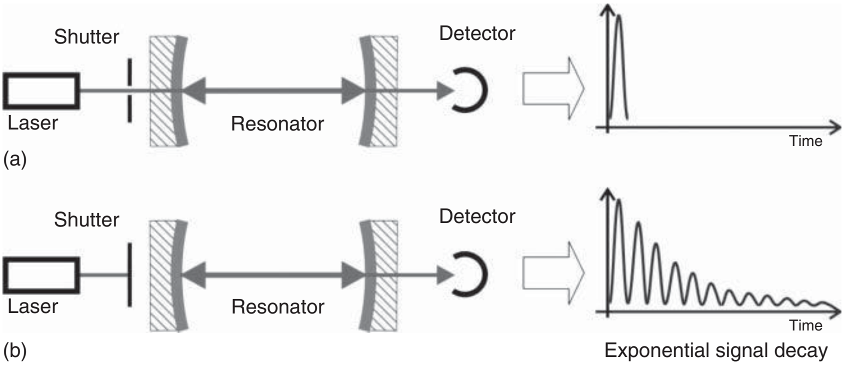

Figure 41.3 Schematic representation of a cavity ring-down experiment. (a) A laser pulse leads to a resonating signal between highly reflecting mirrors. (b) An exponentially decaying signal is detected after the laser is shut off. Spectrum-dependent absorptions of trace amounts of sample lead to an increasingly decaying signal in the spectrum.

41.4.3
Photothermal Techniques

Photothermal techniques are based on the production and proof of thermal waves. Frequency-dependent amplitudes and phase shifts of the thermal waves yield information on the thermal characteristics and their depth profile of a sample. Thermal waves are produced by a local periodic heating up of the sample, for example, with the help of an intensity-modulated laser beam. For the detection of oscillating temperature fields, various techniques are common [41], such as photo acoustics, photo-thermally modulated reflection, and photo-thermally modulated IR radiometry, where radiant heat is detected because of the periodic heating up. All techniques are particularly suitable for remote investigations within the industrial range.

Photoacoustical spectroscopy (PAS) has been increasingly used for selective identification of materials using their optical absorption characteristics. The technique is widely applied to samples in the vapor phase, where the vapor is kept in a chamber with optical windows. In novel approaches a quartz crystal tuning fork (QCTF) is used [42]. The reflected light absorbed by the QCTF generates pressure waves at the air–surface interface and thereby causes quartz to resonate and produce a piezoelectric voltage. These devices are highly sensitive and do not require microphones to detect the sound produced by the photoacoustic effect.

41.5
Laser-Induced Breakdown Spectroscopy (LIBS)

Laser-induced breakdown spectroscopy (LIBS) is a relatively simple plasma spectrochemical technique that uses short-pulsed lasers [43–47]. A laser is focused on a sample to create a microplasma. The microplasma is a transient event with high temperature (10 000–20 000 K) sufficient to break chemical bonds and to produce electronically excited atoms and ions. These excited species give off radiation at specific wavelengths depending on the element. By detecting the light from the microplasma within UV–vis spectral range elements are identified and chemical abundances are measured. LIBS is a real-time standoff measuring technique with typical working distances of 10–20 cm and record-long working distances of about 100 m. The technique requires no sample preparation and can be used for analysis of solids, liquids, and gases. It has the potential to be developed into a compact, rugged, and relatively low-cost instrument.

Currently, LIBS is used for compositional analysis, remote process monitoring, thin-film deposition, and nanofabrication [48–51]. In compositional analysis, concentrations are found by using certified standards. The use of matrix-matched standards is imperative; otherwise, results are biased by the matrix effect that is notorious for LIBS. There, an alternative calibration-free approach exists where the concentrations are calculated from the plasma spectrum using theoretical modeling [52–54]. The basic assumption is that the plasma composition represents exactly that of the solid.

In analytical practice, dual- or multiple-pulse laser systems are popular as they provide better figures of merits compared to that of single-pulse lasers [55]. A significant increase in detection sensitivity occurs because of the enhanced plasma excitation combined with the increased mass removal.

The vast majority of analyses are performed on solid samples [56]. Typical limits of detection are in the low part-per-million range with typical uncertainties of 5–10%. For hybrid techniques, such as laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS), even lower sensitivities at a part-per-trillion level can be achieved [57]. LIBS is often the technique of choice in heavy industry thanks to its remote capability and lack of sample preparation. It is used for microcharacterization of solid samples [58], *in situ* analysis of mineral and metal melts [59, 60], and industrial monitoring [61]. Applied to pharmaceutical products, LIBS allows for rapid multicomponent analysis, depth profiling, and the assessment of product homogeneity [62]. It has been demonstrated that LIBS is also capable of fast and reliable on-line *in situ* detection of hazardous chemical and biological agents [63], sorting industrial and recycled materials [64, 65], and classification of particulate systems [66]. The fingerprinting capability of LIBS improves when it is combined with Raman spectroscopy [67]. The remote capability of LIBS makes this technique ideal for planetary exploration [68].

The detection of trace elements in gases emitted by industrial and incinerator facilities is another important LIBS application [69]. It combines continuous monitoring with the possibility to remotely access a desirable testing site. LIBS proved to be also suitable for the detection of particles and aerosols, allowing the determination of both species composition and total particle mass and size [70, 71].

Thus, LIBS-based techniques become increasingly popular in many applied fields. Operational simplicity, versatility, and relatively low cost are the features that make LIBS the technique of choice for many industrial laboratories.

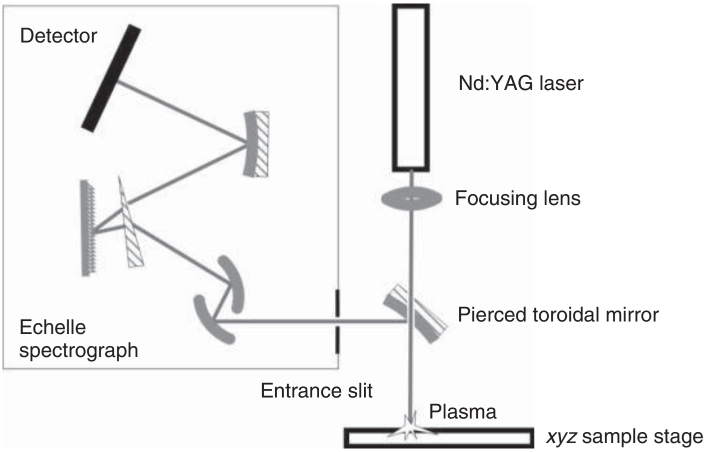

Figure 41.4 Schematic representation of an LIBS spectrometer using an Echelle spectrometer with CCD detector. The sample is excited with a pulsed Nd:YAG laser.

Several commercial LIBS instruments are available on the market and the number of companies offering the instruments steadily grows (Figure 41.4).

41.6
X-Ray Fluorescence Spectroscopy

X-ray fluorescence (XRF) analysis permits qualitative and quantitative evaluation of the elementary composition of a sample. In XRF, X-rays produced by a source irradiate the sample. The source is in most cases an X-ray tube, but it can also be a radioactive material. The elements present in the sample emit fluorescent X-rays with discrete energies that are characteristic for each individual element. By measuring the energies of the radiation emitted by the sample, it is possible to determine which elements are present for qualitative analysis. By measuring the intensities of the emitted energies, quantitative analysis is also straightforward [72].

There are two main types of XRF instruments available on the market: wavelength-dispersive X-ray fluorescence (WDXRF), which is achieved by diffraction using analyzer crystals, and energy-dispersive X-ray fluorescence (EDXRF), which does not use crystals. WDXRF systems provide application versatility, optimal measurement conditions, excellent light element performance, very high sensitivity, and low detection limits. While WDXRF systems are mostly used in laboratories, EDXRF systems offer a lower cost alternative for more routine applications as it is needed for process analytical purposes. Recent developments of new detectors bring significant analytical improvements to these systems [73–75].

Moreover, elemental analysis using EDXRF for *in situ* material flow in production processes is gathering importance nowadays. The use of X-ray radiation for the investigation of material streams is highly competitive and has been investigated extensively. The employment of on-line XRF analysis pays off both in financial as well in time aspects, as it can be used for the economic application of raw materials or, for example, for recycling [76, 77]. Thanks to these technical developments, XRF analysis can be used as information source in the elemental analysis of material in the industrial process without tedious sample preparation steps. It plays no role whether the sample is liquid or solid, a compact body or a bulk material. A smooth surface eases and improves the measurements; less ideal surfaces are also measurable as long as they are homogeneous [78, 79]. XRF analysis is a nondestructive measurement method. In principle, XRF is capable of measuring elements from beryllium (Be) to uranium (U) and beyond at trace levels and up to 100%.

The versatility of the method and the relatively easy sample preparation have paved the way for XRF in many application areas [80]. The technique has become widespread in chemical, food, pharmaceutical, cosmetic industries, as well as for cement, mining, and petrochemical applications, where it provides a valuable tool for manufacturing and quality assurance, monitoring environmental impact, and resource utilization [81]. In some industrial branches, as, for example, in the cement industry, XRF is used currently still off-line, that means that raw materials, intermediate products, process components, and end products are examined in the company's laboratory. This approach delivers temporal-shifted measuring values. For raw materials this approach is not very critical, as long as sufficient storage capacities are available. But because in process control measuring values must be available immediately in order to guarantee a constant and optimal process output and products of the highest quality, an implementation of the XRF instrumentation into the production line should be realized. This XRF on-line analytics for process control slowly becomes accepted. The comprehensive basis of understanding of the method, the easy sample preparation, and the moderate costs of the components produced inlarge scale are strong arguments for its use. Some good application examples in process control are the determination of the zinc content in converter dust for steel production [82], the monitoring of the coal supply to a blast furnace [83], or the application for the removal of impurities in glass recycling.

41.7
Terahertz Spectroscopy

Terahertz (THz) spectroscopy is a focus of research in applied optics [84–87]. At present, its applications include observation of vibrational modes in macromolecules [88], quality control of pharmaceutical products. The method also provides molecular fingerprints and has been demonstrated for explosives, polymorphic forms of active pharmaceutical ingredients (APIs), or illegal narcotic substances [89].

Conventional THz spectroscopy uses the Fourier transform infrared (FTIR) technique in the distant IR around 100 GHz to 10 THz (3–300 cm^{-1}) and it represents a complementary vibrational spectroscopic method to IR and Raman spectroscopy, providing information on lattice oscillations such as low energy molecular, intermolecular, and crystal vibrational processes. Absorption spectra of THz radiation are directly related to the three-dimensional arrangement and low-frequency motions of all atoms in a molecule. It is also sensitive to intermolecular interactions. Many materials are transparent to THz radiation and the radiation harmlessly penetrates several millimeters beneath the surface. THz radiation is nonionizing and therefore safe for biological tissues. As most materials are transparent to THz radiation, samples can be observed through normally opaque intervening layers such as clothing or packaging materials.

Terahertz time-domain spectroscopy (THz-TDS) measures the electric field of the reflected or transmitted radiation of a short pulse of THz radiation, for example, using a picosecond-pulsed laser, which contains frequency components covering the whole THz range.

The method shares similarities with pulsed ultrasonic waves. It provides the phase and amplitude changes of radiation from which the refractive index and the absorptions coefficient can be obtained, and therefore the technique provides more information than conventional FT spectroscopy, which is only sensitive to the amplitude. THz-TDS is typically used from 0.05 to 4 THz, for example, to investigate thickness, density, or defect location in multilayer specimens or composites on a quantitative background. THz-TDS imaging systems are also available. Images can have spatial resolutions down to 1 mm.

THz-pulsed spectrometers are particularly suited to study solids [90]. The terahertz-pulsed imaging (TPI) technology offers unique possibilities in the area of imaging and for investigation of APIs in pharmaceutical manufacturing [91, 92]. Of particular interest is the identification and characterization of drug polymorphs [93]. Femtosecond-pulsed THz radiation has also been utilized for nondestructive 3D internal imaging of pharmaceutical products, surface coating measurements, and for scanning living tissue [94, 95], where the absorption of THz radiation can be used to quantitatively and nondestructively measure the API contents.

41.8
Acoustic Spectroscopy (Ultrasound)

Acoustic and electroacoustic spectroscopy give a unique opportunity to study concentrated dispersions, emulsions, and microemulsions without dilution and hence without changes in equilibrium conditions of surface and rheological properties. The technique is also known as *ultrasound attenuation spectroscopy*. Applications include characterization of ceramics, mixed dispersed systems, emulsions, food emulsions, and microemulsions [96–99].

In acoustic spectroscopy, sound pulses are generated and passed through the sample. Typical operation frequencies are 1–100 MHz. Sound energy losses (attenuation) and sound speed are measured by a receiver, which is sensitive to changes in intensity and phase of the signal. Such changes are due to interaction of sound waves with particles and liquids in the sample system. Acoustics provides reliable *in situ* particle size information as an alternative to light scattering methods. The method works in concentrated dispersions and yields accurate particle sizes in undiluted technical systems eliminating the need for dilution or other sample preparation. The method covers volume fractions up to 0.5 as well as low dispersed systems with volume fractions down to 0.001. Advanced systems allow particle size ranges of, for example, 0.005–100 μm to be measured in a single run. Beyond this, acoustical stresses yield information about the microstructure of the dispersed system, for example, extensional and volume viscosity, and can therefore be treated as acoustic microrheometers.

The technique allows a wide range of technical sample types for investigation such as mixed systems of dissimilar materials, for example, zirconia/alumina or ceramic slip. Particles sizes can, for instance, be determined in polymer solutions with extremely high macroscopic viscosity. Measurements do not require charged particles and can take place with conducting as well as nonconducting material. Samples can be measured in a static sample chamber or circulated in a bypass using a pump.

Data analysis of attenuation data involves fitting of experimental results to theoretical models that are based on different acoustic loss mechanisms. There are several mechanisms of ultrasound interaction with a dispersed system: viscous, thermal, scattering, and intrinsic. Minor interactions are caused by structural and electrokinetic effects. Viscous losses are the dominant losses for small rigid particles below 3 μm and occur because of shear waves of the oscillating particles in the acoustic pressure field due to differences in densities of the particles compared to the surrounding medium. Shear waves are nonstationary, sliding movements of the liquid layers in the vicinity to the particle. For soft particles, the dominant effect is a thermal loss due to the thermodynamic coupling between pressure and temperature. Scattering mechanisms can be compared to light scattering, where acoustic energy is scattered and reflected from the particles. This mechanism becomes more important for high frequencies over 10 MHz as well as larger particles over 3 μm. Effects of direct molecular interactions of sound waves with either particles or the solvent, which result in dissipation of energy, are called *intrinsic effects*. Minor losses are also caused by oscillations of molecule or particle networks, which are bound by specific and nonspecific interactions and also result in attenuation of sound energy. Charged particles may also cause minor energy dissipations due to transformation of sound energy into electrical energy.

Electroacoustic techniques are different depending on the driving field applied [100]: electrokinetic sonic amplitude (ESA) involves generation of mechanical energy by the driving force of an electric field. Colloid vibration current (CVI) techniques detect resultant electric fields or currents by the vibration of colloid electric double layers, which are evoked by sound energy while disturbing the double layer surrounding the particles and shifting the neighboring cloud of counterions. This displacement evokes a dipole moment and can be measured as a resulting electric field by a two-electrode sensor.

Electroacoustic spectroscopy is used to determine the ζ-potential, an electro kinetic potential in colloidal systems describing the potential difference between the medium and the stationary layer of fluid attached to the dispersed particle. Its value can be related to the stability of colloidal dispersions, indicating the degree of repulsion between adjacent, similarly charged particles.

41.9
Dielectric and Microwave Spectroscopy

Dielectric (or impedance) spectroscopy measures the dielectric properties (permittivity) of a medium as a function of frequency and thus provides information on relaxational dynamics of soft matter in a wide frequency range [101–103]. The fluctuations of the sample dipoles are connected to the dynamics on a molecular scale.

Dielectric spectroscopy supplies information on temperature-dependent relaxational dynamics, for example, of polymeric materials and glass-forming liquids, or dynamic (AC) conductivities of polymeric ion conductors. It yields complementary information compared to neutron scattering, which has a limited frequency range but supplies spatial information, which is not obtainable by dielectric spectroscopy. The characteristic relaxation times vary over many orders of magnitude. Two major properties are typically detected for different application: the spatial distribution of the interrogation field and the interrogation frequency range. The former is used in dielectric spectroscopy and enables measurements of bulk or low-penetration surface information. Frequencies are optimized for a particular sample and typically vary from 10^6 to 10^{11} Hz. Normally, a parallel plate capacitor configuration is used to detect attenuation and phase shift of an electric field passing through a sample. One electrode delivers an excitation signal and another electrode measures the resulting signal after passing in an approximately linear manner through the sample. In an alternative setup, the so-called fringing-field sensing, one electrode delivers the excitation signal and a second electrode is placed in a coplanar manner on the same surface such that the original signal passes nonlinearly through the sample.

Dielectric spectroscopy is a continuously evolving PAT. It was applied to study physical properties of pharmaceutical solutions, colloids, microcapsules, gels, and emulsions. Various types of instrumentation, algorithms, and sensing systems present a wide range of applications and capabilities of this method. Principles and design features of dielectric sensors of pharmaceutical applications have recently been discussed [104, 105]. The static dielectric number of solutions can be used to study the solubility of cosolvent systems, reaction rates of pharmaceutical solutions, and drug stability [79]. Colloidal particles with its surrounding electrical layer influence the dielectric response when aggregation or dissociation of colloidal particles occurs. It thus provides information about particle size in the colloidal solutions. Studies of microcapsules as improved drug delivery systems show relations of the relative dielectric permittivity to the thickness of the capsule wall [106]. Impedance spectroscopy also provides volume fractions of microspheres in solution, which influence dissolution rates of microcapsules [79]. Dielectric spectroscopy was used to give insight into structural and interfacial properties of gels, which are complex systems with multiple dielectric relaxation processes, each reflecting different physical characteristics. The method, for example, was applied to differentiate relaxation of water, ions in cetostearyl alcohol bilayers, as well as migration of ions in channels between these bilayers [107]. It has been used to classify the types of emulsions and microemulsions, which act as effective drug delivery systems for drugs that are insoluble in water. Dielectric properties can be used to detect differences between water-in-oil and oil-in-water emulsions [79].

Dielectric spectroscopy, also applied for on-line property measurement, is a key technique for monitoring cure, where the liquid resin first gels and finally becomes a glassy solid. Owing to the dependence of dielectric properties to viscosity, glass transition temperature, cross-linking of the material, the method is used to monitor gelation and increase of viscosity [107]. Such studies can prevent failure of reaction of resins, use of incorrect proportions of resin components, poor mixing, insufficient curing, or incorrect processing conditions.

Microwave (MW) spectroscopy is a further process analytical method for monitoring and control of industrial processes for solids, liquids, gases as well as suspensions. MW spectroscopy is rotational spectroscopy of molecules in the MW range of 0.25–3.20 GHz of the electro magnetic spectrum. MWs normally penetrate all samples with low dielectric numbers such as glass, plastics, ceramics, and composite materials of several centimeter thicknesses but are reflected by metal surfaces. MW spectroscopy reflects the dielectric behavior of the sample such as the dielectric number. Usually, chemometrics is applied on spectral data. As a noninvasive method, it can be used to analyze large sample volumes to yield integral sample properties from the entire sample [108, 109].

Applications have been reported in areas of batch reaction monitoring, for example, on esterification reaction, the determination of acetonitrile or ethanol concentration in water [110] as well as monitoring drying processes, where MW spectroscopy had advances over NIR spectroscopy owing to a significantly reduced calibration data set [111].

Applications 6: Spectroscopy at Surfaces

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

42
Optical Spectroscopy at Surfaces

Georgeta Salvan and Dietrich R. T. Zahn

42.1
Introduction

Optical spectroscopies are commonly not inherently surface sensitive owing to the large penetration depth of light that determines the information depth. Therefore, special experimental arrangements are necessary to achieve the required surface sensitivity. Among the optical characterization tools, Raman spectroscopy is a widely applied technique offering a wealth of information regarding, for example, chemistry at interfaces or electronic properties of interfaces. In order to make Raman spectroscopy surface sensitive, one prerequisite is the employment of resonance effects. Tuning the photon energy of the exciting laser light into an absorption feature of the species to be detected results in a strong signal enhancement and thus allows tiny amounts down to sub-monolayer (ML) coverage to be detected. The characterization of such amounts of material on surfaces usually requires a very clean environment, that is, the application of ultrahigh vacuum (UHV) conditions is needed and the coupling of a UHV chamber to a Raman setup is required. The UHV-Raman system also permits the formation of interfaces to be followed from clean surfaces to thicker films, that is, Raman spectra can be taken continuously during deposition of material. This *in situ* Raman monitoring technique is advantageous compared to *ex situ* Raman measurements as it unfolds the evolution of interface formation. Using the example of organic/inorganic interface formation, namely the UHV deposition of small molecules onto inorganic semiconductors, the capabilities of Raman spectroscopy will be illustrated. Moreover, the deposited organic layers serve as substrates for metal deposition for studying metal/organic semiconductor interfaces. This allows another extremely useful effect for surface/interface characterization to be demonstrated, namely, the surface-enhanced Raman scattering (SERS) effect. The clusters formed during metal deposition induce this effect and the enhanced Raman signal stems from those molecules in the intimate vicinity of the metal. Therefore, this effect is extremely sensitive to the interface formation. More widely used approaches to achieve SERS are based on molecules deposited on nanostructured substrates or on molecules in colloidal solutions, which are not in the focus of this review. Readers

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

interested in the progress made in these fast developing branches of the SERS community are advised to consult recent reviews (e.g., [1–3]).

A widely used thin-film characterization technique, based on the change in polarization on reflection from the thin film surface is spectroscopic ellipsometry (SE). Under favorable conditions [4, 5] even sub-ML resolution can be attained for inorganic semiconductors [4] as well as for organic molecules [5] on semiconductor surfaces. A survey of methods to characterize thin absorbing films with SE appeared recently [6].

Reflection anisotropy spectroscopy (RAS), also known as *reflection difference spectroscopy* (*RDS*) was originally developed for the characterization of inorganic semiconductor surfaces and their reconstructions. RAS gains its surface sensitivity by measuring the difference in the reflection coefficients for two perpendicular directions within the sample surface plane. Considering the cubic symmetry of the most important semiconductors, the bulk contribution is eliminated and only surface contributions remain. Also, this technique can be coupled to a growth apparatus in order to monitor the evolution of the RAS spectra during growth. Especially, RAS was not only applied for UHV-deposition processes but also during gas phase processes such as metal-organic vapor phase deposition or even to study solid/liquid interfaces. This illustrates an important advantage, namely, the applicability of optical spectroscopies in environments other than UHV, compared to electron-based spectroscopy techniques that depend on UHV conditions. More recently, RAS has also been applied to the characterization of organic/inorganic interface formation for which an example will be given.

Impressive interface sensitivity was achieved using X-ray magnetic circular dichroism (XMCD). The absorption of circularly polarized X-rays in the soft-X-ray energy range is different for parallel and antiparallel orientation of the helicity of the incident light with respect to the magnetization direction of the sample [7]. This synchrotron-based technique was routinely applied to measure the magnetization of thin ferromagnetic layers on nonmagnetic substrates. Recently, it was applied to measure the exchange coupling of paramagnetic molecules to magnetic substrates (e.g., [8]).

Methods employing high electromagnetic field strengths that generate a nonlinear response are increasingly used to characterize surfaces and interfaces (see e.g., [9] for a recent review). Second harmonic generation (SHG), for example, is sensitive to surface and interface symmetry, and many experiments have exploited this. Extensive reviews of the application of SHG to semiconductor [10] and molecular interfaces were published [11]. The electric-field-induced optical second harmonic generation (EFISHG) was exploited to map the electric field profile along the channel region at the gate-insulator-active layer interface in pentacene-based organic field effect transistors (OFETs) (see, e.g., [12]). Time-resolved EFISHG measurements were furthermore employed to study the charge carrier dynamics in pentacene OFETs [13].

The development of reliable femtosecond laser systems has, on the other hand, driven the application of sum-frequency generation (SFG) to probe vibrational properties at surfaces and interfaces. The main advantages of SFG compared to conventional infrared (IR) spectroscopies is its surface sensitivity, arising from the detection at the sum-frequency wavelength. This allows the use of much more sensitive detectors operating in or near the visible region and the time resolution associated with short laser pulses. Comprehensive reviews of SFG can be found in [14, 15]. SFG vibrational spectra, in combination with theoretical simulations based on density functional theory (DFT), were successfully used to estimate the molecular orientation of self-assembled MLs [16]. Simultaneous SFG vibrational spectra and electrical measurements of pentacene-based OFETs showed a strong correlation between the dependence of the SFG nonresonant background on gate voltage on one hand and the electronic mobility on the other hand, suggesting that a common molecular structural packing element determines the magnitude of both the electronic mobility and higher order nonlinear optical susceptibilities in oligomeric thin films [17]. Further reports on the application of vibrational SFG to OFETs characterization are summarized in [18]. Elliott, Horvath, and Gordon [18] also present an up-to-date review of various vibrational spectroscopies used to probe various molecule-based devices.

The research interest in organic semiconductors is driven by manifold applications such as organic light-emitting devices (OLEDs), OFETs, and organic photovoltaic cells (OPVCs). Organic semiconductors could be devided in two groups containing either polymers or so-called small molecules. This chapter deals exclusively with the application of optical spectroscopies for the study of molecules within the latter class, demonstrated using two examples from the class of perylene derivatives, 3,4,9,10-perylene-tetracarboxylic-dianhydride (PTCDA) and *N*,*N*′-dimethyl 3,4,9,10-perylene-tetracarboxylic diimide (DiMe-PTCDI). The molecular structure of these two molecules is quite similar. Still, the ‘‘minor’’ change in the functional groups of these molecules has dramatic effects on both molecular orientation on inorganic substrates and interfacial chemistry when an interface with the organic semiconductor is formed by depositing a metal on top of the organic semiconductor. These dramatic effects motivate the choice of these two molecules. They are excellently suited to demonstrate how minor changes of molecular structures can be utilized to influence interfacial and layer properties. At the same time, they allow the sensitivity of the major experimental techniques used in this review, Raman spectroscopy and RAS, to be benchmarked.

PTCDA is an archetype organic molecule that has already been studied on a variety of inorganic substrates by a large number of experimental and theoretical methods [e.g. 19–22], with scanning probe techniques being the ones most widely used. The most commonly used substrate materials have been metals, highly oriented pyrolytic graphite and insulators (NaCl, SiO_2, Al_2O_3) [19], while investigations using the more reactive surfaces of common inorganic semiconductors such as silicon and gallium arsenide (GaAs) have been scarce. In this review, GaAs is the substrate of choice owing to the emphasis in our work on inorganic/organic semiconductor heterostructures.

This chapter is organized as follows. Section 42.2 introduces the molecules and their properties with particular emphasis on the solid phase as molecular crystals, the sample preparation, and the experimental methods, that is, Raman and RAS.

Section 42.3 deals with the initial adsorption of the molecules on GaAs surfaces studied by RAS and Raman spectroscopy, while Section 42.4 focuses on Raman spectroscopy investigations of metal deposition onto organic layers.

42.2
Experimental Methods and Theoretical Calculations

42.2.1
Properties of Perylene Derivatives

The two molecules that are the object of this work belong to the class of heteroaromatic systems, more specifically to the group of perylene derivatives (Figure 42.1): PTCDA and DiMe-PTCDI.

PTCDA is one of the most intensively studied organic molecular semiconductors, for example, for investigations of structural ordering during growth. This is because PTCDA is thermally stable, and very pure, well-ordered thin films can be fabricated by organic molecular beam deposition (OMBD) on various inorganic substrates. The structural formula of PTCDA is shown in Figure 42.1. PTCDA has a planar rectangular geometry consisting of a perylene core (20 carbon atoms, 8 hydrogen atoms) terminated by two electron-withdrawing anhydride (O=C–O–C=O) groups. Three C_2 axes of symmetry can transform the molecule into itself upon rotation by 180°, three planes show reflection symmetry ($\sigma(xy)$, $\sigma(xz)$, $\sigma(yz)$) and an inversion center I is present. The symmetry of all molecular orbitals can be described by the irreducible representations of the D_{2h} point group. All the symmetry classes that are even/odd with respect to the inversion center will be labeled with the indices *g*(*gerade*)/*u*(*ungerade*). Following Suzuki [23], the orbitals are usually denoted by lower case letters, and states by capital letters. As an example, the symmetry of HOMO (highest occupied molecular orbital) is $a_u(xyz)$, that of LUMO (lowest unoccupied molecular orbital) is $b_{1g}(yz)$, and the corresponding states are A_u and B_{1g}. All states are singlet and the usual notation found in literature for the

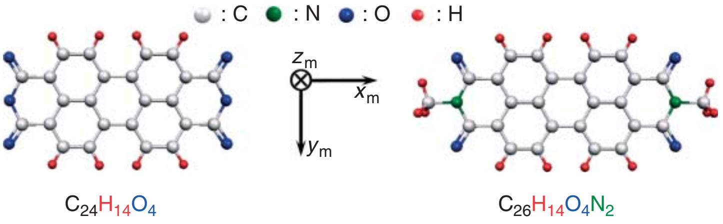

Figure 42.1 The chemical structure of PTCDA and DiMe-PTCDI. The molecular coordinate system is defined such that the x_m and y_m axes are parallel to the long and short axes of the molecules, respectively, and the z_m axis is perpendicular to the molecular planes. The molecular mass is 392 atomic mass units (amu) and 418 amu for PTCDA and DiMe-PTCDI, respectively. Adapted with permission from Ref. [24]. Copyright (2007) American Chemical Society.

corresponding vibronic (electronic plus vibrational) states is S_0 for HOMO, S_1 for LUMO, and S_2 for the next excited state accessible via a dipole-allowed transition. E_{0-0} designates the transition between the ground vibrational states of the electron ground state and first excited state.

DiMe-PTCDI is very similar to PTCDA, and it consists of 26 carbon atoms, 14 hydrogen atoms, 4 oxygen atoms, and 2 nitrogen atoms. The replacement of the bridging oxygen atom of the anhydride group with the three-dimensional methylimide group leads to a deviation from the planar geometry. The molecular structure is also shown in Figure 42.1. Two relative arrangements of the methyl groups are possible: in one of them the hydrogen atoms face each other (C_{2v} molecular symmetry), in the other they are rotated by 180° such that the molecule has an inversion center (C_{2h} symmetry). The electronic levels and vibrational frequencies are not influenced by the difference in the geometry; therefore, the C_{2h} group will only be considered further on for the ease of comparison with PTCDA.

The fact that perylene derivatives often grow in a well-ordered, sometimes even in a quasiepitaxial mode, when thermally evaporated under vacuum conditions was experimentally verified on a variety of substrates ranging from metals to ionic insulators. An exhaustive review was made by Forrest in 1997 [19]. In most cases, the monoclinic crystallographic system ($P2_1/c(C_{2h}{}^5)$) is preferred. For PTCDA two polymorphs are reported [19], whereas for DiMe-PTCDI only one crystal structure is known so far. PTCDA molecules were found to lie almost flat on the substrates [19].

Both molecular crystals have two molecules per unit cell arranged in a herringbone packing in the (102) lattice planes. The inclination of the molecular plane with respect to the (102) plane amounts to $\sim 5^\circ$ for PTCDA [25] and $\sim 8^\circ$ for DiMe-PTCDI (calculated from crystal data [26]). The distance between adjacent planes is ~ 3.2 Å, which is small compared to the other lattice constants. This causes fairly strong interactions of the π-electron systems within the stacks perpendicular to (102) plane.

Both HOMO and LUMO of perylene derivatives are mainly governed by the extended conjugated π-electron system composed of atomic $2p_z$ wave functions [27, 28] of the perylene core. The experimental ultraviolet–visible (*UV–vis*) absorption spectra of isolated molecules (monomer) obtained from diluted solutions of PTCDA in dimethyl-sulfoxide (DMSO) and of DiMe-PTCDI in chloroform are very similar in terms of line shape [29]. In both cases, the vibronic progression of the S_0–S_1 transition with the E_{0-0} peak at 2.38 eV (PTCDA) and 2.36 eV (DiMe-PTCDI) dominates the spectra. It must be noted, however, that the E_{0-0} values are affected by the dielectric constant of the solvent. The E_{0-0} values for PTCDA monomers in an inert environment was determined by means of laser-induced fluorescence of PTCDA in He droplets to be 2.6 eV [30]. A comprehensive analysis of the PTCDA monomer absorption was carried out by Scholz *et al.* [31] taking into account the participation of totally symmetric vibrations in the vibronic progression.

In thin films grown on quartz substrates, the E_{0-0} (S_0–S_1) transitions are red-shifted compared to monomers in solution and the first absorption peaks appear at 2.22 eV (PTCDA) and 2.16 eV (DiMe-PTCDI) (Figure 42.2). Moreover, the broadening is large so that the individual vibronic peaks are not resolved. The same holds for

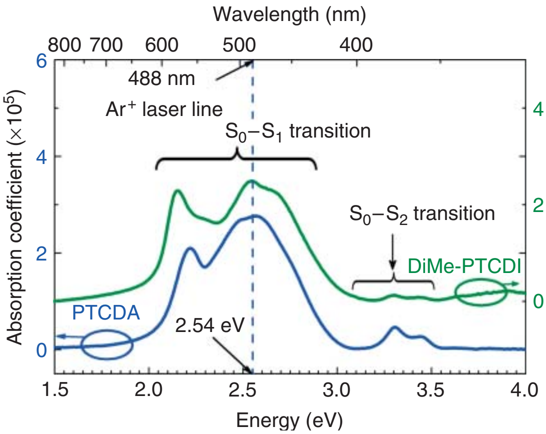

Figure 42.2 Absorption spectra of PTCDA (bottom) and DiMe-PTCDI (top) films (50 nm each) deposited on quartz substrates at RT. The energy position of the excitation line used in Raman experiments is indicated by the dashed vertical line. Adapted with permission from Ref. [24]. Copyright (2007) American Chemical Society.

the S_0-S_2 transition, the dipole of which is oriented along the short molecular axis y_m. The change in absorption line shape of films (crystal) compared to monomers in solution is known as *crystallochromy* and was observed for a large number of perylene derivatives [29]. For PTCDA, it was shown that this change can be related to the transfer of Frenkel excitons between neighboring molecules [31], considering a regular arrangement of the molecules in the crystalline domains having finite size.

42.2.2
Sample Preparation

42.2.2.1 Organic Molecular Beam Deposition (OMBD)

The experiments described in this chapter focus on thin films of PTCDA and DiMe-PTCDI grown on GaAs(100) by OMBD. The PTCDA material was purchased from Lancaster Synthesis, while the DiMe-PTCDI material was purchased from Sensient Imaging Technologies GmbH. Each material was further purified by double sublimation at 310 °C for PTCDA and 300 °C for DiMe-PTCDI under high vacuum ($\sim 10^{-6}$ mbar) and then filled into a quartz crucible mounted in a Knudsen cell. Before the evaporation of the organic material, the Knudsen cell was thoroughly degassed for a few hours at 200 °C. Organic thin films were prepared using OMBD from the Knudsen cells operated at approximately 280 °C for the two organic materials. During OMBD, the GaAs(100) substrates were kept at room temperature (RT). The organic films were deposited at a rate of $\sim 0.2\,\text{nm min}^{-1}$ as monitored by a quartz crystal microbalance located in the vicinity of the sample. A calibration of the microbalance was performed by correlating the frequency shift to the thickness determined by means of atomic force microscopy (AFM). The thickness of the organic coverage varies from submonolayer to 15 nm thick films. We define the thickness of one monolayer (ML) as the amount of PTCDA molecules ($7.6 \times 10^{13}\,\text{cm}^{-2}$) that covers the entire surface assuming flat-lying PTCDA molecules: 1 ML $\cong$ 0.32 nm.

The deposition was interrupted for the Raman and the RAS measurements at certain thicknesses.

42.2.2.2 **Metal Deposition**

The metals were evaporated from boron-nitride Knudsen cells kept at 380 °C for Mg, 830 °C for In, and 930 °C for Ag onto the organic films. Before use, all evaporation sources were thoroughly degassed. The metal was deposited at a rate of approximately 1.6 nm min^{-1} for Ag and 2 nm min^{-1} for In and Mg, in a stepwise manner. The amount of metal deposited onto the sample was monitored using a quartz crystal microbalance.

42.2.3
Reflection Anisotropy Spectroscopy

RAS, also called *reflectance difference spectroscopy*, is an optical technique developed originally by Aspnes [32] for real-time, *in situ* monitoring of semiconductor growth [33–35]. More recently, RAS was used to characterize the surface optical properties of metals [36–39] and even to monitor the growth of different organic molecular systems on metal surfaces [40–42] as well as on semiconductor surfaces [43, 44]. When applied to the investigations of the molecular film growth, RAS allows information on the bonding nature of the molecules on surfaces [45, 46] to be extracted as well as for the determination of the molecular orientation [40, 47, 48]. A complementary technique, differential reflectance spectroscopy (DRS) has also been used to investigate the growth of molecular films, especially on high-symmetry substrate surfaces (see, e.g., [49]), where the application of the RAS technique is limited because of the low signal level.

In the RAS technique, the difference in normal incidence in reflection for light linearly polarized (Figure 42.3) along two orthogonal directions in the sample surface as a function of photon energy is measured. In, for example, cubic materials where the bulk is optically isotropic, the RAS signal vanishes because of a cancellation of the bulk contribution by symmetry.

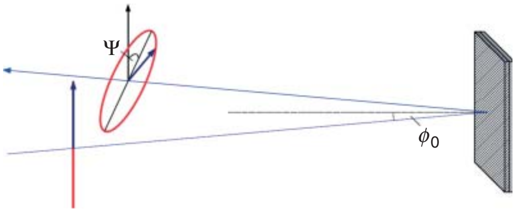

Figure 42.3 Schematic picture of the light propagation in a RAS experiment. The incidence angle ϕ_0 and the polarization states of the light beams before and after reflection on the surface are indicated.

The RAS signal, as defined by Eq. (42.1), measures the difference in reflectivity along two orthogonal axes.

$$\frac{\Delta r}{r} = \mathrm{Re}\left(\frac{\Delta r}{r}\right) + i\ \mathrm{Im}\left(\frac{\Delta r}{r}\right) = 2\frac{r_x - r_y}{r_x + r_y} \tag{42.1}$$

As the RAS measurement is performed at near-normal incidence, the ratio of Fresnel coefficients can be written as follows:

$$\rho = \frac{r_\mathrm{p}}{r_\mathrm{s}} = \frac{r_x}{r_y} \tag{42.2}$$

In the case of extremely small anisotropies, for $\Delta r \ll 1$, the RAS signal becomes

$$\begin{aligned} \mathrm{Re}\left(\frac{\Delta r}{r}\right) &\cong 1 - |\rho| = 1 - \tan\psi \\ \mathrm{Im}\left(\frac{\Delta r}{r}\right) &\cong 1 - \arg\rho \end{aligned} \tag{42.3}$$

For the *in situ* RAS measurements, a spectrometer similar in design to that described by Aspnes [32] (Figure 42.4) was employed. The spectrometer was operated at near-normal incidence in the photon energy range from 1.8 to 5.3 eV. The spectra were recorded by measuring the relative reflectance difference of the sample in two directions corresponding to the [−110] and [110] directions in the surface plane of GaAs(001).

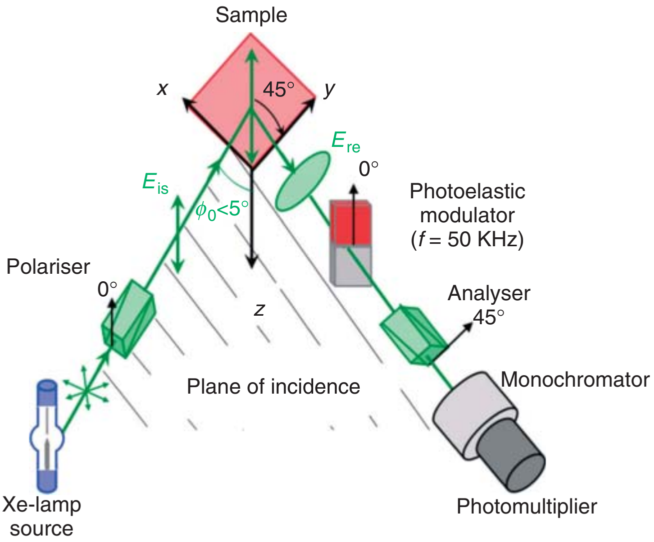

Figure 42.4 A general scheme of a RAS setup. The incident linearly *s*-polarized light (with the direction perpendicular to the plane of incidence) reflects from the sample elliptically polarized. The transmission axes of input polarizer and photoelastic modulator coincide. The transmission axis of analyzer is rotated by 45° with respect to the plane of incidence.

42.2.4
Raman Spectroscopy

In its classical description, Raman scattering is treated as the radiation of light produced by a time-dependent dipole $M(t)$, induced in a molecule by the incident electromagnetic light and modulated by the molecular vibrations. The highly monochromatic incident light required in Raman spectroscopy is provided by laser sources having a light frequency ν_L usually much larger than the vibrational frequency ν_j involving the motions of nuclei. Therefore, only electrons can respond to the external electromagnetic field. The dipole moment induced in the molecule can be written as

$$M(t) = \alpha(t) \cdot E(t) + {}^1\!/_2\beta(t) \cdot E^2(t) + \cdots \tag{42.4}$$

Here, $E(t) = E_L \cdot \cos(2\pi\nu_L t)$ is the electric field component of the incident light with the amplitude E_L, α is the electronic polarizability of the molecule (or susceptibility in inorganic crystals), and β is the hyperpolarizability, which is responsible for the hyper-Raman effect.

In general, the direction of the induced dipole M does not coincide with that of the electric field. Therefore, the polarizability in the relation $M = \alpha\ E$ must be a second-rank tensor:

$$\begin{pmatrix} M_x \\ M_y \\ M_z \end{pmatrix} = \begin{pmatrix} \alpha_{xx} & \alpha_{xy} & \alpha_{xz} \\ \alpha_{yx} & \alpha_{yy} & \alpha_{yz} \\ \alpha_{zx} & \alpha_{zy} & \alpha_{zz} \end{pmatrix} \begin{pmatrix} E_x \\ E_y \\ E_z \end{pmatrix} \tag{42.5}$$

The matrix constructed with the elements of the polarizability tensor derived with respect to the normal coordinate q_j of the vibration j is denoted as Raman or scattering tensor:

$$\delta\alpha^j = \begin{pmatrix} \alpha^j_{xx} & \alpha^j_{xy} & \alpha^j_{xz} \\ \alpha^j_{yx} & \alpha^j_{yy} & \alpha^j_{yz} \\ \alpha^j_{zx} & \alpha^j_{zy} & \alpha^j_{zz} \end{pmatrix} q_j \tag{42.6}$$

where

$$\delta\alpha^j_{\eta\sigma} = \alpha^j_{\eta\sigma} q_j = \left(\frac{\partial\alpha_{\eta\sigma}}{\partial q_j}\right)_0 q_j$$

Taking into consideration the wave-particle duality of the light, Raman scattering processes involve at least two quanta acting instantaneously (scattering time is on the order of 10^{-14} to 10^{-15} s) with the conservation of energy and momentum between the initial and final states of the light-matter system:

$$h\nu_L = h\nu_S \pm h\nu_j(k_j) - \text{energy conservation} \tag{42.7}$$

$$\mathbf{k}_L = \mathbf{k}_S \pm \mathbf{k}_j - \text{momentum conservation} \tag{42.8}$$

Here $h\nu_{L,S}$ and $\mathbf{k}_{L,S}$ are the energy and momentum of the incident (L) and scattered (S) light. $h\nu_j$ and $\mathbf{k}_j$ are the energy and momentum related to a transition between

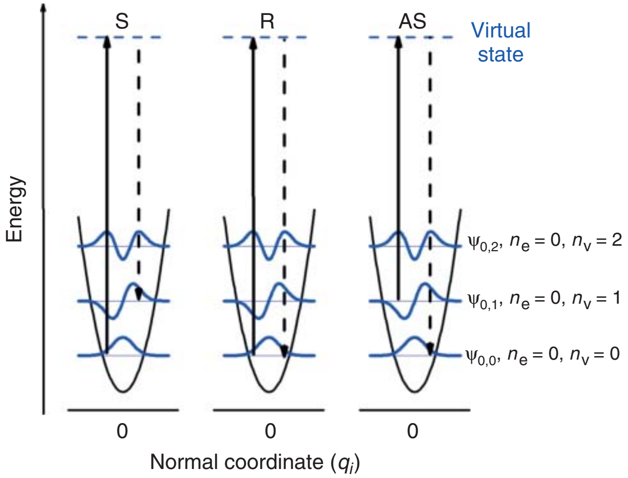

Figure 42.5 Comparison of energy diagrams for scattering processes: Raman Stokes (S), Rayleigh (R), and Raman anti-Stokes (AS). Each energy level of the harmonic oscillators is labeled with the electronic quantum number (n_e) and the vibrational quantum number (n_v).The energy of the exciting and emitted photon is indicated by a continuous and by a dash-dotted arrow, respectively. Adapted with permission from Ref. [24]. Copyright (2007) American Chemical Society.

the vibrational states of a normal vibration *j*. For a visualization of the energy diagram of the processes, see Figure 42.5.

In an elastic Rayleigh scattering process, a photon having the same energy as the incident one is emitted and the molecule/crystal remains in the initial vibrational state. In the case of an inelastic Raman process, the energy of the emitted photon is not the same as that of the impinging one and there is a net change in the vibrational state of the molecule. The Stokes process brings the molecule into a higher vibrational state, and the energy of the emergent photon is lower than ν_L (Figure 42.5). During the anti-Stokes (AS) process, the molecule suffers a transition to a lower energy vibrational state and the emitted photon has a higher energy compared to the incident one. Typically, the intensity of the Rayleigh line is about 10^{-3} of the incident light intensity, while the Raman bands are at least another factor 10^3 weaker. As the population of the ground vibrational state is higher by a Boltzmann factor compared to that of the first excited state, Stokes processes are more probable than AS ones [50]. Therefore, the more intense Stokes Raman spectrum on the low-energy side of the exciting line is usually recorded.

For PTCDA and DiMe-PTCDI, the excitation light (488 nm line of an Ar^+ laser) for the Raman spectroscopy experiments throughout this work falls in the S_0–S_1 absorption band (Figure 42.2). This provides favorable conditions for the resonant Raman effect. As the S_0–S_1 transition dipole moment lies along the x_m axis, mainly the vibrations with a large R_{xx} component of the Raman tensor will be enhanced during the process. For PTCDA, this condition is fulfilled by the 19 vibrations originating from the A_g modes of the isolated molecule. In the case of DiMe-PTCDI, only those A_g modes with low off-diagonal components in the Raman tensor will be resonantly enhanced by the 488 nm excitation line, that is, those modes preserving the rectangular symmetry of the perylene core. Therefore, a similar number of vibrations are expected to occur in the resonant Raman spectra of PTCDA and DiMe-PTCDI.

The total number of degrees of freedom associated with internal vibrations is $Z{\cdot}(3{\cdot}N\text{-}6)$, with Z being the number of molecules in the crystal unit cell. The remaining $6{\cdot}Z$ degrees of freedom determine the orientation of the Z molecules in space and can describe movements of entire molecules, that is, lattice vibrations. These vibrations will be termed as *external modes*, or simpler *phonons*. As in inorganic crystals, three of the phonons have an acoustic character. From the remaining $6{\cdot}Z-3$ of optical origin, three have a translational character and the rest involve rotations of the rigid molecules around their fixed axes. The symmetry of external vibrations is determined by irreducible representations of the crystal space group. As both PTCDA and DiMe-PTCDI belong to the same factor group with $Z = 2$, they have the same representation for the external modes:

$$\Gamma_{\text{ext}} = 3A_g + 3B_g + 3A_u + 3B_u \tag{42.9}$$

Six of the optical phonons are symmetric with respect to the inversion center of the unit cell and are Raman active and those with B_u symmetry are IR active. The acoustic phonons have A_u symmetry.

The broadening of the Rayleigh band is dominated by the spectrometer resolution and can thus serve for the determination of the experimental resolution. The line shape of a Stokes/AS band originates from the limited lifetime of the vibrations convoluted with the instrumental resolution. Generally, it can be described by a Lorentz function convoluted with a Gaussian function. When the width of the Gaussian function is small enough, the line shape of Raman bands can be approximated by a Lorentz function. Unless otherwise specified, the Raman spectra throughout this work were fitted with Lorentzian functions using a least square error algorithm.

The samples investigated by means of Raman spectroscopy were prepared in a UHV chamber (base pressure 2×10^{-10} mbar), which also serves as the analysis chamber. It is optically coupled to a Raman spectrometer allowing *in situ* measurements and *online* growth monitoring to be performed. The Raman spectra shown in this work were excited with the 488 nm (2.54 eV) emission line of an Ar^+ laser. The scattered light is collected by a Dilor XY 800 triple monochromator operated in the subtractive mode and equipped with a multichannel charge-coupled device detector. The spectral resolution ranged from 2 to $\sim$3.5 cm^{-1} as determined from the full width at half maximum (FWHM) of the Rayleigh line.

For the *in situ* measurements, the angle between the incident and scattered light is fixed by the position of the corresponding UHV windows. The sample surface was always oriented parallel to the collection window, that is, the scattered light was collected in the direction parallel to the sample normal. The incidence angle was 30°. The diameter of laser light focused on the sample was $\sim$300 μm and the collection angle was $\sim$18°.

The laser power was measured in front of the UHV window. Typical power values were in the range from 50 to 100 mW. The power densities lie below the damage threshold of the absorbing PTCDA and DiMe-PTCDI films and crystals in all configurations used.

Two polarization configurations were used in the present work. The polarization of the analyzer was always kept the same and only the polarization of incident light was rotated. For example, ''crossed polarization'' means that the electric field vector of the incident light was in the plane of incidence and the electric field vector of the analyzed scattered light was perpendicular to it; ''parallel polarization'' means that both electric field vectors are perpendicular to the plane of incidence and hence parallel to the sample surface. If the polarization configuration is not specified in the text, it means that the polarization of the scattered light was not analyzed.

As the incidence angle for the *in situ* measurements is rather small (30°), this quasi-backscattering geometry will be denoted in all cases according to the Porto notation, that is, $z(yx)\bar{z}$ and $z(xx)\bar{z}$ for the parallel and perpendicular polarization configurations, respectively. Here, z and $\bar{z}$ indicate that the direction of the incident and analyzed scattered light, respectively, are parallel to the sample surface normal, while x and y denote the direction of the electric field vector of incident and analyzed scattered light, respectively.

42.2.4.1 **Calculation of Vibrational Frequencies**

Vibrational frequencies are computed by determining the second derivatives of the energy with respect to the Cartesian nuclear coordinates and then transforming to mass-weighted coordinates. In general, DFT methods slightly overestimate vibrational frequencies [51]. Therefore, it is common practice to introduce scaling factors for the frequencies of 0.95–0.99 in order to get a lower root-mean-square error between calculated and experimental modes. However, in some cases, calculated modes can match experimental values or even underestimate them slightly. As the situation is rather complicated for oxygen-containing compounds such as PTCDA and DiMe-PTCDI, no general scaling for the calculated mode frequencies was performed. The relative order of the Raman-active and IR-active modes calculated using the 6-31G(d) basis set corresponds well to the ordering of the experimental frequencies. However, the smaller 3-21G basis set results in the best agreement with the experimental findings in terms of the root-mean-square deviations [51]. As it also requires less calculation time, in particular for larger systems such as PTCDA + Si, the 3-21G basis was used for all frequency calculations within this work.

42.2.4.2 **Vibrational Properties of *PTCDA***

The first vibrational spectra of PTCDA films were reported in 1987 by Akers *et al.* [52] who proposed an empirical assignment of internal modes. Several theoretical works were devoted in recent years to the study and identification of the vibrational modes. Scholz *et al.* [27] used a DFT code and compared the frequencies of the calculated A_g modes with those observed in thin PTCDA films. A similar DFT time-dependent method was used in the Gaussian 98 [53] package with several basis sets for the molecular wavefunctions. The correspondence between the resulting Raman-active modes and the experimental ones is discussed in detail in Ref. [28]. However, the calculations were all performed for nonresonant conditions, while the experimental spectra of films were obtained in resonance; therefore, a direct correspondence between the calculated cross sections and the experimental ones must be considered with care.

Polarization-dependent measurements performed on a single crystal using the 488 nm (2.54 eV) Ar^+ line enabled recently the first observation of the Davydov splitting in this system [54]. The Raman spectra from Ref. [54] are shown in Figure 42.6. For the determination of the Raman mode frequencies and intensities in the spectra shown in Figure 42.6, a least square fitting algorithm with Lorentzian peaks was employed. The Raman tensor for the A_g component of the Davydov doublet has three diagonal components of different magnitude and nondiagonal components, while the tensor of the B_g mode has only nondiagonal components [54]. For the experimental geometry employed by Tenne *et al.* [54], the B_g bands appear only in the crossed polarization geometry $z(yx)\bar{z}$, while the A_g modes are present in both configurations depending on the magnitude of their Raman tensor components.

Table 42.1 summarizes the assignment of the PTCDA modes observed under resonant conditions. The second and the third columns contain the frequencies of Davydov components observed in a crystal [54], while the fourth column gives the calculated frequencies in a free molecule [28]. The last two columns describe the symmetry of the corresponding vibrations in the isolated molecule and which part of the molecule is predominantly involved. As depicted in Figure 42.7, a PTCDA

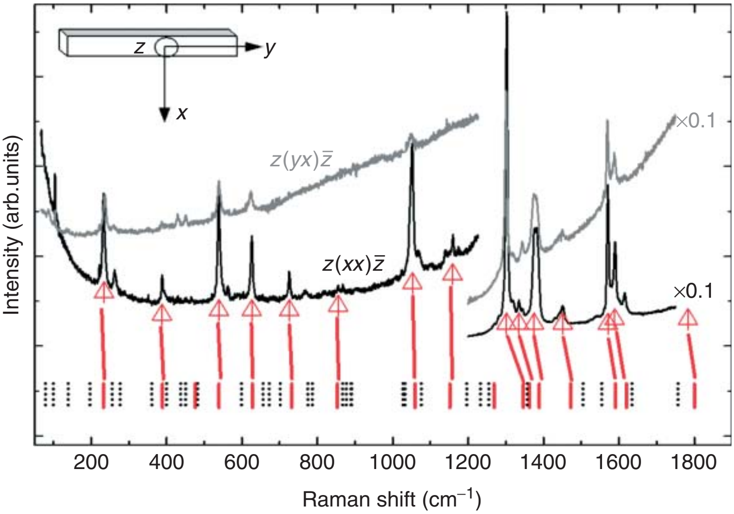

Figure 42.6 Raman spectra of a PTCDA single crystal recorded at RT in crossed (gray line) and parallel (black line) polarization configurations. The triangles represent experimental frequencies of A_g modes and the vertical lines represent calculated frequencies of A_g (thick lines) and B_g (dotted lines) modes.

molecular breathing along the x_m axis gives rise to the lowest frequency internal mode (233 cm^{-1}), while the mode at 1303 cm^{-1} – with the largest cross section – is related to C–H bending vibrations. The stretching of C–C bonds governs the modes around 1580 cm^{-1}. There are two groups of modes, namely, around $\sim$1150 cm^{-1} and between 1320 and 1360 cm^{-1} where the assignment is still ambiguous owing to their very similar cross section and polarization behavior.

The observation of external modes in PTCDA was reported in 2000 [54, 55, Figure 42.6, left]. The symmetry assignment was performed by analogy with the modes reported for β-perylene [56], which has the same monoclinic structure as PTCDA and therefore similar intermolecular forces can be assumed. Considering the difference in mass for the two molecules ($m_{\text{PTCDA}} = 392$ amu and $m_{\text{perylene}} = 252$ amu), the frequencies of PTCDA phonons were calculated using the proportionality relation of two harmonic oscillators with the same force constant:

$$\frac{\omega_{\text{perylene}}}{\omega_{\text{PTCDA}}} = \sqrt{\frac{m_{\text{PTCDA}}}{m_{\text{perylene}}}} = 0.8 \tag{42.10}$$

The properties of phonons observed in PTCDA are summarized in the first six rows in Table 42.1. The frequencies calculated as described are given in column five and their elongation patterns are displayed in Figure 42.8. The assignment of the mode at 60 cm^{-1} is not clear because, according to the comparison with the perylene phonons, it should be a B_g mode, but in PTCDA it is observed in parallel polarization as the A_g modes. The lowest energy phonons employ rotations around the x_m axis of the molecules, while for the higher energy ones the molecules rotate around their z_m axis [57]. A sketch of the vibrational pattern for selected modes can be seen in Figure 42.8. It must be noted that DFT methods (B3LYP:3-21G)

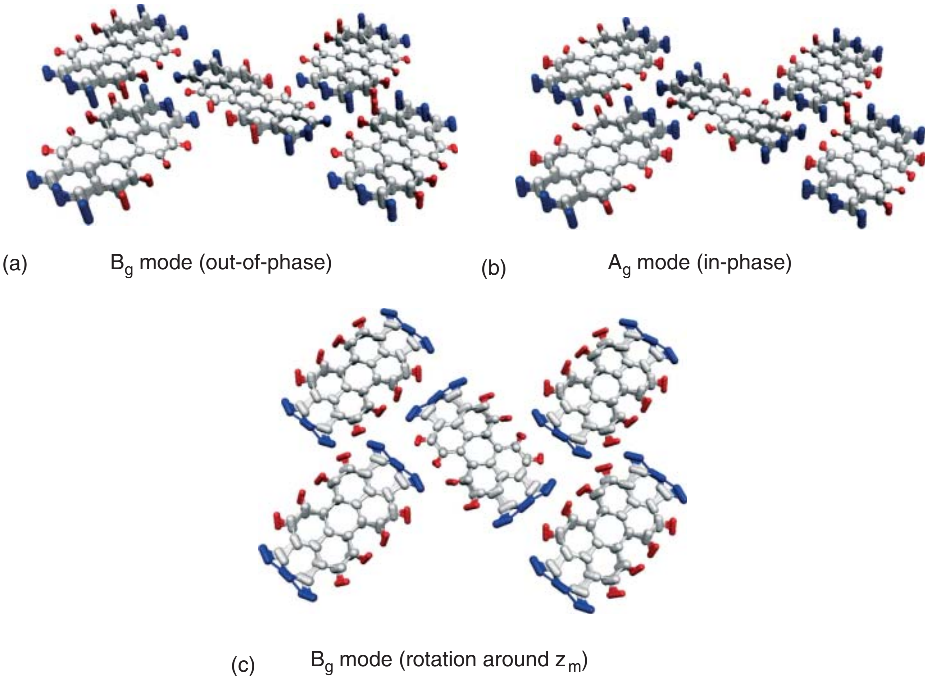

Figure 42.8 Elongation patterns of selected phonons of the α-PTCDA crystal: the lowest frequency phonons employ out-of-phase (a) and in-phase (b) rotations around the x_m axis of the molecules; in the highest frequency B_g phonon (c) the molecules rotate around their z_m axis. predict the existence of three out-of-plane (OOP) internal modes below 150 cm^{-1}: one B_{2g} ($\delta_{C-C-C} + \delta_{C-O-C}$) mode at 78 cm^{-1}, and two B_{1g} (δ_{C-C-C}) modes at 99 and 138 cm^{-1}. In-plane (IP) and OOP modes stem for vibrational elongations involving movement of atoms within the molecular plane and perpendicular to it, respectively.

Muck *et al.* [57] reported the presence of more than six modes below 125 cm^{-1} in Raman spectra measured at 20 *K*, some of them showing strong polarization dependence. They proposed a model that explains the large number of modes based on the coupling between internal and external modes mediated by pure van der Waals interactions. Even though the number of the observed modes and their ordering were reproduced fairly well, the calculated frequencies were highly overestimated, in particular for the C–H and C=O related modes.

42.2.4.3 **Vibrational Properties of DiMe-PTCDI**

Gosh and Aroca [58] were again the first to report Raman spectra of films and proposed an empirical assignment. For the mode assignments used in this work, DFT was employed with the same basis set as for PTCDA (B3LYP:3-21G) (Figure 42.9).

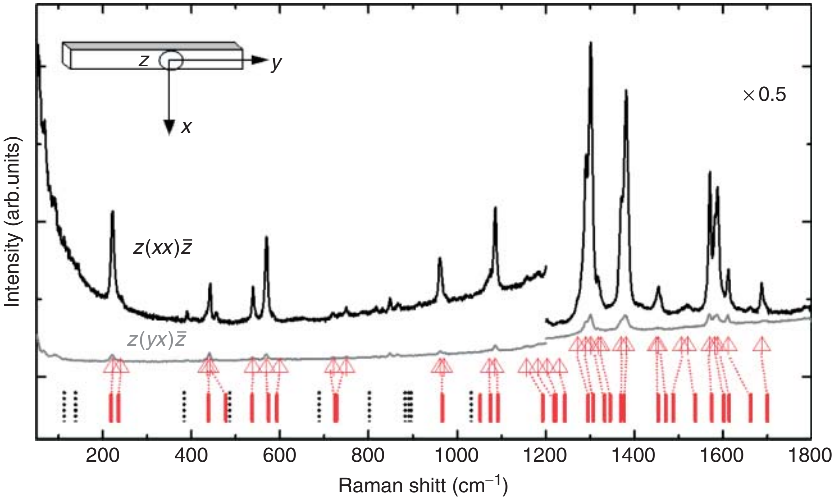

Figure 42.9 Raman spectra of a DiMe-PTCDI single crystal recorded at RT in parallel (black line) and crossed (gray line) polarization configuration. The triangles represent experimental frequencies of A_g modes and the vertical lines represent calculated frequencies of A_g (thick lines) and B_g (dotted lines) modes. Adapted with permission from Ref. [24]. Copyright (2007) American Chemical Society.

As in the case of PTCDA, polarization measurements on a single crystal were performed under resonant conditions using an excitation energy of 2.54 eV and a resolution of 2 cm^{-1}.

A concept widely used in the literature dedicated to quantitative analysis of the sample polarization response is the depolarization ratio [59]. This is defined as the ratio between the Raman signals obtained in crossed polarization configuration to that obtained in parallel configuration:

$$\mathrm{Dep} = \frac{I_{yx}}{I_{xx}} \tag{42.11}$$

The frequencies obtained for the parallel and crossed polarization spectra are tabulated in the second and third column of Table 42.2. In column five, the intensities in parallel polarization relative to the strongest mode at 1301.4 cm^{-1} are provided. The experimental depolarization ratios are listed in column six. The calculated frequencies, the mode symmetry, and their character are listed in column four, seven, and eight. Selected elongation patterns of several modes of a neutral DiMe-PTCDI molecule are displayed in Figure 42.10. No scaling factor was applied to the calculated frequencies for consistency with the model applied to PTCDA [51].

A large number of similarities can be found between the vibrational spectra of DiMe-PTCDI and PTCDA owing to their perylene core, which determines the rectangular symmetry of both molecules. For instance, the breathing mode at 220.5 cm^{-1} has the same character as the corresponding one in PTCDA and its frequency is by a factor 0.95 lower compared to the 233 cm^{-1} mode of PTCDA

As in the case of PTCDA, a mode with OOP character involving deformation of C–C and C=O bonds appears at 441 cm^{-1}. The C–H deformation modes with some contribution from CH_3 groups, C–N stretching or bending appearing around 1300 and 1380 cm^{-1}, dominate the spectra. The C–C stretching modes accompanied by C–H deformations govern the region around 1600 cm^{-1}. There are few modes originating exclusively from the methylimide groups ($-N-CH_3$) in the spectra: a shoulder at 239 cm^{-1} stems from the stretching of C–N bonds, and the modes at 961, 1086, and 1157 cm^{-1} are due to the rocking of CH_3 groups.

In crossed polarization configuration $z(yx)\bar{z}$, the internal modes almost vanish. This leads to low depolarization ratios (0.1–0.2) for most of the A_g modes involving vibrations of the perylene core. The few modes with depolarization above 0.5 have either *OOP* (B_g) or *IP* C–H or C–N–C deformation character. The amount of Davydov splitting is generally less than that observed in PTCDA owing to different relative orientation of the molecules in the unit cell.

The external vibrational modes of DiMe-PTCDI were observed for the first time in a Raman experiment in 2003 [60]. Their observation in a femtosecond pump-probe experiment was also reported by Hasche *et al.* [61].

Figure 42.12 shows the polarization dependence in the phonon region in both PTCDA and DiMe-PTCDI crystals for the experimental geometry shown in the insets. Even though the relative intensities are different for the two crystals, clear polarization dependence is observed in both cases. Modes that are strong in parallel polarization become very weak or even vanish in crossed polarization, enabling the symmetry assignment proposed for DiMe-PTCDI in Table 42.3. When rotating the DiMe-PTCDI crystal around the z axis, the polarization behavior changes and

several modes appear at different frequencies. The frequencies are summarized for both situations in columns one to four of Table 42.3. In column five, the frequencies reported in Ref. [61] are provided. Columns six and seven contain the frequencies and the symmetry assignment proposed [61] by comparison with the phonons reported for perylene [56]. The correspondence in number of modes and frequency positions is good, except for the presence of two modes at 4.7 and 25 cm^{-1}. These were assigned to a Davydov splitted internal mode with B_g symmetry, which is predicted by DFT calculations to appear at 16 cm^{-1}. On the other hand, the B3LYP:3-21G methods predict the existence of four Raman-active internal modes with B_g(OOP) character below 125 cm^{-1}, but none of them has such a low frequency: 77, 86, 111, 112 cm^{-1} (A. Y. Kobitski, private communication). The mode at 25 cm^{-1} is also observed in the Raman spectra.

Moreover, it was found that three modes located at 50, 54, and 57 cm^{-1} correspond to the B_g mode at 57 cm^{-1} reported by Hasche *et al.* [61], whereby the mode observed at 50 cm^{-1} behaves rather like an A_g mode. Also, the Raman modes at 96 and 101 cm^{-1} correspond to the same A_g mode in the time-resolved experiment. The large number of modes could be understood in the frame of the model proposed by Muck *et al.* [57] as originating from the coupling between internal and external modes. Because a comprehensive theoretical model is still lacking, the modes below 125 cm^{-1} will be considered as external modes according to the assignments in Table 42.1 (for PTCDA) and Table 42.3 (for DiMe-PTCDI) throughout this work, even though a contribution from the internal modes cannot entirely be ruled out.

42.3
Initial Adsorption of Molecules on Inorganic Semiconductor Surface

Early studies of organic molecule adsorption on low-index faces of inorganic semiconductors such as GaAs (100) suggested that a passivated surface was necessary for ordered growth. It was found that, for example, PTCDA formed ordered layers on GaAs (100) if the surface had been passivated by a selenium (Se) ML, while the order was significantly poorer when the growth took place on clean GaAs surfaces [62]. It was proposed that the GaAs surface bonds are saturated by Se and the organic molecules attach through weak van der Waals bonding to the surface. As a result of this weak interaction, the molecules have sufficient mobility on the surface to arrange into an ordered, quasi-epitaxial overlayer. It is thus expected that the quality of the passivated surfaces will influence the organic film structure. On the other hand, the molecular functional groups, namely, the anhydride and the methylimide groups, may also play a role in determining the strength of interaction with the passivated surface and the surface defects. In this section, the nature of the interface bonding and its role in determining the structure of the organic film are investigated by combining Raman spectroscopy and RAS.

42.3.1
Reflection Anisotropy Spectroscopy Investigations

A typical reflectance anisotropy (RA) spectrum measured for a sulfur-terminated GaAs(001) surface is shown in Figure 42.13 and represents an RA fingerprint for

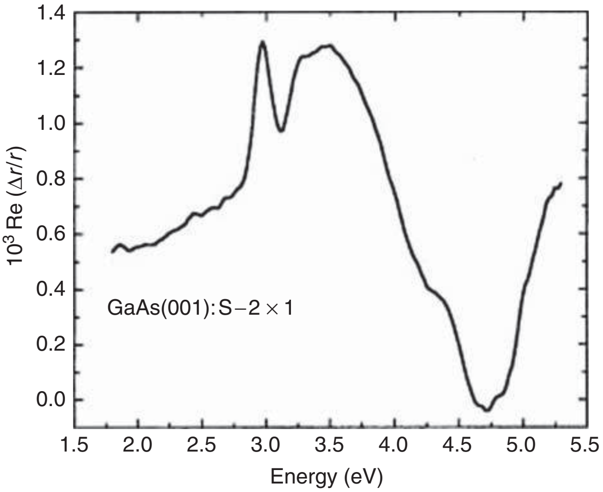

Figure 42.13 RAS spectrum of sulfur-passivated GaAs(001). Adapted with permission from Ref. [63]. Copyright (2001) American Vacuum Society.

the sulfur-induced (2 × 1) reconstruction of the GaAs surface. The sharp derivative-like feature around 3 eV is attributed to the E_1 and $E_1 + \Delta_1$ critical points of GaAs [64], while the broad dip at 4.7 eV is associated with the E'_0 and E_2 critical points of GaAs. The feature near 3.5 eV is related to the sulfur passivation. Its origin is, however, still under discussion. While Hughes *et al.* [65] attributed its occurrence to a transition involving sulfur dimers, other explanations such as transitions within Ga–S bonds are also possible [66].

The evolution of RA spectra with increasing PTCDA coverage is demonstrated in Figure 42.14 for layers with nominal thicknesses of 1, 3, 5, and 10 nm. Note that

the features in the RA spectrum of clean GaAs appear as very weak in this figure, clearly illustrating the pronounced optical anisotropy induced by the presence of the PTCDA layer. Features indicated by arrows can clearly be assigned to PTCDA and their energy positions are listed in Table 42.4. It is important to note that these positions do not necessarily coincide with transition energies observed in optical absorption or ellipsometry ($\mathrm{Im}\langle\varepsilon\rangle$) spectra owing to the low symmetry of PTCDA. Still, a comparison of the region enlarged in the inset of Figure 42.14 with optical absorption spectra [67] reveals good correspondence strengthening the assignment of the indicated features to PTCDA. The observation of a finite RAS response in the energy range 2–2.7 eV, where no GaAs-related features are present and the anisotropy of the starting surface is small, rules out that crystallites are completely random in their azimuthal orientation.

The RA line shape of the GaAs-related feature at 3 eV hardly changes by deposition of PTCDA, thus suggesting that the underlying GaAs surface is quite likely to remain intact and chemical interaction between organic molecules and the sulfur passivated substrate is very weak.

42.3.2
Raman Investigations

To clarify the nature of the interaction between the PTCDA molecules and the GaAs substrate, Raman spectroscopy studies are employed. On one hand, the Raman modes of the GaAs substrate are monitored upon the PTCDA deposition to detect eventual changes in the band bending of the substrate. On the other hand, the spectral range containing the molecular modes with the strongest intensity, that is, the C–C and C–H modes, will be studied for very low molecular coverage of the substrate to prove that the chemical structure of the molecules adsorbed on the substrate remains intact.

42.3.2.1 Monitoring of the GaAs Substrate Modes During Organic Film Growth

One of the advantages when choosing a low frequency range for the monitoring of the film growth is the observation of the substrate phonons. An example of Raman monitoring of PTCDA film growth on S-GaAs(100):2×1 substrates kept at RT is presented in Figure 42.15. For each spectrum, an accumulation period of 1 min was taken at an incident power of 100 mW. The evaporation rate was about $\sim$0.3 nm min^{-1} and the final thickness of the film was 40 nm. From Figure 42.15 it can be deduced that the relative areas of longitudinal optical (LO) and Ω^- GaAs modes remain constant during the organic film deposition at RT. The band bending of the substrate can be determined from the ratio of the GaAs modes according to Refs. [68, 69]. The results are displayed in Figure 42.16.

The difference in the doping levels of the GaAs substrates used for the growth of the present PTCDA and DiMe-PTCDI films (1.8×10^{18} and 2.7×10^{18} cm^{-3}) and slight experimental variations in the S-passivation of the GaAs substrates are likely to be responsible for the difference in the band bending of the two substrates before the organic film growth. One source of errors in the evaluation

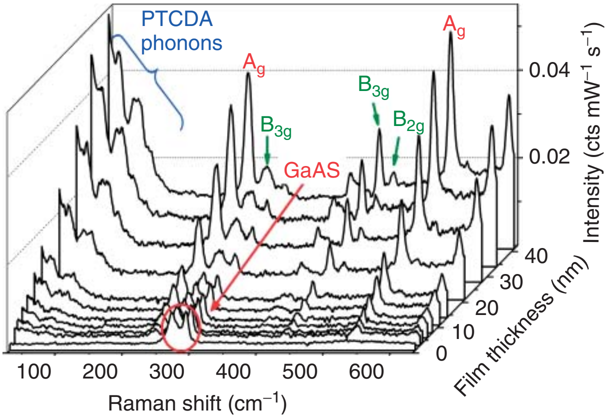

Figure 42.15 Raman spectra recorded *online* during the growth of PTCDA on S-GaAs(100):2 × 1 substrates at RT.

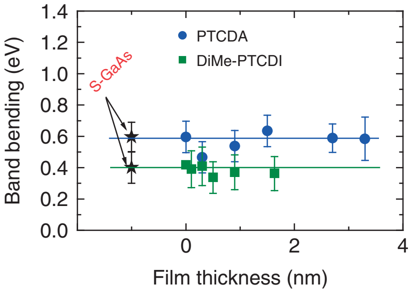

Figure 42.16 Evolution of the band bending of the GaAs substrates upon organic film deposition as determined from the Raman spectra. Adapted with permission from Ref. [24]. Copyright (2007) American Chemical Society.

of spectral intensities is the presence of a weak broad band stemming from an internal molecular vibration that overlaps with the Ω^- GaAs mode in films thicker than 4 nm: the B_{3g} mode at $\sim$262 cm^{-1} in PTCDA and the A_g mode at 239 cm^{-1} in DiMe-PTCDI.

From the RAS measurements it was concluded that no reacted layer is formed when PTCDA is deposited onto GaAs at RT. Therefore, it can be assumed that the relevant processes that might lead to a change in the substrate band bending should take place upon the deposition of the first MLs and the evolution of the GaAs phonons is followed up to an organic film thickness of 4 nm. Neither PTCDA nor DiMe-PTCDI changes the electronic band bending of the S-passivated substrate when deposited at RT. This is in very good agreement with photoemission results that demonstrated a preferential adsorption of molecules at defect sites, which leads to a reduction of the inhomogeneous Fermi level pinning leaving thereby the band bending unchanged [24].

42.3.2.2 Monitoring of the Molecular Modes During Organic Film Growth

In this section, the Raman spectra of sub-ML coverages of PTCDA on S-GaAs(100) surfaces are analyzed and compared with theoretical frequency calculations in order to explore the initial interface formation. Similar experiments were also performed for the PTCDA/Se-GaAs system. During the Raman monitoring of PTCDA deposition onto Se-passivated GaAs surfaces, the thickness-dependent spectra in the region of the most intense vibrational modes with C–H and C–C character resembled those of single crystals [55]. Hence, the interaction between the PTCDA molecules and the Se-passivated GaAs substrate was proposed to be weak and comparable with intermolecular interaction. It must be noted, however, that the lowest investigated thickness was 1.8 nm, which corresponds to roughly six ML.

The evolution of PTCDA modes with contributions from C–C and C–H vibrations as a function of film thickness was recorded in $z(y,x)\bar{z}$ polarization configuration (with $x = [001]$, $y = [010]$, $z = [100]$ defined by the main axis of the GaAs substrate) and is presented in Figure 42.17. All spectra are normalized to the height of the $\nu_{\text{C–C}} + \delta_{\text{C–H}}$ mode at 1572 cm^{-1}. Owing to the low signal-to-noise ratio, each spectrum required an accumulation time of up to 3 h, a period for which the growth was interrupted.

The Raman spectrum of a 40 nm thick PTCDA/S-GaAs(100) layer recorded *in situ* is considered as reference, as it resembles that of PTCDA single crystal in terms of line-shape and frequency positions.

Several differences can be noticed when comparing the spectra of the 0.18 nm with that of the 40 nm thick PTCDA film. A novel feature is observed with high intensity at 1290 cm^{-1}. The other modes are shifted toward lower frequencies, for example, by ~2.4 cm^{-1} for the totally symmetric (A_g) C–C stretching mode at 1572 cm^{-1}. The amount of shift is reduced for the modes at 1303 cm^{-1}(C–H

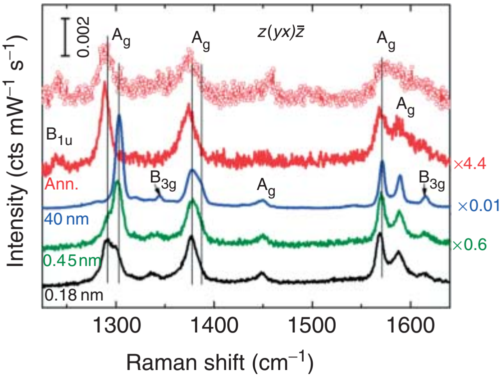

Figure 42.17 Raman spectra in the region of C–C and C–H modes for several thicknesses of PTCDA films (from bottom to top: 0.18, 0.45, and 40 nm) on S-GaAs(100) and after annealing a 14 nm thick film for 30 min at 350 °C (second from the top), taken in crossed polarization. The topmost spectrum was recorded after annealing a 20 nm thick film grown on H–Si(100) substrate at 410 °C for 15 min. Adapted with permission from Ref. [24]. Copyright (2007) American Chemical Society.

bending with A_g symmetry) and 1572 cm^{-1} upon increasing thickness to 0.45 nm. The intensities of these modes increase, while that of the 1290 cm^{-1} band remains almost constant. Obviously, there are molecules experiencing a different type of interaction in the initial phase of adsorption compared to the intermolecular interaction specific to thicker films and single crystal PTCDA. The spectral contribution, and hence the number of such molecules, remains almost constant upon increasing the coverage above 0.18 nm.

Further insight in the molecule–substrate interaction and the origin of the new band at 1290 cm^{-1} is obtained by annealing a 14 nm thick PTCDA film at 350 °C for 30 min. This temperature is higher than the desorption temperature for PTCDA multilayers, which is determined to be 325 °C for PTCDA on glass substrates [70]. Thus, only molecules experiencing a bonding to the substrate stronger than the intermolecular interaction should remain on the GaAs surface. The spectrum after annealing is shown in the upper part of Figure 42.17. By comparing the height of the C–C mode at 1572 cm^{-1} for the annealed and the as-deposited 0.18 nm film, a number of molecules corresponding to $\sim$0.04 nm nominal coverage are evaluated as remaining on the surface, that is, approximately 1/8 of an ML. However, it must be noted that a precise determination of the absolute number of molecules from the Raman peak intensities may be limited by a number of parameters, for example, the growth mode or the resonance conditions. The photoemission measurements have shown from the attenuation of the substrate core levels that at RT on Se- as well as on S-passivated GaAs(100) [71] surfaces, the first PTCDA ML should be completed before the second one starts to form. Hence, the signal from a 0.18 nm film most probably originates only from molecules in direct contact with the substrate. In the following, it will be shown that the interaction between the molecules and the surface after annealing does not involve the disruption of the molecule. It should thus not modify significantly the resonant conditions for Raman scattering and hence the relative intensities of the Raman modes. Therefore, the relative change in the intensity of the C–C mode when comparing the spectra of the as-deposited 0.18 nm and the annealed film is expected to give a fairly reasonable estimate on the number of the molecules remaining on the surface after annealing.

At the doping level used in this experiment ($N_d = 2.7 \times 10^{18}$ cm^{-3}), the number of Si dopant atoms on the GaAs (100) surface should be at least 10^{12} cm^{-2} among 6×10^{14} cm^{-2} surface atoms. Furthermore, previous investigations of ZnSe films grown on GaAs(100) have shown that already upon annealing at 280 °C for 40 min Si dopant impurities diffuse toward the GaAs surface, leading to the occurrence of silicon clusters [72]. Considering the PTCDA molecules lying flat on the substrate when grown at RT as well as after annealing, the nominal coverage of 1/8 ML ($\sim$0.04 nm) determined from the Raman spectra after annealing would correspond to $\sim 10^{13}$ cm^{-2}, that is, sufficient to cover all surface defect sites induced by Si dopant atoms. Further evidence of the interaction of molecules mainly with the Si dopant atoms is provided by the similarities between the spectra recorded after annealing the 14 nm PTCDA film grown on S-GaAs(100) and after annealing of a 20 nm PTCDA film grown on H-passivated Si(111) substrate (topmost spectrum in Figure 42.17). Additional defect sites such as missing S atoms, domain boundaries, and step edges [73] may also be present and can probably explain the large value of 10^{13} molecules cm^{-2}.

In the spectrum after annealing, the band at 1303 cm^{-1} is entirely replaced by the novel feature at 1290 cm^{-1}. This is a clear hint of the origin of the band at 1290 cm^{-1} as being a shifted variant of the 1303 cm^{-1} mode in agreement with the argument used for molecules adsorbed on Ag(111) substrates [74]. The band at 1290 cm^{-1} is thus proposed to be characteristic for molecules having direct contact with the surface defects, while the band at 1303 cm^{-1} is characteristic of molecules in a molecular crystalline-like environment.

The approximately 1/2 ML (~0.18 nm) coverage PTCDA corresponds to a number of molecules that are about four times larger than the number of molecules remaining on the surface after annealing. Thus, the corresponding Raman spectrum should contain three types of contributions: from molecules in contact with defects, from molecules in contact with the passivated surface, and from molecules also interacting with other molecules. The experimental spectrum, however, appears as a combination of the spectra of molecules interacting with defects and of the spectra of thick films. The intensity of the 1290 cm^{-1} mode is approximately equal to that of the 1303 cm^{-1} mode. The intensity ratio of these modes reflects that at least half of the molecules at the surface are not interacting exclusively with the surface defects. Consequently, the molecules interacting with the passivated surface must contribute to the spectrum in a similar way as the molecules involved in intermolecular agglomerations; hence, the strength of the interaction between the molecules and the passivated GaAs surface is likely to be comparable to that of the intermolecular interaction.

Considering the adsorption of the PTCDA molecules at surface Si dopant atoms (or other defects) at the GaAs surface, several mechanisms may be involved. The prediction of the Raman spectra corresponding to the PTCDA molecules interacting with Si defects requires the knowledge of the adsorption geometry as well as theoretical tools capable of handling systems with a large number of atoms comprising the PTCDA molecule and the topmost five layers of the S-GaAs substrate. To our knowledge, additional experimental evidence regarding the exact location of the Si defects with respect to the surface sites and the adsorption geometry of the PTCDA molecules on the defects is missing. The calculation of the Raman spectra within the Gaussian 98 package is possible only under coarse approximations of the interaction between single molecules and defects. Therefore, the calculated Raman spectra can be only qualitatively compared to the experimental ones.

Charge transfer between a molecule and one defect was first considered and approximated by charging an isolated PTCDA molecule with one positive or negative elementary charge. Frequency calculations with the B3LYP:3-21G functional predict dramatic shifts for the C–C stretching Raman modes [75] that are not detected in the spectra after annealing.

In a second approach, complexes consisting of a PTCDA molecule and one Si atom are considered and the corresponding Raman spectra are calculated with the same functional. The high affinity of Si atoms having dangling bonds to form σ-bonds with C atoms was experimentally proved by the chemisorption

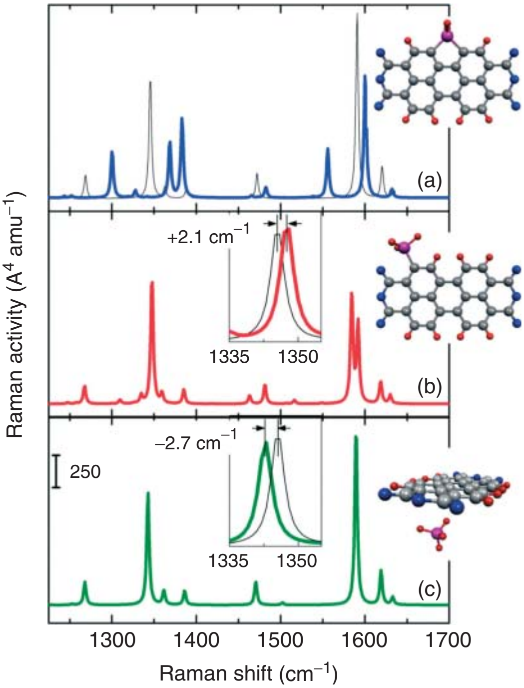

Figure 42.18 Calculated Raman spectra (thick lines) for a PTCDA molecule bonded to one Si atom via two σ-bonds (a), one σ-bond (b) and for a PTCDA molecule with a passivated Si atom below the molecular plane (c). The calculated spectrum of a neutral molecule is shown for comparison in the graph (a) and in the insets (b) and (c) by the thin continuous lines. The Raman bands were modeled with Lorentz oscillators having an FWHM of 3.5 cm^{-1}. Adapted with permission from Ref. [24]. Copyright (2007) American Chemical Society.

process of maleic anhydride onto clean nonpassivated Si(100):2 × 1 surfaces [76] accompanied by the rehybridization of the C atoms from sp^3 to sp^2. Therefore, complexes having σ-bonds between one Si atom and carbon atoms of the perylene core of PTCDA were considered.

As can be seen in the calculated Raman spectra in Figure 42.18 a,b, the formation of two σ-bonds between Si and PTCDA also leads to dramatic shifts of all modes, while the C–H Raman modes of the complex with a single σ-bond are slightly shifted toward higher frequencies. Thus, none of the two complexes can explain the spectral changes observed on annealing.

Finally, calculations for a single Si atom with all valence electrons saturated with H atoms situated below the molecular plane of PTCDA were performed. Most of the modes in the spectral region of interest shift to lower frequencies by at most 1.5 cm^{-1}, while the mode at 1346 cm^{-1} (calculated for isolated molecule, 1303 cm^{-1} in experiment) experiences the largest amount of shift (2.7 cm^{-1}) to lower frequencies (Figure 42.18c). This situation provides the best qualitative match to the experimentally observed shift, but the amount of shift is still lower than the experimentally observed one. The amount of accompanying static charge transfer from the PTCDA molecule is only 0.007 of an elementary charge. Besides strengthening the assignment of the mode at 1290 cm^{-1} as being a shifted variant of the 1303 cm^{-1}, these calculations also show that small changes in the molecular environment can lead to significant frequency shifts for modes with pure C–H deformation character.

An additional feature of the Raman spectra after annealing should be noted. A normally IR-active band ($B_{1u}(\gamma)$, $\delta_{\mathrm{C-H}}$) occurs at 1243 cm^{-1}. Its presence can either be explained by a symmetry lowering to C_v for the molecules adsorbed at defect sites (by analogy with the case of D_{6h} molecules [77]) or by a dynamical charge transfer [78]. Therefore, the molecules are proposed to interact with surface defects due to Si dopant atoms via a charge transfer modulated by molecular vibrations and/or accompanied by a molecular deformation. This conclusion is supported by the observation of the mode at 1243 cm^{-1} along with the one at 1290 cm^{-1} in the spectra of Ag/PTCDA or In/PTCDA interfaces (Section 42.4) or in the Raman spectra of PTCDA MLs on Ag(111) [79, 74].

In summary, the molecules with a different spectral signature compared to those in a molecular crystalline environment are proposed to be adsorbed at defects mainly due to Si dopant atoms at the GaAs surface. The interaction involved is sufficiently strong to retain these molecules at the surface upon annealing above the desorption temperature of PTCDA. A comparison of the experimentally observed characteristic features and the calculated spectra excludes static transfer of an elementary charge or the formation of σ-bonds between the Si atom and the molecule as being responsible for this interaction. However, the observed breakdown of selection rules points to an interaction mediated by dynamical charge transfer. From the similarity between the spectral response of molecules arriving at the surface after the defects are saturated and that of molecules in a crystalline environment, the interaction between PTCDA molecules and the S-passivated surface is estimated to be comparable to the intermolecular one.

The Raman spectra of DiMe-PTCDI on S-GaAs(100) starting from a sub-ML coverage are presented in Figure 42.19.

In order to verify if the DiMe-PTCDI molecules stick at the surface defect sites via interactions comparable to those between the PTCDA and the defects on S-GaAs(100), a ~15 nm thick DiMe-PTCDI was annealed at 325 °C for 10 min. This was sufficient to leave a coverage of only 0.08 nm DiMe-PTCDI on the substrate, which corresponds to a coverage fraction of 0.25 ML. This value was estimated by comparing the intensity of the C–C stretching band at 1570 cm^{-1} with that in the spectrum of a 0.36 nm thick film (taken under the same experimental conditions).

The spectrum of molecules remaining on the surface after annealing presents a B_u mode at 1248 cm^{-1} (Figure 42.19). The C–H modes at 1290 and 1300 cm^{-1} merge into one band, downshifted to 1287 cm^{-1}. The two modes at 1369 and at 1380 cm^{-1} also merge into one band at 1375 cm^{-1}. The shift of the C–C stretch band at 1570 cm^{-1} is very small (0.5 cm^{-1}) and toward larger frequencies, while the band at 1290 cm^{-1} shifts to lower frequencies.

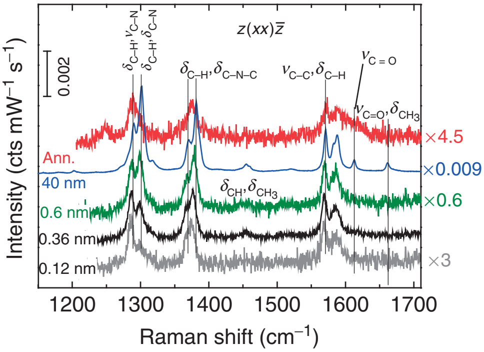

Figure 42.19 Raman spectra in the region of C–C and C–H modes for several thicknesses of DiMe-PTCDI films on S-GaAs(100) recorded in parallel polarization configuration. Spectra are normalized with respect to the height of the mode at 1570 cm^{-1}. Adapted with permission from Ref. [24]. Copyright (2007) American Chemical Society.

The number of bands, their broadening, and relative intensities are very similar to those observed in the parallel polarization configuration for the annealed PTCDA/S-GaAs sample. The frequency positions in the spectra of the annealed DiMe-PTCDI and PTCDA films on S-GaAs differ by at most 4.8 cm^{-1} (Table 42.5), which might be an indication of molecular fragmentation with a loss of CH_3 groups. Fragmentation of molecules adsorbed on Ag(110) substrates with the desorption of CH_3 groups was detected by mass spectroscopy when annealing the substrate at 455 °C [80], which is 100 °C higher compared to this experiment. We assume that the DiMe-PTCDI molecules remaining on the surface are involved in processes of fractional charge transfer with the defect sites similar to the case of PTCDA, that is, via the π orbitals. As a result, the $N-CH_3$ bonds are weakened, possibly enabling the molecular fragmentation already at 325 °C.

Let us consider now the spectrum of an as-deposited 0.12 nm thick film. Here the B_u mode is not observed. If the first deposited DiMe-PTCDI molecules

adsorb at superficial defects – following the interpretation proposed for PTCDA on S-GaAs(100) in the previous section – the defect sites must already be saturated at this coverage. Thus, the spectra of 0.12 nm and higher coverage should contain information about three types of molecules: molecules interacting with the surface defects, molecules interacting with the S-passivated GaAs(100):2 × 1 surface, and molecules having additional interactions with other molecules. All bands except for the one at 1300 cm^{-1} (see Figure 42.10c for its vibrational pattern) are shifted to lower frequencies compared to the reference spectrum. The largest shift is observed for the band at 1290 cm^{-1}, which originates from the vibrational deformation of C–H bonds as well as CH_3 groups (Figure 42.10b). The band appearing in thicker films at 1300 cm^{-1} is very broad and has a lower height compared to the band at 1290 cm^{-1}. The frequency position of the $\delta_{CH} + \nu_{CC}$ mode at 1570 cm^{-1} in thicker films is shifted downward by -1.5 cm^{-1}, less than the corresponding band in PTCDA. Moreover, the B_u mode is not observed. This might indicate that the interaction between the perylene core and the passivated GaAs substrate is weaker for DiMe-PTCDI than for PTCDA molecules. The umbrella deformation of CH_3 groups at 1454 cm^{-1} and the C=O deformations (Figure 42.10 e,f) are not observed.

For a DiMe-PTCDI coverage of 0.36 nm the mode at 1300 cm^{-1} becomes well resolved, probably due to the larger number of molecules interacting only with the passivated surface and with other molecules. The umbrella deformation of CH_3 groups at 1454 cm^{-1} is also resolved, although its intensity relative to the band at 1570 cm^{-1} is lower compared to thicker films. A broad band is observable at the position of the C=O antisymmetric stretching at 1610 cm^{-1}, while the symmetric C=O stretching at 1688 cm^{-1} is still not resolved.

In the next section, it is shown that in thicker films the DiMe-PTCDI molecules are oriented with their molecular plane making an angle of ~56° with the substrate plane. Assuming the same orientation also for the molecules at the interface, this would mean that the interaction between the molecule and the substrate takes place via the CH_3 group at one side of the molecule. This situation could be achieved through the formation of C–H–S bridges considering the high electron affinity of S. Such an adsorption geometry would explain the low activity of the CH_3 umbrella deformation and of the C=O vibrations in the Raman spectra of sub-ML coverages.

To summarize, the interface formation between the two perylene derivatives and differently treated GaAs(100) surfaces was assessed by means of Raman spectroscopy. It was proposed that initially molecules adsorb at the defects sites of the passivated surfaces additionally, leading to a reduction in inhomogeneous band bending as revealed by photoemission experiments [24].

Moreover, by means of Raman spectroscopy, the strength of the interaction between the molecules and the S-passivated surface is estimated to be comparable to the intermolecular one.

42.4 Metals on Organic Layers

Metal deposition onto 15 nm thick films of PTCDA and DiMe-PTCDI was monitored by means of Raman spectroscopy in two spectral regions: below 600 cm^{-1} where the interest is focused on the intermolecular phonon-like and intramolecular breathing modes, and between 1200 and 1700 cm^{-1} where the C–H deformation and C–C and C=O stretching modes are located. The latter is the only region where a sufficient signal was obtained from an ML organic coverage. Figure 42.20 shows the Raman spectrum of a bare 15 nm PTCDA film and its evolution upon the stepwise deposition of indium.

The overall signal intensity increases with the In thickness up to 15 nm and decreases for higher metal coverages, as shown by the normalization factors in Figure 42.20. The same behavior is observed when Ag is deposited onto PTCDA and for both metals deposited onto DiMe-PTCDI [81, 82]. This effect is known as *SERS* [83–85]. The SERS effect has been widely investigated for various molecules adsorbed on rough metallic surfaces or on metallic clusters in colloids. Reviews on this topic can be found, for example, in Refs. [85–87]. The enhancement of normally Raman-active modes is a consequence of the enhancement of the electric field of the incoming and scattered radiation in the vicinity of a rough metal film upon coupling with the dipolar plasmon resonances in the metal clusters. This enhancement affects molecules located up to even 10 nm away from the metal surface [84, 85]. The enhancement factors are essentially determined by the electronic properties of the metal and by the morphology of the metal film.

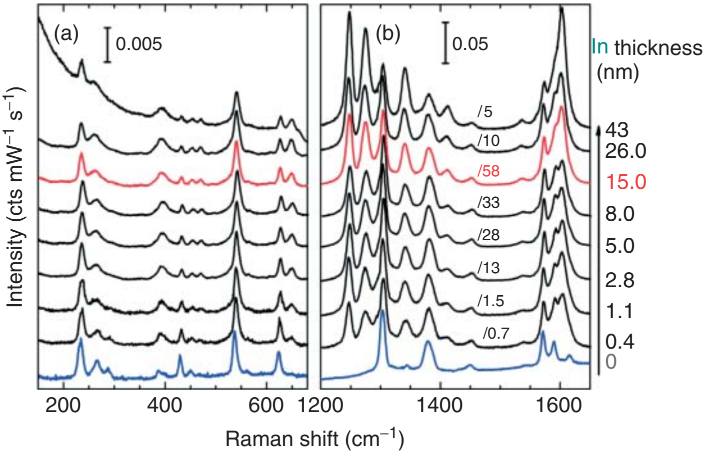

Figure 42.20 (a,b) Raman spectra of PTCDA acquired upon successive deposition of Indium onto a 15 nm PTCDA film. The spectra normalization is done with respect to the intensity of the C–C stretch modes (1572 cm^{-1}). Adapted with permission from Ref. [24]. Copyright (2007) American Chemical Society.

In addition to the enhancement of the totally symmetric modes, the deposition of 0.4 nm In leads to the appearance of some modes in the higher frequency region. The same modes were also observed when depositing In or Ag onto an ML of PTCDA on S-GaAs, only with different relative intensities (Figure 42.21). They, therefore, must be a signature of the molecules in direct contact or in the very near vicinity of a metal surface. In general, such a breakdown of the selection

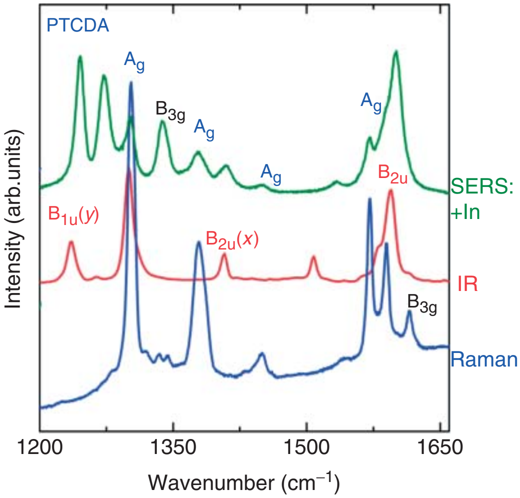

Figure 42.22 Example of the activation of infrared-active modes in the Raman spectrum for the case of indium deposition onto PTCDA. Adapted with permission from Ref. [24]. Copyright (2007) American Chemical Society.

rules accompanies the SERS effect and can be induced by several mechanisms: structural deformation of the molecule, charge transfer from the molecule into the metal or *vice versa*, or formation of new chemical bonds. Thus, the spectral changes induced by SERS can be used to extract information about chemical reactions at the interface, as well as about the morphology of the metal film.

The band at 1338 cm^{-1} was identified in Ref. [75] to be a B$_{3g}$ band based on its frequency and intensity in the crystal spectra, while a band 1292 cm^{-1} is likely to be a shifted variant of the C–H deformation A$_g$ mode at 1303 cm^{-1} in the single crystal [88]. The other bands correspond to modes that normally show IR activity (Figure 42.22).

Considering that all the modes occurring upon In and Ag deposition are normal modes of the PTCDA molecule, the observed breakdown of the Raman-IR selection rules was proposed to originate from a weak charge transfer between the molecules and the metal surface mediated by molecular vibrations [82]. This is in contradiction to previous findings of Hirose *et al.* [89] and Kera *et al.* [90], who proposed the formation of an In$_4$PTCDA complex.

In order to assess the effect of a metal-PTCDA complex formation on the vibrational frequencies theoretical calculations were preformed with the Gaussian 98 package on the In$_4$PTCDA complex using the B3LYP functional and the basis set LANL2DZ, which takes into account possible relativistic effects due to the presence of the heavy metal atoms [53]. Four In atoms were assumed to interact with the PTCDA molecule via the O atoms in the anhydride groups according to Ref. [90]. The optimized geometry, the electronic levels, and the charge distribution over the complexes are similar to those reported in Ref. [89]. Figure 42.23 shows the

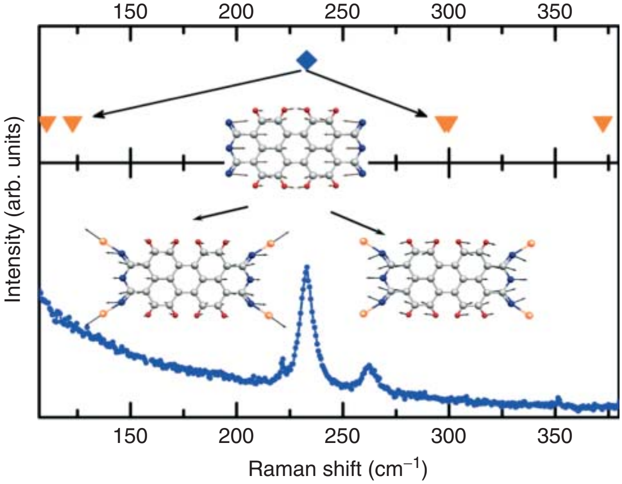

Figure 42.23 Raman spectrum of a PTCDA crystal along with calculated frequencies for a single molecule (rhombus) and for a In$_4$PTCDA complex (triangles). Adapted with permission from Ref. [24]. Copyright (2007) American Chemical Society.

spectrum of a PTCDA single crystal together with the calculated frequencies for a single PTCDA molecule (rhombus) and for an In_4PTCDA complex (triangles).

The most dramatic effect of the complex formation resides in the twofold splitting of the breathing mode at 233 cm^{-1} (see the elongation patterns in Figure 42.23). A first component originates from a breathing of the whole complex and the significant increment of mass compared to the single PTCDA molecule results in a dramatic shift toward lower frequencies (110 cm^{-1}). For the second component, the In atoms are fixed and constrain the breathing of the PTCDA molecule, increasing its frequency to 299 cm^{-1}. In the Raman experimental spectra (Figure 42.20) of the In/PTCDA interface formation, the molecular breathing mode is still observed at 233 cm^{-1}, ruling out the possibility of this chemical reaction. This conclusion is further supported by IR spectroscopic studies [82] and by high-resolution photoelectron spectroscopy (PES) results [24].

In Figure 42.24, the Raman spectra of 15 nm films of PTCDA are shown for metal coverages of 5 nm In, 4.5 nm Ag, and 5 nm Mg. The spectra in the low-frequency windows are normalized to the height of the molecular breathing mode at 233 cm^{-1}. The normalization in the high-frequency region is again performed with respect to the C=C stretch mode (1572 cm^{-1}).

The Raman spectra of the (5 nm) Mg/(15 nm) PTCDA system also exhibit the breakdown of selection rules, with the occurrence of the modes observed in the other two metal/organic heterostructures (Figure 42.24). In addition, several modes with significant intensity (marked with asterisks in Figure 42.24) appear at 307, 502, 598, 696, 1088 cm^{-1} as well as at 1225 and 1433 cm^{-1}. The assignment of

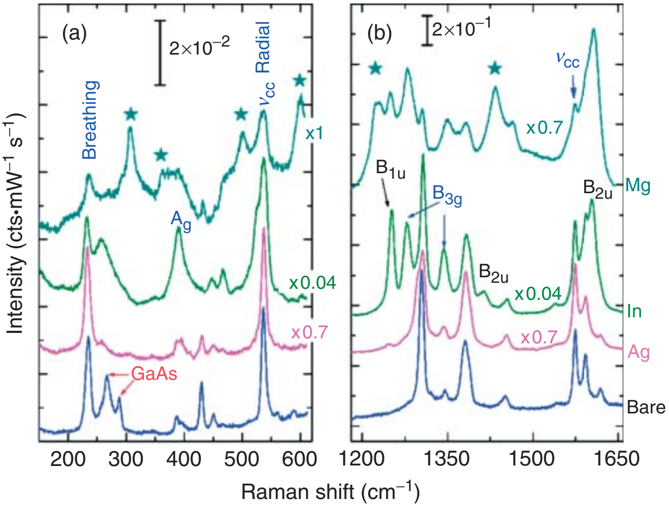

Figure 42.24 Raman spectra for In (5 nm), Ag (4.5 nm), and Mg (5 nm) coverages on 15 nm thick PTCDA films, compared with the spectrum of the bare PTCDA film in the spectral region of the internal breathing mode (a) and in the spectral region of C–H deformation and C=C stretching modes (b). Adapted with permission from Ref. [24]. Copyright (2007) American Chemical Society.

these modes cannot yet be done unambiguously. The frequency of the mode at 598 cm^{-1} is very close to the calculated value of 592 cm^{-1} for a B_{3g} mode of an isolated PTCDA molecule [51].

Frequency calculations performed with the same basis set and density functional methods in Gaussian 98 as in Ref. [51] but for a modified PTCDA molecule, in which the central O atom in the anhydride group is removed, deliver several frequencies that may be candidates for the assignment of the experimentally observed modes: 308, 500, 581, 702, and 1090 cm^{-1}. Raman-active modes in MgO (magnesium oxide) microcrystals [91] were observed at 595, 719, and 1096 cm^{-1}. Thus, the modes observed in the present work at 598, 696, and 1088 cm^{-1} may indicate the formation of MgO as a result of the interaction between Mg and PTCDA. No modes of PTCDA or the modified molecule are found in the vicinity of 1225 cm^{-1}.

Whatever the final assignment of the new modes, they are not activated in the molecules in contact with either Ag or with In. Therefore, it can be concluded that the model of weak charge transfer is not sufficient to describe the interaction at the Mg/PTCDA interface. Indeed a chemical reaction with the loss of the central O atom of the anhydride group and formation of MgO was confirmed by photoemission spectroscopy results [24].

In Figure 42.25, the spectra of 15 nm DiMe-PTCDI films for metal coverages of 5 nm In, 4.5 nm Ag, and 5 nm Mg are shown. The spectra in the low-frequency windows are normalized to the height of the breathing mode at 221 cm^{-1}. The normalization in the high-frequency region is performed with respect to the C–C stretching modes (1570 cm^{-1}).

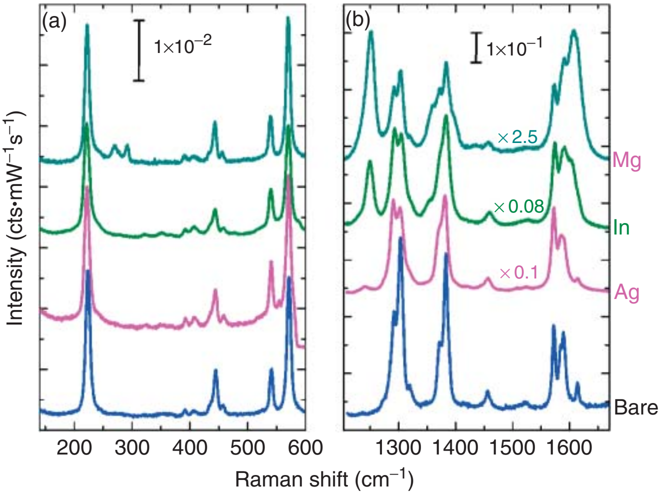

Figure 42.25 Raman spectra for In (5 nm), Ag (4.5 nm), and Mg (6 nm) coverages on 15 nm thick DiMe-PTCDI films, compared with the spectrum of the bare DiMe-PTCDI film. Adapted with permission from Ref. [24]. Copyright (2007) American Chemical Society.

In the case of DiMe-PTCDI, all the investigated metals, that is, Ag, In, and Mg, lead to the breakdown of selection rules with the occurrence of normally IR-active modes at 1246 and 1606 cm^{-1}. The breathing mode at 221 cm^{-1} survives with increasing metal coverage. Thus, a chemical reaction between these metals and the O atoms of DiMe-PTCDI molecules can be ruled out. Interestingly, the features potentially assigned to MgO phonons do not appear in the spectra even for higher coverages of Mg. It can thus be concluded that the methylimide group in the DiMe-PTCDI molecule is less reactive compared to the O atoms in the anhydride group of PTCDA.

Raman spectroscopy showed that Ag and In behave similarly in terms of chemical reactivity when deposited onto PTCDA and DiMe-PTCDI. Both metals induce a breakdown of selection rules, which was interpreted to be the result of a dynamical charge transfer process. The vibrational signature of Mg deposited onto PTCDA is very different compared with the other metals, indicating that a strong chemical interaction between the two partners takes place. High-resolution photoemission measurements, together with sophisticated core-level line-shape analysis, deliver a deeper insight into the physics and chemistry of the metal/organic interfaces and confirm the conclusions drawn from Raman experiments [24].

The external modes of PTCDA disappear almost completely after depositing 0.4 nm In, while they only get broader and decrease in intensity after Ag and Mg deposition (Figure 42.26).

In Figure 42.27, the spectra of the external modes are shown upon stepwise metal deposition onto 15 nm of PTCDA. For a quantitative evaluation, the spectra of Ag/PTCDA and Mg/PTCDA were fitted using Lorentzian functions.

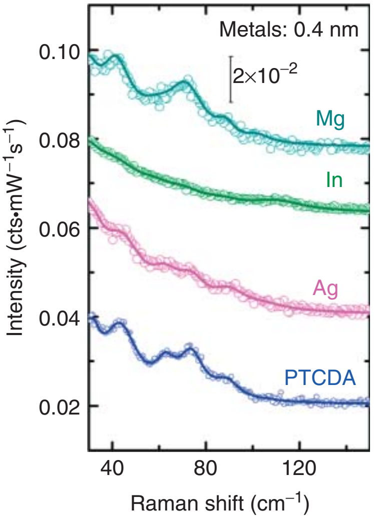

Figure 42.26 Raman spectra of 15 nm thick PTCDA films covered with Ag, In, and Mg in the region of the external modes. Adapted with permission from Ref. [24]. Copyright (2007) American Chemical Society.

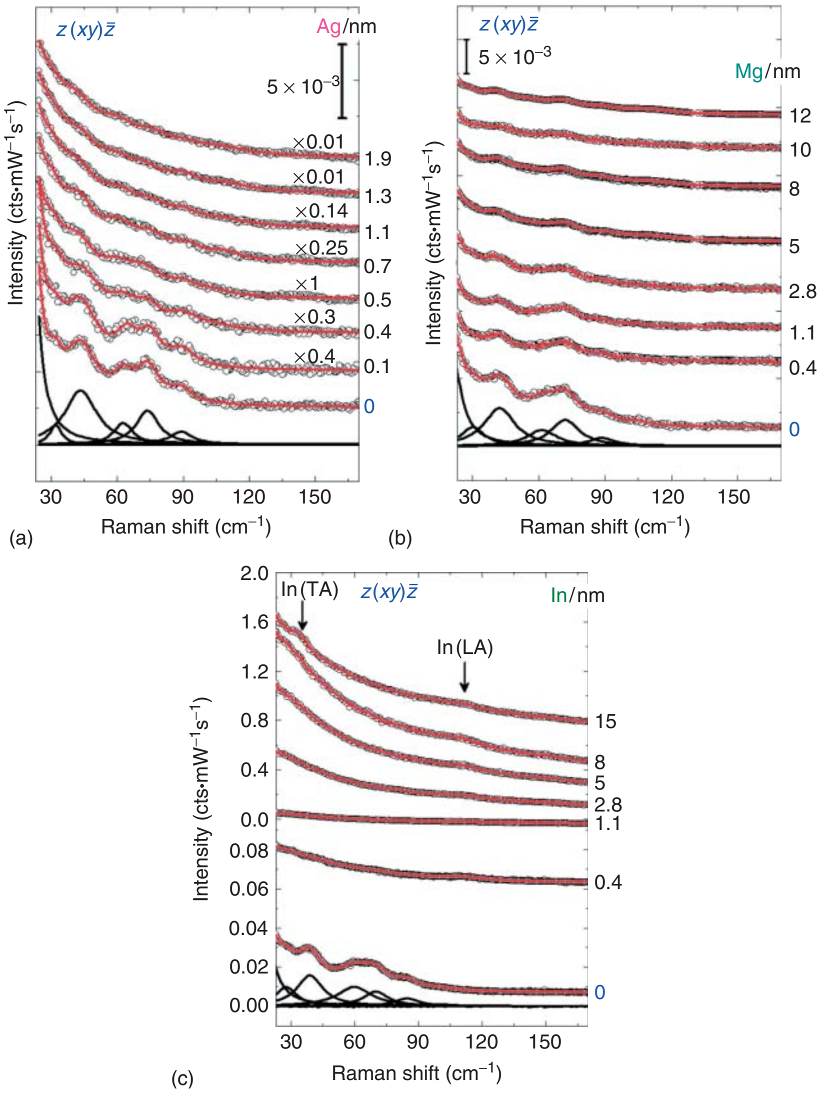

Figure 42.27 Raman monitoring in the external mode region upon metal deposition: Ag (a), Mg (b), and In (c). The experimental spectra are shown by open symbols and the fitted spectra by red lines. The Lorentzian functions used for curve fitting of the Raman spectrum of the pure PTCDA film are shown by lines in the lower part of the figures. The spectra are normalized for Ag/PTCDA for a better observation of the phonons. Adapted with permission from Ref. [24]. Copyright (2007) American Chemical Society.

The evolution of the FWHM as a function of Ag and Mg thickness is plotted in Figure 42.28 for the external mode at 41 cm^{-1}. This mode is fairly well separated from its neighbors and hence the fitting parameters of the corresponding Lorentzian function are less correlated. As the metal thickness increases, the FWHM of the external modes increases faster in Ag/PTCDA compared to Mg/PTCDA.

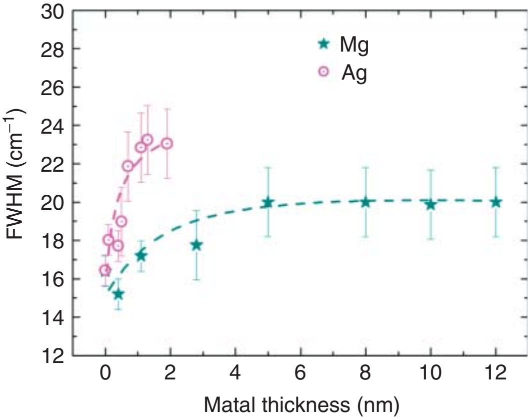

Figure 42.28 Evolution of the FWHM of the external mode at 41 cm^{-1} as a function of the metal coverage relative to the initial values before the metal deposition: for Ag (asterisk) and Mg (open circle). The dashed lines are guide for the eyes. Adapted with permission from Ref. [24]. Copyright (2007) American Chemical Society.

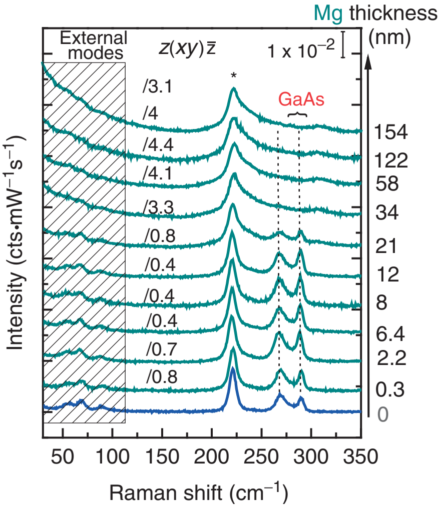

Figure 42.29 Raman spectra of DiMe-PTCDI upon Mg deposition in the region of external modes and GaAs phonons. The spectra are normalized with respect to the intensity of the breathing mode at 221 cm^{-1}. Adapted with permission from Ref. [24]. Copyright (2007) American Chemical Society.

For Mg the external modes are still visible at 12 nm coverage, whereas they are almost completely smeared out at 1.3 nm of Ag. This is a clear indication that the crystalline structure of the organic layers is less affected by the Mg deposition compared to Ag. However, it should be noted that curve fitting of the spectra in the case of Ag/PTCDA is complicated by the significant increase in the low-frequency background (which was already subtracted in Figure 42.26). The background evolution reflects an increasing degree of roughness, which is consistent with an increasing number of metallic clusters that diffusely scatter the light. A strong increase in the low-frequency background is also observed for the case of In deposition onto PTCDA, while it hardly affects the spectra of Mg/PTCDA, supporting the conclusion that the roughening due to Mg is lower compared to that of the Ag and In.

While the external molecular modes disappear in the first deposition stages for In/PTCDA, two new modes develop at 33 and 112 cm^{-1} above In coverage of 2.8 nm. They may correspond to the transverse acoustic and longitudinal acoustic phonons located at 34 and 114 cm^{-1}, respectively, in bulk indium [92, 93] activated because of the low dimension of the In clusters. This observation, corroborated by the concomitant increase in the low-frequency background, indicates the formation of metallic In clusters. Moreover, the enhancement of the internal modes also increases dramatically above 2.8 nm In, supporting the conclusion of metallic cluster formation.

In the case of Mg deposition onto DiMe-PTCDI, the external modes are attenuated only for an Mg nominal coverage above 21 nm, that is, similar to the case of Mg/PTCDA, indicating that the Mg atoms do not protrude into the crystalline molecular islands (Figure 42.29). On the other hand, the relative intensities of the GaAs-related features change already for low Mg coverages (Figure 42.29), reflecting a change in the GaAs band bending. This can only occur if the Mg atoms reach the GaAs surface in the large voids between the DiMe-PTCDI islands and react with it as also learned from the PES results [24].

NEXAFS Studies at Surfaces

Maria Benedetta Casu and Thomas Chassé

43.1
Introduction

The interaction of electromagnetic radiation with matter is the basis of several spectroscopies.

Whenever electromagnetic radiation encounters matter, three events may occur: the radiation can be reflected, can propagate through matter, or can be absorbed. In particular, photon and matter interaction generates several phenomena, among others the photoelectric effect, the Compton scattering, and, in addition, two processes with very small energy transfer: Thomson (elastic) scattering on a ‘‘free’’ electron, that is, the redirection of low-energy photon without change in energy, and the Rayleigh (coherent) scattering that results from a combined (coherent) action of an atom as a whole. In the photoelectric effect, electrons are emitted from matter (metals and nonmetallic solids, liquids, or gases) as a consequence of their absorption of energy from electromagnetic radiation with a frequency greater than a critical threshold frequency. The emitted electrons that may be referred to as *photoelectrons* have kinetic energy E_{kin} determined by the Einstein relationship [1]

$$E_{\mathrm{kin}} = h\nu - E_{\mathrm{b}} \tag{43.1}$$

where $h\nu$ is the energy of the incident radiation and E_{b} is the binding energy of the emitted electrons. Equation (45.1) indicates that radiation will be absorbed for incident energies larger than the binding energy of the electrons in the system (Figure 43.1). X-rays have enough energy to ionize atoms by emission from both valence electrons and core electrons.

The concept of absorption spectroscopy refers to a bunch of techniques that measure the absorption of radiation. The sample absorbs energy from the radiating field. The intensity of the absorption varies as a function of frequency/energy, and this variation leads to an absorption spectrum. The X-ray absorption spectrum is typically divided into two regimes: near-edge X-ray absorption fine structure spectroscopy (NEXAFS) and extended X-ray absorption fine structure spectroscopy (EXAFS). Despite the fact that the two stem from the same physical origin, this distinction is convenient for the interpretation. NEXAFS is strongly sensitive to

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

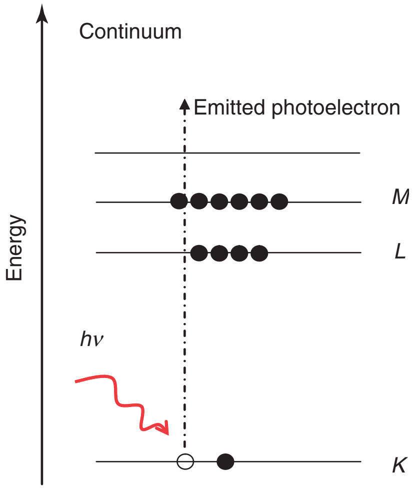

Figure 43.1 Schematic view of the photoelectron effect.

formal oxidation state and coordination chemistry (e.g., octahedral, tetrahedral coordination) of the absorbing atom, while EXAFS is used to determine the distances, coordination number, and species of the neighbors of the absorbing atom.

In this chapter, we report some basic concepts that represent the background of the photon absorption in the X-ray range by electrons distributed within specific orbitals in a population of molecules or atoms. In doing so, we refer to the classical work of Stöhr [2], Koningsberger and Prins [3], and Iwasawa [4]. Other specific references are also given in the following text.

43.2
Near-Edge X-Ray Absorption Fine Structure: Basic Principles

X-ray absorption is a process, for certain aspects, very similar to optical absorption. It obeys the Lambert–Beer law that relates the absorption of light to the properties of the material through which the light is traveling:

$$I = I_0 \exp(-\mu l) \tag{43.2}$$

where I is the transmitted light, I_0 the incident light, μ the absorption coefficient, and l the thickness of the absorbing medium (Figure 43.2). At most X-ray energies, the absorption coefficient μ is a smooth function of energy, with a value that depends on the sample density ρ, the atomic number Z, the atomic mass A, and the X-ray energy E roughly as

$$\mu \simeq \rho Z^4 / AE^3 \tag{43.3}$$

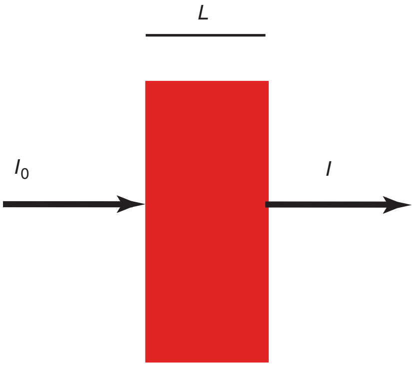

Figure 43.2 Schematic view of X-ray absorption. I_0 is the intensity of the incoming X-ray beam. After the X-ray has traveled a distance l into the material, the intensity has been reduced to $I = I_0 \exp(-\mu l)$, where μ is the definition of the absorption coefficient.

The strong dependence of μ on both Z and E is a fundamental property of X-rays.

Owing to the Z^4 dependence, the absorption coefficient, for example, for O, Ca, Fe, and Pb are very different, spanning several orders of magnitude, so that a good contrast between different materials can be achieved for nearly any sample thickness and concentration by adjusting the X-ray energy. This gives also the possibility of using X-ray absorption as a key technique in microscopy, as, for example, in scanning transmission X-ray microscopy or tomography.

As in optical absorption, the transition rate can be calculated by Fermi's golden rule that describes the transition rate (T) from one energy eigenstate ($\psi(i)$) of a quantum system into a continuum of energy eigenstates ($\psi(f)$), due to a perturbation H':

$$T_{\mathrm{if}} \ \alpha | < \psi(f) | H' | \psi(i) > |^2 \rho_f \tag{43.4}$$

where ρ_f is the density of final states, and the matrix element is $\mathrm{M}_{\mathrm{if}} = <\psi(f)\ |H'|\ \psi(i)>$.

In particular, NEXAFS is the absorption of X-ray radiation close to a given edge. In NEXAFS, the photon energy is scanned in a region of about 30 eV above the edge and the absorbed X-ray intensity is measured. NEXAFS is element specific because each element has its own binding energy, that is, absorption energy and, consequently, absorption edge. It is possible to gain information about the unoccupied states, the environment of specific chemical elements, bonding properties, and local charge distributions.

This means that NEXAFS is sensitive to the local order as well as to the middle- to long-range order and it can be used to investigate both amorphous and crystalline samples.

The NEXAFS spectra for a given K-edge are characterized by features at the pre-edge and at the edge, that stem from transitions from the 1s states to excited bound states; thus, they are also known as *resonances*. These transitions can be described within the framework of molecular orbitals or band structure for metals and semiconductors. In general, the NEXAFS features at slightly higher photon energy can be seen as transitions to an unbound final state or to the continuum, and they can be described by multiple scattering theories. Resonances related to shake up or multielectron excitation satellites are also visible. Shape, energy position, and intensities of NEXAFS features give information on chemical bonds, oxidation states, and coordination numbers for the element related to the investigated edge.

As mentioned, the transition rate in NEXAFS can be described by Fermi's golden rule (Eq. (45.4)) containing the perturbation operator H', which represents the electromagnetic radiation and can be approximated as

$$H' \propto -\frac{e}{2mc}(\widehat{p}\cdot\widehat{A}+\widehat{A}\cdot\widehat{p}) \tag{43.5}$$

where $\widehat{p}$ is the momentum operator and $\widehat{A}$ is the vector potential of the electromagnetic radiation. $\widehat{A}$ can be written as

$$\widehat{A}(\mathbf{r},\mathbf{t}) = \mathbf{e}\cdot A_0\cdot e^{i(\mathbf{kr}-\varpi t)}$$

where **e** describes the polarization direction of the light. In vacuum, the Coulomb calibration can be applied

$$\vec{\nabla}\cdot\widehat{A}=0\rightarrow\widehat{p}\cdot\widehat{A}=0$$

Thus, H' can be simplified as $2\cdot(\widehat{A}\cdot\widehat{p})$.

Now, if the wavelength of the type of electromagnetic radiation that induces or is emitted during transitions between different atomic energy levels is much larger than the typical size of an atom, the exponential term can be expressed as a series, and only its first term, 1, is taken into account (electric dipole approximation). It follows that

$$M_{if} \sim \langle\psi_f|\mathbf{e}\cdot\widehat{p}|\psi_i\rangle \tag{43.6}$$

is known as *dipole matrix element*.

At this point, we can understand why the interpretation of a NEXAFS spectrum is certainly a complicated issue. Looking at the dipole matrix element, we observe that the initial and the final state appear. There are several methods to determine the initial state that corresponds to the electronic ground state; for example, semiempirical methods, *ab initio* calculations, and density functional theory can describe this state. On the contrary, here the final state is a state with a core hole and an exited electron in a previously unoccupied state.

To solve this problem, there are essentially two approaches: the *ab initio* molecular orbital theory, and the multiple scattering theory.

The molecular orbital approach is based on Hartree, Hartree–Fock, and local density approximations applied to a system, just as a cluster surrounds the absorbing atom. In this approach, the final state is seen as a core-level photoemission state with an additional electron that occupies one of the previously unoccupied molecular orbitals. One of the most used methods of this kind is the *ab initio* method (GSCF3) that was developed by Kosugi [5–7]. These calculations have proved to give good values, for example, for the energy positions and intensities of the π*-resonances of large compounds, such as subunits of polymers [8–10].

The other approach consists in solving the one-electron Schrödinger equation. In this respect, good performances have been obtained, for example, with the effective scattering amplitude F_{eff} (FEFF) program [11]. FEFF is a self-consistent real-space multiple-scattering code for simultaneous calculations of X-ray absorption spectra and electronic structure. The approach builds in core-hole effects and can include local fields. It works for clusters and atoms, as well as for crystalline systems such as inorganic semiconductors [12].

The one-electron description of X-ray absorption works for all K edges; however, applying these codes to systems such as transition metal oxides one finds excellent agreement for the metal and oxygen K edges, whereas for the other edges, in particular metal $L_{2,3}$ edges, the agreement is poor. The reason for this discrepancy is that the density of states (DOS) is not observed in X-ray absorption processes, while it is calculated in the one-electron approach. The reason for the deviation from the DOS is the strong overlap of the core wave function with the valence wave functions. The overlap of core and valence wave functions is present also in the ground state, but because all core states are filled, it is not effective and it is possible to approximate the core electrons with their charge. In the final state of an X-ray absorption process, there is a partly filled core state. In case systems with a partly filled 3d-band are investigated, the final state will have an incompletely filled 3d-band. The 2p-hole and the 3d-hole have radial wave functions that overlap significantly. This wave function overlap is an atomic effect that can be very large. It creates final states that are found after the coupling of the 2p and 3d wave functions. This effect is well known in atomic physics and actually plays a crucial role in the calculation of atomic spectra. Experimentally, it has been shown that while the direct core-hole potential is largely screened, these so-called multiplet effects are hardly screened in the solid state. This implies that the atomic multiplet effects are of the same order of magnitude in atoms and in solids. Upon this approach, a bunch of codes have been developed. One of the most successful in calculating the X-ray absorption of metal oxides is the TT-multiplets (TT after Theo Thole, one of the authors) [13]. This is a set of computer programs designed to calculate core-level spectra of correlated systems. It is presently maintained by de Groot [14, 15]. He also developed his own version of the TT-multiplets' above-mentioned code, the CTM4XAS Charge Transfer Multiplet Program, packaged with a convenient graphical front end to allow for the simulation of the transition metal 2p and 3p X-ray absorption spectroscopy (XAS), X-ray photoemission spectroscopy (XPS), and X-ray magnetic circular dichroism (XMCD) spectra using atomic multiplets [16–18].

Coming back to the dipole matrix element (Eq. (45.6)), we can also observe that the intensity of the NEXAFS resonances depends on the mutual orientation of the molecular orbital involved in the given transition and the incident radiation. This aspect of the NEXAFS spectroscopy can be used to calculate the molecular orientation (angle between the molecular plane and the substrate) directly from the spectra when investigating adsorbates onto a substrate (Figure 43.3). This model

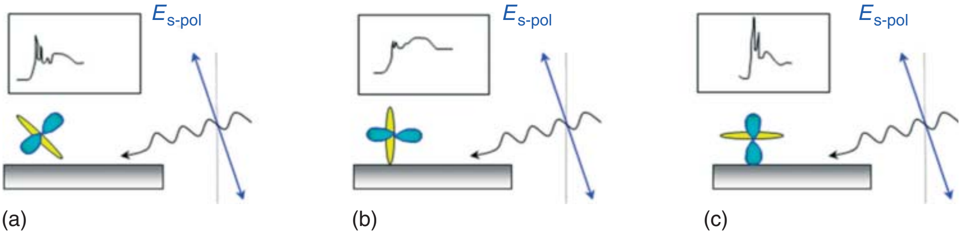

Figure 43.3 (a,b,c) Examples of changes in the π*-resonances intensities for different molecular orientation keeping a fixed geometry of the NEXAFS experiment.

was introduced for the first time by Stöhr [2, 19], and it is widely used for structural investigation of molecular thin films.

In this model, all molecules are classified into general groups depending on the fact that the final state molecular orbital points into a specific direction (vector case) or it is energy degenerate and it spans a plane (plane case). The general equations are derived for both cases, showing the angle dependence of the NEXAFS π* and σ* resonances on the polarization plane of the incident radiation.

In particular, it can be shown for a vector-type orbital and a threefold symmetry of the substrate that the resonance intensity along the direction of the dominant component of the incident electric field is given by [19] [20]

$$I \propto (\cos^2\theta \, \sin^2\alpha + 2\sin^2\theta \, \cos^2\alpha) \tag{43.7}$$

with α angle between the normal to the surface and the orbital, and θ angle between the incident radiation and the normal to the surface. Measuring the intensity for two different polarization directions with respect to the surface, in normal (θ_1) and in grazing incidence (θ_2), it is possible to determine α from the following equation:

$$\frac{1}{\tan^2\alpha} = \frac{1}{2P}\left(P - \frac{1-q}{\sin^2\theta_2 - q\sin^2\theta_1}\right) \tag{43.8}$$

where P is the polarization degree and q is the ratio between the intensities of the chosen resonances for the two different polarizations

$$q = \frac{I(\theta_2)}{I(\theta_1)} \tag{43.9}$$

43.3
NEXAFS Measurements and Data Analysis

We have seen previously that an X-ray absorption event creates a core hole. There are two main mechanisms for the decay of the excited state. The first is X-ray fluorescence, in which a higher energy core-level electron fills the deeper core hole, ejecting an X-ray of well-defined energy. The fluorescence energies emitted in this way are characteristic of the atom; thus, they can be used to identify the atoms in a system and to quantify their concentrations. The second process for the decay of the core hole is the Auger effect, in which an electron drops from a higher electron level and a second electron is emitted into the continuum. In the hard X-ray regime (>2 keV), X-ray fluorescence is more likely to occur than Auger emission, but for lower energy X-ray absorption, Auger processes dominate.

Now, to measure a spectrum, it is essential to realize a good measure of $\mu(E)$ (Eq. (45.3)). The main experimental challenge is getting a X-ray source that can be tuned in energy. Nowadays, the X-ray source typically used is a synchrotron, which provides a full range of X-ray wavelengths. In addition, this radiation has very peculiar properties necessary for NEXAFS such as high brightness and high intensity, many orders of magnitude more than with X-rays produced in conventional X-ray tubes, high level of polarization (linear or elliptical), high brilliance, exceeding other natural and artificial light sources by many orders of magnitude in third-generation sources [21].

Experimentally, different detection modes can be chosen. The traditional detection has been for a long time the transmission mode, as shown in Figure 43.2. However, this technique can be applied only to self-standing systems thin enough to allow the transmission of the X-ray radiation through the sample. As a consequence, the signal contains contributions that are due to the complete thickness of the investigated system. Unless the elements present at the surface are different from those in the bulk, as in the case of adsorbates, and the spectra can be chemically resolved, this technique is essentially bulk sensitive; thus, we do not further address its specifics in this chapter.

Further detection modes are total electron yield (TEY), partial electron yield (PEY), Auger electron yield (AEY), and fluorescence yield (FY), as shown in Figure 43.4.

In TEY, all emitted electrons (i.e., Auger plus secondary electrons) are detected. On the one hand, this detection method yields high signal intensity, on the other hand, there is a high background due to low-energy electrons. The electrons can be detected with a channeltron or microchannelplate. Alternatively, the sample current, that is, the current between sample and ground, can be measured

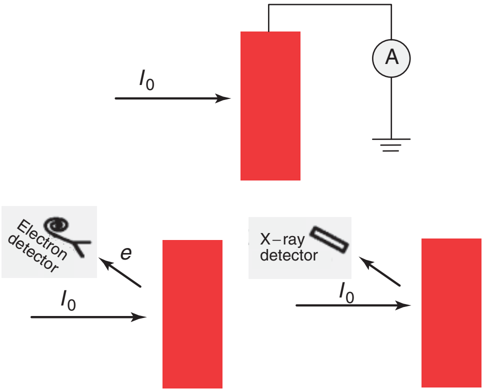

Figure 43.4 Different methods used for measuring NEXAFS are sketched.

with a multimeter down to the picoampere regime, which represents the least experimental effort for NEXAFS measurements.

To increase the signal-to-background ratio, a negative retarding field can be applied to a grid in front of the electron detector (channeltron/channelplate). This is done in PEY. Thus, the background signal from low-energy electrons can be drastically reduced.

A possible configuration of a PEY detector is shown in Figure 43.5. The photoemitted electrons travel trough a metal grid, kept at ground potential, while the low-energy electrons are repelled by a second grid kept at a negative retarding voltage. The retarding voltages depend on elements; typical values are −200 V for carbon, −320 V for nitrogen, and −450 V for oxygen K-shell [2]. The electron signal is amplified by two channel plates, whose voltages are supplied by metallic contact rings. The electron output is finally gathered by a collector, which is connected for current measurements to a floating battery box. The collector is kept at a voltage around 100 V higher than the ring contact of the second channel plate.

The best signal-to-background ratio can be obtained in AEY, if only the Auger electrons are detected with an electron energy analyzer. This detection mode also enhances the chemical sensitivity, as the analyzer energy is tuned to an element specific Auger line (e.g., C-KLL at 266 eV, O-KLL at 512 eV). In addition, NEXAFS has the highest surface sensitivity in the AEY mode because electrons from deeper layers, which lose energy on their way out of the sample, are not detected.

As mentioned, when X-rays are absorbed, the excited core hole can relax back also via emission of fluorescent X-rays. In FY, the fluorescence emission is detected. Fluorescence detection was principally used in experiments with hard X-rays because its use in the soft X-ray range was hampered by the extremely low values of the FY. With the availability of high-brilliance third-generation synchrotron radiation sources, new opportunities exist for the application of FY. However, this detection mode is also more bulk sensitive and therefore better suited when structural information from the bulk of the sample is needed.

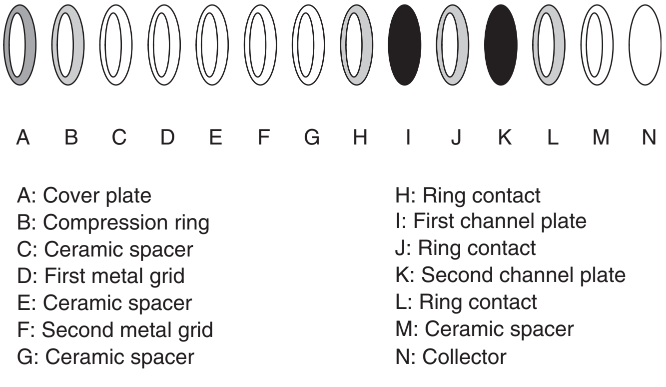

Figure 43.5 Schematic configuration of a double-channel plate partial electron yield detector.

Here, we mention for the first time the surface sensitivity of NEXAFS spectroscopy. Surface sensitivity in a technique is given by the relationship between kinetic energy of the photoemitted electrons and their inelastic mean free path. The inelastic mean free path is defined as the average distance traveled by an electron between inelastic collisions. It depends on the kinetic energy according to a general behavior that is similar for all materials, the so-called universal curve. The surface sensitivity is determined by the depth perpendicular to the surface from which the electrons escape, which is proportional to the inelastic mean free path via the cosines of the emission angle of the electrons relative to the surface normal. Thus, the surface sensitivity of an experiment can be varied accordingly: the inelastic mean free path has a minimum at around 50 eV, corresponding to a few Angstrom. For kinetic energies up to 2000 eV, its value is 70 Å large. Thus, in the X-ray regime, when the chosen detection mode collects emitted photoelectrons (e.g., PEY and AEY), their largest inelastic mean free path is on the order of magnitude of few nanometer [22].

Data analysis in NEXAFS represents a very crucial post-experiment phase. The recorded signal always contains also the absorption of the entire setup for a given edge. A traditional example is the absorption at the carbon edge of the mirrors used at beamlines. As in optical spectroscopy, the signal of the analyzed sample is multiplied by the signal due to the setup; thus, a normalization is necessary.

There are two methods to determine the normalizing signal: flux (I_0) current and clean substrate current [2].

The I_0 current method consists in measuring, when possible simultaneously, the TEY current of a clean metallic grid, usually of gold, put in front of the sample and the NEXAFS signal of the sample itself. The clean substrate method is useful when adsorbates are deposited onto a surface, that is, a substrate. The NEXAFS signal of the adsorbate is normalized in this case at each edge by using the NEXAFS signal of the substrate.

Upon normalization, which can be considered completely correct when the background line before the pre-edge region is simply a line parallel to the energy axis, that is, there is no absorption due to the investigated edge, we subtract a constant value corresponding to the smooth pre-edge function, to get rid of any instrumental background (this is the case, for example, with synchrotron radiation due to the slight small differences in the beam orbit after every injection), and absorption from other edges. At this point, it is usual to consider the signal in the region after the edge due to transitions to continuum, that is, the edge jump, equal to 1. This procedure gives the opportunity to compare NEXAFS spectra at a given edge taken at different synchrotrons, with different set ups, and so on.

The use of high-brilliance synchrotron radiation and ultrahigh-resolution monochromators has immensely broadened the potential of the NEXAFS method, given also the opportunity to resolve new fine structures. However, the high resolution requires even major care in handling of the data and it requires (i) accurate calibration of the energy scale and (ii) perfect intensity normalization in order to avoid errors such as spurious features. From this point of view, normalizing data taken at the carbon edge can be rather problematic and requires particular care and effort because of the unavoidability of carbon contaminations of the optical elements of a beamline.

Last but not least, the development of the modern synchrotrons (from third generation on) has had a real impact and importance in NEXAFS spectroscopy. Most of the recent not previously explored properties of gas, liquid, or solid state by using NEXAFS owe their discovery to the existence of such a powerful source in synergy with the high degree of knowledge reached in ultrahigh vacuum science and technology. We do not address it in detail and we suggest that the readers refer to the existent literature [21, 23].

43.4
Applications

In the following, we will report some NEXAFS experiments from the existing literature in order to show the potential of this technique, and how it can be used to answer questions ranging from basic research to solve problems also relevant in technology.

43.4.1
NEXAFS as a Fingerprint in Oxides

Single crystals of TiO_2 have been intensively studied. Titanium oxide is the most investigated single-crystalline system among all metal oxides [24]. The potential of applications is enormous, ranging from medicine to electronics [24, 25]. TiO_2 exists mainly in three different crystallographic phases: rutile, anatase, and brookite. Their electronic structure as well as their surface structure is well understood. NEXAFS spectra constitute a clear fingerprint of titanium oxides. Figure 43.6 shows the NEXAFS spectra at the Ti 2p edge of stoichiometrically well-ordered rutile $TiO_2(110)$ and anatase $TiO_2(101)$ surfaces. They show significant differences depending on the crystallographic phase as well as on the degree of Ti reduction [26–32]. In particular, TiO_2 single-crystal spectra show well-resolved peaks in the range between 455 and 470 eV corresponding to the various Ti 2p → 3d transitions [20, 21–24], as shown in Ref. [24]. The Ti 2p edge shows two groups of peaks arising from the spin-orbit splitting of the Ti 2p core level into $2p_{3/2}$ and $2p_{1/2}$ levels with $\sim$6 eV energy separation. These levels are further split because of crystal-field effects [26, 27]. This rich structure is absent in the case of TiO and Ti_2O_3 [26]. Their spectra present broader features, and the splitting due to crystal-field effects is quenched by the fact that the Ti 3d spectral weight is redistributed by the core-hole influence. An analogous behavior is seen in the spectra of metallic Ti [30].

Nowadays, there is the need to go beyond single-crystal characterization toward applications that require different types of surfaces. TiO_2, in polycrystalline form and as thin film, has already attracted a great deal of attention in biology and medicine because of the standard methods (e.g., machined or sandblasted Ti) used to build implant devices. In addition, titanium oxide thin films are also useful for

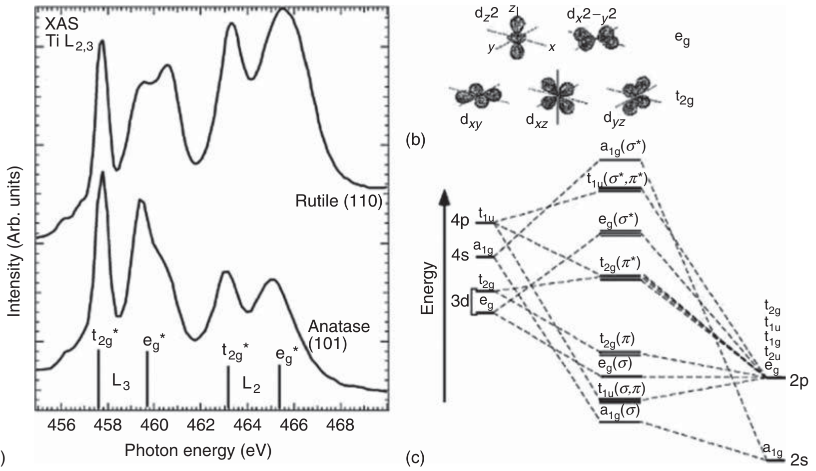

Figure 43.6 NEXAFS spectra at the Ti 2p edge of stoichiometric well-ordered rutile $TiO_2(110)$ and anatase $TiO_2(101)$ surfaces. The effect of the crystal field of the oxygen ligands is also sketched. (Reprinted from Ref. [24], Page 107, Copyright 2002, with permission from Elsevier.)

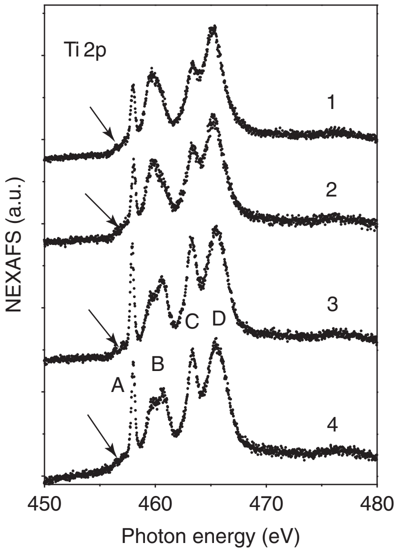
applications such as catalysis, optical coatings for selective filters, dye-sensitized photovoltaic cells, and electrochemical sensors [33–36]. A possible method of growing thin films of titanium oxide is given by magnetron sputtering [37–44]. Despite the large number of applications, only a few studies have been published investigating the electronic structure of titanium oxide films [45, 46], and not much has been done on magnetron-sputtered films [41].

For example, we have investigated two sets of magnetron-sputtered TiO_2 thin films by using NEXAFS [47]. The detailed analysis of the Ti 2p (Figure 43.7) and O 1s NEXAFS spectra allows determining the polymorphs and the degree of order of the investigated samples. We find that thin films grown by using reactive sputtering with a Ti target and lower deposition rates have a rutile-like character, while by using a TiO_2 target and higher deposition rates we obtain amorphous/mixed thin films. The NEXAFS results and the assignment to specific polymorphs are in good agreement with the corresponding X-ray diffraction (XRD) patterns. This work clearly shows the extension of possibilities given by the use of such a powerful tool as NEXAFS, not only to investigate single crystals but also TiO_2 thin films. The



Sample	Target	Composition (sccm)	Time (min)	*P* (mbar)	Nominal thickness (nm)	Phase
1, 2	Ti	Ar : O = 80 : 30	120	7.7×10^{-3}	50	Rutile-like
3, 4	TiO_2	100 Ar	120	7.2×10^{-3}	100	Amorphous/mixed

Figure 43.7 Ti 2p NEXAFS spectra of sample set 1, subgroups 1 and 2, as indicated. A vertical offset is used for clarity. The arrows evidence pre-edge features. The table gives the preparation parameters of the investigated samples investigated and the phase of the films as obtained from the NEXAFS investigations.

strong correlation between the electronic structure and the structural phase allows assigning directly from the NEXAFS spectra the polymorphs, even in the case of very thin films for which diffraction techniques may not provide unambiguous information and for the surface region, which is important for the interface properties especially in case of implants.

43.4.2

Molecular Orientation, Interaction with the Substrate, and Intermolecular Interaction of an Organic Absorbate: Copper Phthalocyanine Thin Films on a Polycrystalline Gold Substrate

Organic small molecules have been extensively investigated in recent years because of the fascinating opportunities related to their use in electronics, ranging from flexible, stretchable displays to transparent ones, via new lighting concepts, where lamp structures or walls are the light-emitting objects themselves. To use the molecules in a device, it is necessary to grow a film. The orientation of the molecules is known to determine the electronic properties at the interfaces, and consequently the device performances. A method that can be used to determine this structural parameter is NEXAFS spectroscopy. As discussed previously, it is necessary to vary the polarization of the incident radiation and to measure NEXAFS spectra for at least two different polarization angles. At third-generation synchrotron radiation sources, given the high brilliance at undulator beamline, it is possible to investigate also very thin films, down to the submonolayer regime. It is worth mentioning that under these experimental conditions, the radiation damage issue has to be taken into account, and all possible precautions have to be taken to avoid data artifacts.

Among small molecules, the most investigated ones, because of their importance as a model system and as an active layer in devices, are certainly the acenes, the phthalocyanines (Pcs) and the perylene-based molecules [48, 49].

The family of Pcs is one of the most promising candidates for a variety of applications [50–52] owing to their electronic and optical properties and their variability in functional group substitution. Anisotropic electrical transport properties are often observed in these materials, caused by the preferred molecular orientation [53–55]. A very high degree of orientation in evaporated films was observed on several substrates [49, 56–60], even on relatively ill-defined technically relevant substrates [61].

A series of N1s edge NEXAFS spectra at different beam incidence angles were recorded from thin films with thicknesses up to 3 nm (Figure 43.8) [62]. For the spectra of the 0.5 nm thick film, a strong angle dependence is observed, with a maximum π^* absorption for grazing beam incidence and a minimum π^* absorption for normal beam incidence. This shows that the π^* molecular orbitals are perpendicular to the sample plane, indicating that the molecules are oriented parallel to the substrate surface. The data set for 1.0 nm film thickness shows reduced angle dependence with respect to the 0.5 nm film, whereas almost no angle dependence is observed for the 3.0 nm film. The observed initial growth mode of the first layers can be understood by means of the competing molecule–substrate and molecule–molecule interactions at the interface [61, 63, 64]. This has been

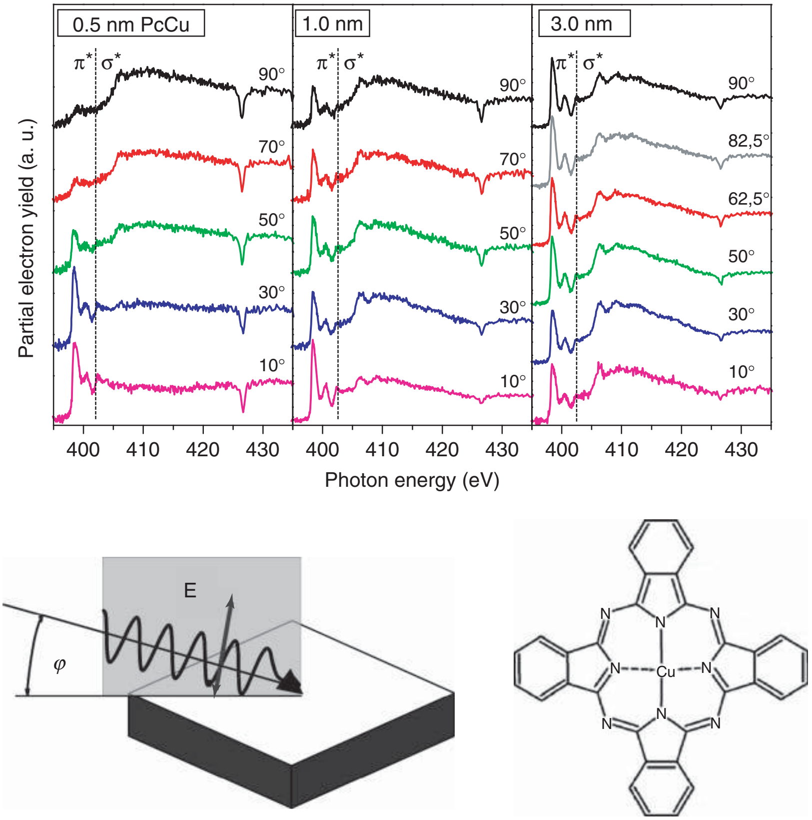


Figure 43.8 Series of N1s NEXAFS spectra of copper phthalocyanine thin films on gold foil substrates taken with different angles of beam incidence $\varphi = 90^\circ$ corresponds to normal, $\varphi = 10^\circ$ to grazing incidence, according to the geometry of the experiment that is also shown. The angular dependence of the π* features for the 0.5 nm film reveals the "lying orientation" of the molecules. The spectra for the 1.0 and 3.0 nm films show a weaker or almost no angle dependence, pointing to a change of molecular ordering with growing film thickness. The molecular structure of copper phthalocyanines is also shown.

observed for substituted and unsubstituted Pcs on single-crystalline metal substrates [65] and single-crystalline germanium [61], as well as for copper Pcs on molybdenum disulfide [66] and on native silicon [67]. For higher coverages, the molecule–substrate interaction becomes negligible, and the intermolecular interaction and surface energy of the molecular film are the structure-determining parameters [63, 64, 68]. The molecules may form stacks parallel to the sample surface consisting of standing molecules, as the interfacial layers act as a van der Waals substrate.

How the molecules oriented themselves in the film plays an important role also from a technological point of view. Photoelectron spectroscopy of conjugated organic compounds, an ω-dihexyl-sexithiophene and a-sexithiophene, on Ag(111), combined with first principles calculations have revealed the existence of a surface dipole built into molecular layers. Its magnitude depends on the orientation of molecules relative to the surface. In particular, the ionization potentials of the molecules change by up to 0.6 eV depending on whether they are flat lying or standing upright with respect to the substrate [69].

Thus, opportunely tuning the molecular orientation by appropriate preparation parameters, or substrate patterning, it is possible to optimize the barriers for charge injection in organic electronics.

43.4.3
Molecular Orientation and Growth Modes

Investigating the perylene deposited on $Al_2O_3/Ni_3Al(111)$ by NEXAFS spectroscopy [70], we found that it is possible to ''tune'' the molecular orientation by choosing an appropriate set of growth parameters during the deposition. The NEXAFS spectra show that there is no evidence of any reorientation of the molecules upon annealing.

This means that the possibility to tune the molecular geometry in the film is directly related to the adsorption mechanism. As a consequence, the monolayer can be deposited varying the molecules orientation from flat lying on the substrate toward a more upright standing position. Because of the relationship between the films thickness and the molecular orientation, we conclude that the molecules have their short axis parallel to the substrate plane, while the long axis is out of plane. In the multilayers, the minimum obtainable value for the molecular orientation is 53°. In this case, we cannot discern by using only NEXAFS data whether it is a real intermediate phase or it is a coexistence of several phases. In thicker films prepared by using higher deposition rate and keeping the substrate at room temperature (RT), we obtain an almost upright molecular orientation close to the single-crystal value. We have described the driven mechanisms in terms of the classical theory of nucleation.

Atomistic theories, based on a general thermodynamic approach, describe the role of individual atoms or small clusters during the earliest stage of the film formation [71, 72]. We apply this approach to molecules, seen now as the elemental building blocks. The reason for this choice is based on the fact that (i) this theory answers the questions why, how, and where different preparation conditions play a role in the film growth. (ii) It relates the preparation with a different dimensionality of the growth. (iii) It has been already applied to the growth of tetracene, pentacene, and perylene thin films, showing how the growth of organic thin films on inert substrates closely mimics the epitaxial growth of inorganic materials [73, 74].

The orientation of the molecules is the specific parameter that defines the difference between atomic and molecular growth. Thus, the most innovative aspect of this work is the relationship between the changes in the molecular orientation, investigated by NEXAFS, and the calculated supersaturation during growth (Figure 43.9).

This relationship, molecular orientation versus supersaturation, is a step forward in aiming at a general description of the organic thin-film growth.

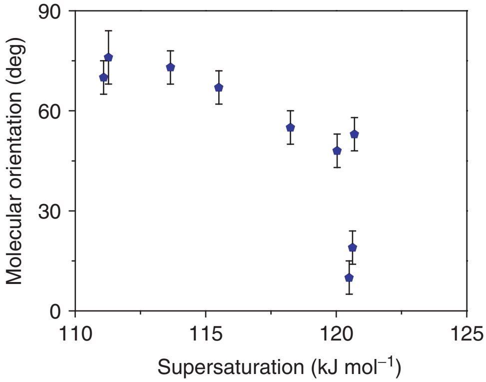

Figure 43.9 Molecular orientation as calculated from the NEXAFS spectra versus supersaturation.

43.4.4
Thickness Dependence of the Electronic Structure and Local Geometry in MnO: Differences between Bulk and Thin Film Properties

Binary transition-metal oxides have been attracting fundamental scientific interest for many years. Their strong electron–electron interaction combined with their compositional simplicity makes them important model compounds for understanding the effects of strong correlation in phenomena such as magnetism and electron transport. Novel properties are predicted for ultrathin films of these oxides on metallic substrates [75]. These properties are expected to differ from bulk properties because of both the reduced dimensionality and the influence of the interface. The metallic substrate may have a purely electronic contribution to the properties of ultrathin films by changing the electron density at the interface [76]. This may change either the ground state of the oxide film or the screening in response to an electronic excitation [77, 78]. In case of less inert metallic substrates, interface reactions, to various extent, can take place [79–83]. Furthermore, interface strain effects may be observed in epitaxial layer systems with a lattice mismatch [84]. It is of basic interest whether these different influences can be used to tune the properties of ultrathin films systematically. As discussed earlier, NEXAFS can probe the orientation of molecular orbitals. More generally, polarized X-ray absorption can sense the charge anisotropy of the valence states involved in the core excitation process. In most cases, the anisotropy of the charge in the atomic volume is caused by anisotropy in the bonding, that is, by the electrostatic potential.

Thus, NEXAFS is a very useful investigation method in this framework. Ultrathin films of MnO on Ag (001) have been investigated by using thickness-dependent XAS [85]. In the MnO bulk structure, manganese is octahedrally coordinated by oxygen. Therefore, no polarization dependence is expected in the XAS spectra of the MnO(001) crystal. The peak positions, the relative intensities, and the overall intensity after normalization with respect to the edge jump remain unchanged for the reference crystal when going from normal to grazing incidence. In contrast, clear changes in the peak positions and the relative intensities are visible in the polarization-dependent Mn $L_{2,3}$ edge spectra of the ultrathin films. These changes become evident in different angular-dependent sets of spectra recorded at the different film thicknesses, and shown in Figure 43.10a.

Subtracting the normalized spectra taken at an angle of 70° from the spectra at 0° (that is the definition of linear dichroism) and plotting them together (Figure 43.10b, also with the related simulations scaled by a factor of 10 to match

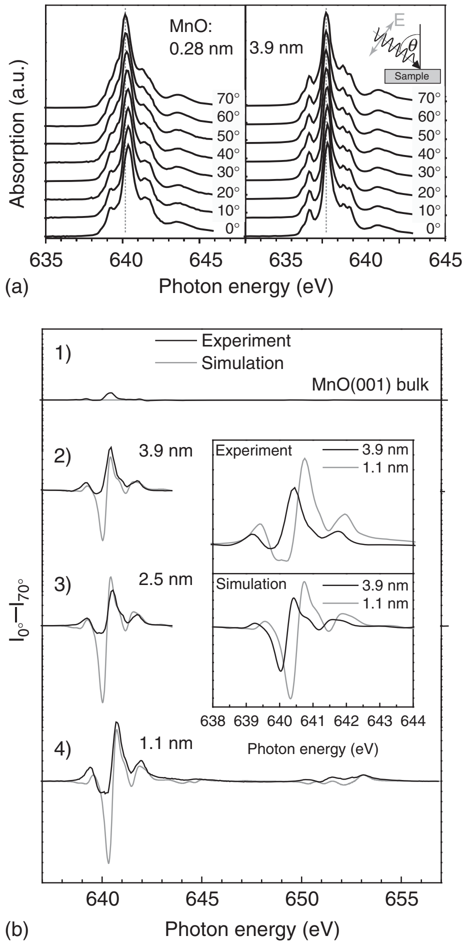

Figure 43.10 (a) Polarization-dependent Mn L_3 XA spectra of a 0.28 nm (left) and a 3.9 nm (right) MnO (001) film on Ag (001). (b) Linear dichroism of the Mn $L_{2,3}$ X-ray absorption spectra of (1) a MnO (001) single crystal, (2) a 3.9 nm, (3) a 2.5 nm, and (4) a 1.1 nm thick film of MnO (001) on Ag (001). The experimental spectra (black solid curves) are directly compared to the theoretical simulations (dashed gray curves). The inset shows the experimental and theoretical findings of the L_3 edge for two different film thicknesses.

the total intensity), it is clear that the linear dichroism plot of the bulk MnO shows only a small artifact at the position of the highest absorption intensity. On the contrary, in the linear dichroism plots of the films, the dichroism decreases and the features shift to lower energies with increasing film thickness. The synergy between experiment and simulation is a key point in understanding this behavior. The simulations were performed assuming that the epitaxially grown manganese oxide layers on a silver substrate are tetrahedrally distorted MnO_6 octahedrons. This describes the observed linear dichroism reasonably well. The influence of the substrate on the layer decreases with increasing film thickness. Consequently, the distortion of the MnO structure by the matching to the Ag substrate decreases with increasing film thickness, as also verified by the simulation.

43.4.5

Charge Transfer Between Metal 3d Electrons and Metal Surfaces in Transition-Metal Phthalocyanine/Metal Interfaces

X-ray absorption is also a technique that is proved to be useful to investigate the interface between transition-metal Pcs and metal surfaces. In addition to the well-known material properties of the Pcs family, transition-metal Pcs have magnetic properties because of the presence of the partially empty d levels of the central metal. This aspect makes them promising candidates for their use in spintronics.

Thickness-dependent angle-resolved NEXAFS measurements performed on well-ordered CoPc thin films deposited on Ag(111) show an evident dichroism at the Co L-edge that is different depending on thickness (Figure 43.11) [86]. The strong dependence of the Co L XAS on polarization reflects the different d-orbital character of the unoccupied metal atom states.

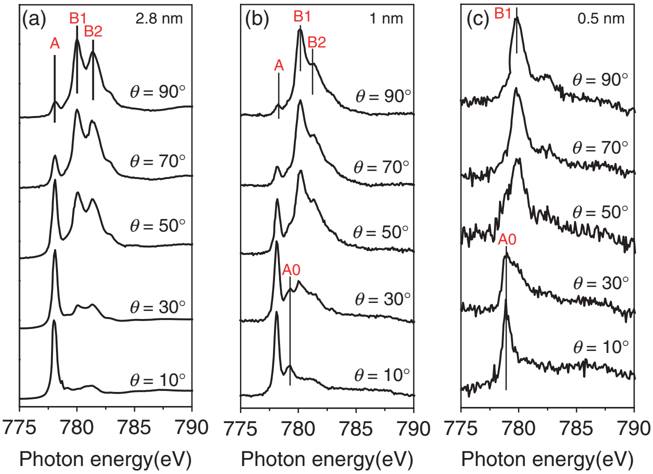

Figure 43.11 Co $L_{2,3}$ edge XAS spectra for the CoPc/Ag(111) system for different film thicknesses: (a) 2.8 nm, (b) 1 nm, and (c) 0.5 nm measured at different incident angles of the X-ray beam.

Petraki *et al*. demonstrate that this phenomenon is related to the occurrence of charge transfer between the metal 3d electrons of the Pcs and the metal surface underneath. A charge donation from the metal substrate to the central metal Co atom of the Pc molecules on top of the substrate itself leads to a redistribution of the 3d electron-inducing changes in the Co-related absorption spectra. A similar, although weaker, effect is also found at the interface in MnPc thin films deposited on Ag(111).

43.4.6
X-Ray Magnetic Circular Dichroism

XMCD is very commonly used currently to measure the difference in absorption of circular polarization with opposite helicity.

XMCD is the difference spectrum of two X-ray absorption spectra taken in the presence of a magnetic field, once with left circularly polarized light and once with right circularly polarized light. By closely analyzing the difference in the XMCD spectrum, information can be obtained on the magnetic properties of the atom, such as its spin and orbital magnetic moment. Because the allowed core-to-valence transition follows the dipole selection rule excitation at different absorption edges, XMCD provides selectivity to the angular momentum of the valence-electron states. For example, L-edge (2p) excitation in cobalt probes the cobalt 3d valence subshell, while K-edge (1s) excitation probes the cobalt 3p valence electrons [87, 88]. The large size of the circular dichroism effects (up to 30% in XMCD and tens of degrees in magnetooptical rotation) allow the study of very dilute and/or weak moments [89].

XMCD is a powerful technique that has been used to investigate various aspects. For example, XMCD at the Co L_3 and L_2 edges in Co/Pd multilayers gave evidence of a greatly enhanced orbital moment compared to that in bulk Co. The results also show that, in general, there is no simple relationship between the dichroism signal and either the spin moment or the total moment [90].

Magnetic impurities in solids cause manifold changes in their macroscopic properties, such as anomalous low-temperature resistance due to Kondo screening, reduction in the superconducting transition temperature due to local suppression of the order parameter. They create magnetic signatures in semiconductors and lead to inelastic spin excitations in tunnel junctions. With XMCD, it is possible to investigate the properties of such impurities and the huge difference with the bulk elemental spectra [91].

43.5
Conclusions and Future

The aim of this chapter has been to give an overview of a faceted technique as NEXAFS spectroscopy is. NEXAFS investigations not only give information on the unoccupied states but their use also shed light on several aspects as oxidation states, bonding of adsorbates with substrates, molecular orientation, and structural properties in thin films.

The detailed understanding of complex materials requires the use of state-of-the-art experimental techniques that provide information on electronic and magnetic properties of the materials. The advent of third-generation synchrotron sources has immensely increased the possibilities offered by NEXAFS because of the high energy resolution reached. However, the increasing miniaturization of components furthermore demands the use of techniques with spatial resolution down to the nanometer range. Thus, a good way to satisfy both requirements is to combine the distinctive properties of standard XAS with those of electron microscopy as in X-ray photoemission electron microscopy, which opens further ways to the use of XAS and to the investigations of not yet revealed phenomena.

44
The X-Ray Standing Wave Technique

Alexander Gerlach and Frank Schreiber

44.1
Introduction

The X-ray standing wave (XSW) technique provides element-specific information on surface structures and adsorbate sites by combining a diffraction-based approach with spectroscopic measurements. After pioneering work by Batterman in the 1960s [1, 2] and various others thereafter, the increased availability of brilliant and tunable synchrotron light has stimulated the application of this technique to a wide range of problems in surface and interface science; see, for example, Refs. [3–5].

The conventional concept is based on the excitation of characteristic, element-specific signals, that is, photoelectrons, Auger electrons, or fluorescence light, in an XSW field, which is generated by the superposition of the incoming and the reflected wave. The interference character of this technique allows for high spatial resolution, typically a few percent of the wavelength used in the experiment. There are several variations of the XSW technique, which differ in the way the standing wave field is generated. While the most common approach is based on single-crystal Bragg reflections, the use of thin-film Bragg reflections, total external reflection, or reflection from layered synthetic multilayers are also well established in the study of interfaces at different length scales [4].

In this article, we first give a short overview of the theory used to describe X-ray wave field in crystals (Section 44.2), then we discuss briefly about some specific experimental requirements of the technique (Section 44.3). Finally, we look at some typical XSW applications in the field of organic adsorbates, where atomic length scales are probed (Section 44.4).

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

44.2
Theory

44.2.1
Wave Fields in Crystals

The dynamical theory of X-ray diffraction derives the wave fields in crystals from the Maxwell equations [6] for a periodic electron density $\rho(\vec{r})$ at each point $\vec{r}$ inside the crystal. As shown in Figure 44.1, the wave vectors of the incident and diffracted waves, $\vec{K}_0$ and $\vec{K}_{\mathrm{H}}$, fulfill the Bragg condition

$$\vec{K}_{\mathrm{H}} = \vec{K}_0 + \vec{H} \tag{44.1}$$

with $|\vec{K}| = \lambda^{-1}$ and $\vec{H}$ being a reciprocal lattice vector. Because, in periodic media, Bloch functions are the solutions to linear differential equations, the fields are expanded as a sum of plane waves (with $\vec{\mathcal{A}}$ corresponding to the electric and magnetic vectors fields $\vec{\mathcal{E}}, \vec{\mathcal{D}}, \vec{\mathcal{H}}$, and $\vec{B}$)

$$\vec{\mathcal{A}} = \sum_H \vec{\mathcal{A}}_{\mathrm{H}} e^{-2\pi i \vec{K}_{\mathrm{H}}\cdot\vec{r}} = \left[\sum_H \vec{\mathcal{A}}_{\mathrm{H}} e^{-2\pi i \vec{H}\cdot\vec{r}}\right] e^{-2\pi i \vec{K}_0\cdot\vec{r}} e^{-2\pi i \nu t} \tag{44.2}$$

Using this representation, one finds that because the equations have to be valid for all points in space and time, the following conditions for each reciprocal lattice vector $\vec{H}$

$$\vec{K}_{\mathrm{H}} \times \vec{\mathcal{E}}_{\mathrm{H}} = \nu\mu_0\vec{\mathcal{H}}_{\mathrm{H}} \tag{44.3}$$

$$\vec{K}_{\mathrm{H}} \times \vec{\mathcal{H}}_{\mathrm{H}} = -\nu\vec{\mathcal{D}}_{\mathrm{H}} \tag{44.4}$$

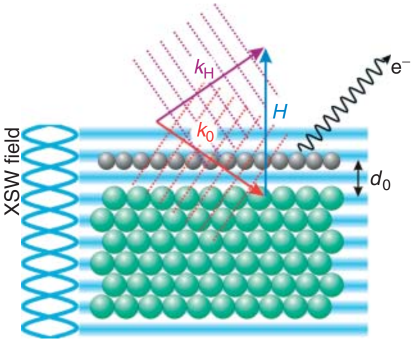

Figure 44.1 XSW principle. The standing wave field can be produced by Bragg reflection of monochromatic X-rays from a single-crystal substrate. The variation in the photo (or fluorescence) yield, when scanning the photon energy through the Bragg condition, depends on the adsorbate position d_0.

Here, the electron density $\rho(\vec{r})$ enters via the complex structure factor $\mathcal{F}_{\mathrm{H}} = \mathcal{F}_{\mathrm{H}} + i\mathcal{F}'_{\mathrm{H}}$ and the corresponding susceptibility χ given by

$$\mathcal{F}_{\mathrm{H}} = \int \rho(\vec{r}) e^{2\pi i \vec{H}\cdot\vec{r}} \mathrm{d}^3 r \tag{44.5}$$

$$\chi(\vec{r}) = 1 - \Gamma \sum_{H} \mathcal{F}_{\mathrm{H}} e^{-2\pi i \vec{H}\cdot\vec{r}} \tag{44.6}$$

with $\vec{\mathcal{D}} = \chi \epsilon_0 \vec{\mathcal{E}}$ (using $\Gamma = r_e \lambda^2/(\pi V)$ with the classical electron radius $r_e = 2.82 \times 10^{-5}$ Å and the unit cell volume V). From this it is found that

$$\vec{\mathcal{D}}_{\mathrm{H}} = \epsilon_0 \vec{\mathcal{E}}_{\mathrm{H}} - \epsilon_0 \Gamma \sum_{P} \mathcal{F}_{\mathrm{H}-P} \mathcal{E}_{\mathrm{P}} = \epsilon_0 (1 - \Gamma \mathcal{F}_0) \mathcal{E}_{\mathrm{H}} - \epsilon_0 \Gamma \sum_{P \neq H} \mathcal{F}_{\mathrm{H}-P} \mathcal{E}_{\mathrm{P}} \tag{44.7}$$

Inserting this into Eq. (44.3), one obtains a set of fundamental equations that describe the wave fields inside the crystal

$$\left[k^2(1 - \Gamma\mathcal{F}_0) - (\vec{K}_{\mathrm{H}} \cdot \vec{K}_{\mathrm{H}})\right] \vec{\mathcal{E}}_{\mathrm{H}} - k^2 \Gamma \sum_{P \neq H} \mathcal{F}_{\mathrm{H}-P} \vec{\mathcal{E}}_{\mathrm{P}} + (\vec{K}_{\mathrm{H}} \cdot \vec{\mathcal{E}}_{\mathrm{H}}) \vec{K}_{\mathrm{H}} = 0 \tag{44.8}$$

For the case that only one reciprocal lattice point contributes to the diffraction, that is, there is only the incidence wave $\vec{\mathcal{E}}_0$ and the reflected wave $\vec{\mathcal{E}}_{\mathrm{H}}$, this is reduced to two equations for σ-polarization

$$\left[k^2(1 - \Gamma\mathcal{F}_0) - \vec{K}_0 \cdot \vec{K}_0\right] \vec{\mathcal{E}}_0^{\sigma} - k^2 \Gamma \mathcal{F}_{\overline{\mathrm{H}}} \vec{\mathcal{E}}_{\mathrm{H}}^{\sigma} = 0 \tag{44.9}$$

$$-k^2 \Gamma \mathcal{F}_{\mathrm{H}} \vec{\mathcal{E}}_0^{\sigma} + \left[k^2(1 - \Gamma\mathcal{F}_0) - \vec{K}_{\mathrm{H}} \cdot \vec{K}_{\mathrm{H}}\right] \vec{\mathcal{E}}_{\mathrm{H}}^{\sigma} = 0 \tag{44.10}$$

This set of equations only has a nontrivial solution for $\mathcal{E}_0^{\sigma}/\mathcal{E}_{\mathrm{H}}^{\sigma}$ if the determinant is zero, that is, the wave vectors $\vec{K}_0$ and $\vec{K}_{\mathrm{H}}$ have to fulfill the equation

$$\begin{vmatrix} k^2(1 - \Gamma\mathcal{F}_0) - \vec{K}_0 \cdot \vec{K}_0 & -k^2 \Gamma \mathcal{F}_{\overline{\mathrm{H}}} \\ -k^2 \Gamma \mathcal{F}_{\mathrm{H}} & k^2(1 - \Gamma\mathcal{F}_0) - \vec{K}_{\mathrm{H}} \cdot \vec{K}_{\mathrm{H}} \end{vmatrix} = 0 \tag{44.11}$$

For Bragg diffraction from a centrosymmetric crystal ($\mathcal{F}_{\mathrm{H}} = \mathcal{F}_{\overline{\mathrm{H}}}$), this reduces to

$$\frac{\mathcal{E}_{\mathrm{H}}}{\mathcal{E}_0} = -[\eta \pm \sqrt{(\eta^2 - 1)}] \tag{44.12}$$

where η is the generalized angle

$$\eta = \frac{\Gamma\mathcal{F}_0 - \Delta\theta \sin(2\theta_{\mathrm{B}})}{\Gamma\sqrt{\mathcal{F}_{\mathrm{H}}\mathcal{F}_{\overline{\mathrm{H}}}}} \tag{44.13}$$

and $\Delta\theta = \theta - \theta_{\mathrm{B}}$ the deviation from the kinematical Bragg angle θ_{B}.

From Eqs. (44.12, 44.13) not only the intrinsic shape of the reflectivity curve can be calculated but also the phase ν between the incident and reflected wave. As shown in Figure 44.2, ν changes by π across the Bragg reflection. The corresponding shift of the nodes (and antinodes) of the standing wave field by half a lattice plane spacing is the key ingredient of the XSW technique.

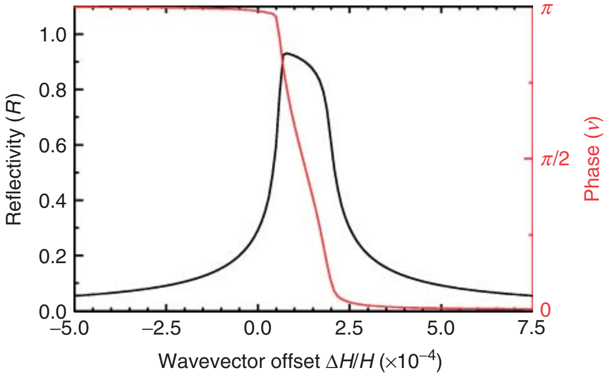

Figure 44.2 Theoretical angle/energy dependence of the reflectivity R and phase ν for Si(111) around the (111) Bragg reflection, that is, H along the [111] direction. Note that the x-axis denotes the wave vector offset relative to the Bragg condition in kinematical approximation.

44.2.2
Standing Waves

The two-beam approximation of dynamical theory assumes that only two wave vectors $\vec{K}_0$ and $\vec{K}_\mathrm{H}$ satisfying the Bragg condition contribute with a nonnegligible amplitude [6]. Therefore, the electrical field can be described by the superposition of the incident wave $\vec{\mathcal{E}}_0$ and the Bragg reflected wave $\vec{\mathcal{E}}_\mathrm{H}$, which are given by

$$\vec{\mathcal{E}}_0(r) = \sum_s \vec{e}_{0s}\mathcal{E}_0\, e^{-2\pi i \vec{K}_0\cdot\vec{r}} \tag{44.14}$$

$$\vec{\mathcal{E}}_H(r) = \sum_s \vec{e}_{\mathrm{H}s}\mathcal{E}_\mathrm{H}\, e^{-2\pi i \vec{K}_\mathrm{H}\cdot\vec{r}} \tag{44.15}$$

with the polarization vectors $\vec{e}_{is}$ of the two possible states $s = \sigma, \pi$ which for $\vec{e}_{0\sigma}$ and $\vec{e}_{\mathrm{H}\sigma}$ ($\vec{e}_{0\pi}$ and $\vec{e}_{\mathrm{H}\pi}$) are perpendicular (parallel) to the plane defined by the two wave vectors $\vec{K}_0$ and $\vec{K}_\mathrm{H}$ (Figure 44.3).

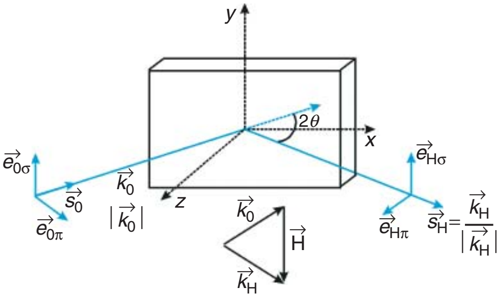

Figure 44.3 Scheme of the scattering geometry. The two plane waves $\mathcal{E}_0$ and $\mathcal{E}_\mathrm{H}$ with the wave vector $\vec{K}_0$ and $\vec{K}_\mathrm{H}$ and the polarization vectors $\vec{e}_0$ and $\vec{e}_\mathrm{H}$.

As the resulting electrical field is given by

$$\vec{\mathcal{E}}(\vec{r}) = \sum_s (\vec{e}_{0\mathrm{s}}\mathcal{E}_0\; e^{-2\pi i\vec{K}_0\cdot\vec{r}} + \vec{e}_{\mathrm{Hs}}\mathcal{E}_{\mathrm{H}}\; e^{-2\pi i\vec{K}_{\mathrm{H}}\cdot\vec{r}}) \tag{44.16}$$

an XSW field with the intensity $I(\vec{r}) = |\vec{\mathcal{E}}(\vec{r})|^2$ is generated. Inserting Eq. (44.13) and using the polarization factor

$$C = \vec{e}_{0\mathrm{s}} \cdot \vec{e}_{\mathrm{Hs}} = \begin{cases} 1, & \sigma\,\text{polarization} \\ \cos 2\theta, & \pi\,\text{polarization} \end{cases} \tag{44.17}$$

one finds

$$I(\vec{r}) = I_0(1 + R + 2C\sqrt{R}\cos(\nu - 2\pi\vec{H}\cdot\vec{r})) \tag{44.18}$$

where R is the reflectivity with $\mathcal{E}_{\mathrm{H}} = \sqrt{R}\mathcal{E}_0 e^{i\nu}$. The periodicity of the standing wave field is given by the lattice spacing $d_{\vec{H}} = |\vec{H}|^{-1}$.

44.2.3
The Photo Yield

Within the X-ray interference field, the atoms absorb some of the incoming photons (which is why one can see them as local probes for the standing wave field). As a result, photoelectrons or Auger electrons are excited from the core levels of specific atoms (Figure 44.4). As shown below the photoelectron yield, Y_{p} around the Bragg condition depends on the position of the emitting atom relative to the lattice planes.

According to Fermi's golden rule, the photoelectron yield Y_{p} for excitation from the initial state i to the final state f is proportional to the square of the transition

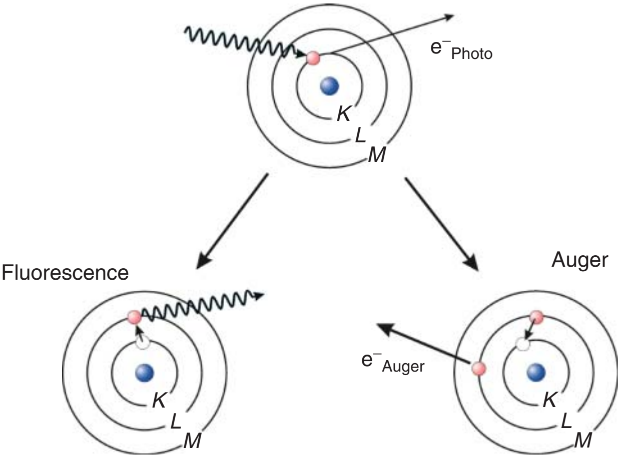

Figure 44.4 Photoelectrons excited from core levels because of the absorption of X-rays can be used as element-specific signals for XSW measurements. Also, secondary processes as fluorescence and Auger electron emission can be exploited.

matrix element M_{fi}, with

$$M_{fi} = \langle f | e^{2\pi i \vec{k}\cdot\vec{r}} \vec{e} \cdot \nabla | i \rangle \tag{44.19}$$

For two coherent wave fields, one therefore obtains [7]

$$Y_{\mathrm{p}}^{\mathrm{XSW}} \propto |M_{fi}^{\mathrm{XSW}}|^2 = |\mathcal{E}_0 \langle f | (e^{2\pi i \vec{K}_0\cdot\vec{r}} \vec{e}_0 \cdot \nabla) | i \rangle + \mathcal{E}_{\mathrm{H}} \langle f | (e^{2\pi i \vec{K}_{\mathrm{H}}\cdot\vec{r}} \vec{e}_{\mathrm{H}} \cdot \nabla) | i \rangle|^2 \tag{44.20}$$

In case $|\vec{K}_0 \cdot \vec{r}| \langle 1$ (long wavelength limit), the so-called dipole approximation can be used to evaluate this expression

$$\begin{aligned} Y_{\mathrm{p}}^{\mathrm{XSW}} \propto\ & |\mathcal{E}_0|^2 \ |\langle f | \vec{e}_0 \cdot \nabla | i \rangle|^2 + |\mathcal{E}_{\mathrm{H}}|^2 \ |\langle f | \vec{e}_{\mathrm{H}} \cdot \nabla | i \rangle|^2 \\ & + \left|\mathcal{E}_0 \mathcal{E}_{\mathrm{H}}\right| (e^{-i(\nu - 2\pi \vec{H}\cdot\vec{r}) \langle f|\vec{e}_0\cdot\nabla|i\rangle \times \langle f|\vec{e}_{\mathrm{H}}\cdot\nabla|i\rangle^*} + e^{i(\nu - 2\pi \vec{H}\cdot\vec{r}) \langle f|\vec{e}_0\cdot\nabla|i\rangle^* \times \langle f|\vec{e}_{\mathrm{H}}\cdot\nabla|i\rangle}) \end{aligned} \tag{44.21}$$

For σ polarized light, where $\vec{e}_0$ and $\vec{e}_H$ are parallel to each other, this can be simplified to

$$\begin{aligned} Y_{\mathrm{p}}^{\mathrm{XSW}} & \propto 1 + \left|\frac{\mathcal{E}_{\mathrm{H}}}{\mathcal{E}_0}\right|^2 + 2\left|\frac{\mathcal{E}_{\mathrm{H}}}{\mathcal{E}_0}\right| \cos(\nu - 2\pi \vec{H} \cdot \vec{r}) \\ & = 1 + R + 2\sqrt{R} \cos(\nu - 2\pi \vec{H} \cdot \vec{r}) \end{aligned} \tag{44.22}$$

This expression is similar to Eq. (44.18), and thus shows that under these conditions the photo yield $Y_{\mathrm{p}}^{\mathrm{XSW}}$ is proportional to the intensity $I(\vec{r})$ of the standing wave field at the center of the excited atom. Nondipolar effects in the photoemission process can be taken into account by modifying this equation. Related issues are discussed in detail in Refs. [8, 9] (theory) and Refs. [10–14] (experiment).

By scanning the angle θ or the photon energy E of the incident wave through the Bragg condition, the phase ν of the interference field changes by π and, as a consequence, the nodal planes of the standing wave field shift by half a lattice constant [3]. As the absorption of X-rays depends on the position $\vec{r}$ of the atoms within this wave field, the photoelectrons or Auger electrons [15, 16] can be used as element-specific signals, which reveal the position of the atoms. The measured photoelectron yield $Y_{\mathrm{p}}^{\mathrm{XSW}}$ exhibits a characteristic shape that is related to the position of a given atom. Figure 44.5 illustrates the effect that different atomic positions $\vec{r}$ have on the photo yield.

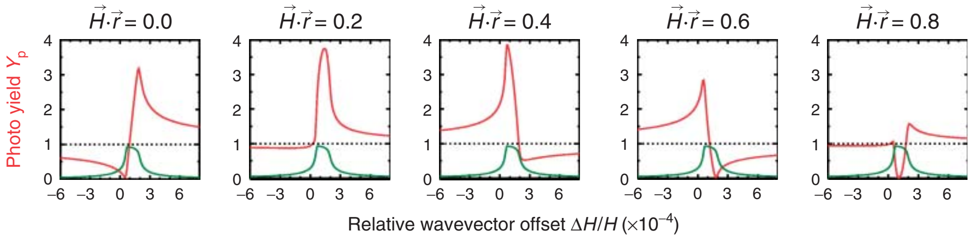

Figure 44.5 Theoretical normalized photo yields for different values of $\vec{H} \cdot \vec{r}$ in Eq. (44.22). The extraordinary sensitivity of Y_{p} to the position of the atom $\vec{r}$ is demonstrated.

For an (partly) incoherent system with atoms on nonequivalent atomic sites, a normalized distribution function $n(\vec{r})$ that describes the spread of atoms around their average lattice position has to be introduced [3–5]. Equation (44.22) is then generalized to

$$Y_{\mathrm{p}}^{\mathrm{XSW}} = \int Y_{\mathrm{p}}(\vec{r})n(\vec{r})\mathrm{d}^3r = 1 + R + 2C\sqrt{R}\int n(\vec{r})\cos(\nu - 2\pi\vec{H}\cdot\vec{r})\mathrm{d}^3r \tag{44.23}$$

with the polarization factor C given by Eq. (44.17).

A more convenient form of this averaging equation is obtained by introducing two new parameters: the *coherent position* $P_{\mathrm{H}} = \vec{H}\cdot\vec{r}$ and the *coherent fraction* f_{H}.

$$Y_{\mathrm{p}}^{\mathrm{XSW}} = 1 + R + 2C\sqrt{R}f_{\mathrm{H}}\cos(\nu - 2\pi P_{\mathrm{H}}) \tag{44.24}$$

This is the basic equation for most XSW experiments as P_{H} and f_{H} contain all structural information on the specific system. The coherent position $0 \le P_{\mathrm{H}} \le 1$ now gives the atomic position relative to the diffraction planes associated with the vector $\vec{H}$, whereas the coherent fraction $0 \le f_{\mathrm{H}} \le 1$ describes the degree of coherent order in the system.

This is best illustrated by considering two extreme cases: a random distribution of atoms on the surface, for example, a thick incoherent film of molecules, with $f_{\mathrm{H}} = 0$ results in $Y_{\mathrm{p}} = 1 + R$, that is, depending on the absorption $Y_{\mathrm{p}} \le 2$. A perfectly ordered adlayer with $f_{\mathrm{H}} = 1$, in contrast, amplifies the XSW yield to $Y_{\mathrm{p}} \le 4$.

The equivalence of Eqs. (44.23, 44.24) can be used to explore the physical meaning of the coherent fraction f_{H} [17]. By equating both expressions, we obtain a relation

$$f_{\mathrm{H}}\cos(\nu - 2\pi P_{\mathrm{H}}) = \int n(\vec{r})\cos(\nu - 2\pi\vec{H}\cdot\vec{r})\mathrm{d}\vec{r} \tag{44.25}$$

which has to hold for any value of ν. An expansion of the cosine sums on both sides now gives

$$\begin{aligned} \cos\nu\, f_{\mathrm{H}}\cos(2\pi P_{\mathrm{H}}) + \sin\nu\, f_{\mathrm{H}}\sin(2\pi P_{\mathrm{H}}) \;=\; & \cos\nu \int n(\vec{r})\cos(2\pi\vec{H}\cdot\vec{r})\mathrm{d}\vec{r} \\ & + \sin\nu \int n(\vec{r})\sin(2\pi\vec{H}\cdot\vec{r})\mathrm{d}\vec{r} \end{aligned} \tag{44.26}$$

As $\sin\nu$ and $\cos\nu$ are linear independent functions, this relation can only be satisfied if the individual coefficients are equal, that is,

$$f_{\mathrm{H}}\cos(2\pi P_{\mathrm{H}}) = \int n(\vec{r})\cos(2\pi\vec{H}\cdot\vec{r})\mathrm{d}\vec{r} \tag{44.27}$$

$$f_{\mathrm{H}}\sin(2\pi P_{\mathrm{H}}) = \int n(\vec{r})\sin(2\pi\vec{H}\cdot\vec{r})\mathrm{d}\vec{r} \tag{44.28}$$

Using complex numbers, this can finally be summarized by

$$f_{\mathrm{H}}\exp\;(2\pi iP_{\mathrm{H}}) = \int n(\vec{r})\exp\;(2\pi i\vec{H}\cdot\vec{r})\mathrm{d}\vec{r} \tag{44.29}$$

Therefore, the coherent fraction f_H is the first Fourier component of the distribution function $n(\vec{r})$ multiplied by a phase factor containing the coherent position P_H. This means that by measuring photo yields for sufficiently many reciprocal lattice vectors $\vec{H}$, it is, in principle, possible to determine the Fourier representation of the atomic density of a specific element [18].

44.3
Experiment

Different types of experimental setups have been used at various synchrotron light sources. The principal mode of detection (fluorescence light versus photoelectrons) and the accessible photon energies determine, to a large extent, the design of the instrument. Two typical examples are beamline 5ID-C at the APS (advanced photon source) (mostly fluorescence detection) and beamline ID32 at ESRF (European Synchrotron Radiation Facility) (mostly photoelectron detection).

Here, we briefly describe the setup used at the ESRF, which was used to measure the XSW data presented in the following section. The ultrahigh vacuum system shown schematically in Figure 44.6a is used for XSW studies and high-energy XPS (X-ray photoelectron spectroscopy) measurements. The chamber is equipped with a hemispherical electron analyzer (150 mm radius), a sample manipulator with five degrees of freedom (all motions stepper motor driven), a sample holder with possibilities of heating the sample up to 1000 K and cooling down to 30 K with a copper braid connected to a He-cryostat, a rear-view low-energy electron diffraction (LEED) system, a sputter gun for sample preparation, a load-lock chamber with a transfer rod to introduce samples into the main chamber under UHV (ultrahigh vacuum) conditions, a three-way gas line for different gases, a residual gas analyzer (RGA), several evaporation sources (Knudsen cells) for thin

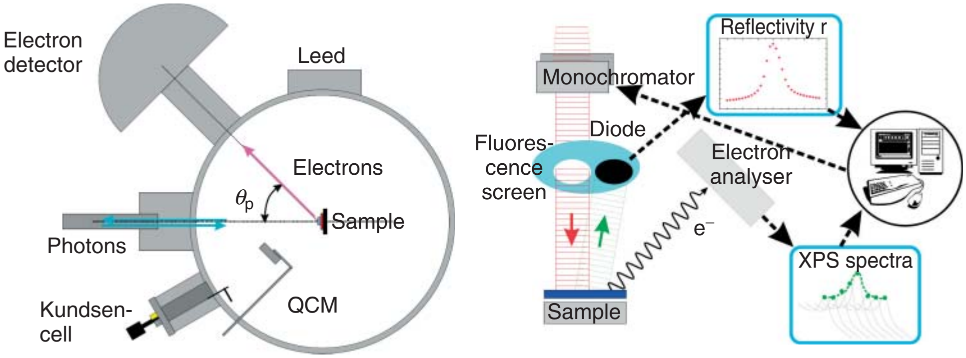

Figure 44.6 Experimental setup for XSW measurements at beamline ID32 at the ESRF. (a) Schematic of the UHV chamber. (b) Principle of XSW measurements.

film preparation, a quartz crystal microbalance (QCM) to control the deposition rate, a port for solid-state X-ray fluorescence detector and some spare ports for user-defined equipments.

Examples: Organic Adsorbates

The interaction strength between the adsorbed molecule and the substrate, possible distortions of the molecule on the substrate, and possibly the orientation of the molecules are fundamental properties of organic adsorbates. These structural details do not only influence the growth process beyond the first layer [19, 20] but are also important for the energy level alignment at the organic/metal interface and the corresponding efficiency of charge-carrier injection into the organic material [21]. Therefore, the precise and chemically resolved structural information, which can be obtained by normal incidence XSW experiments even for relatively large organic molecules [22], improve the general understanding of these systems.

Subsequently, we shall discuss a number of experimental results for the molecules shown in Figure 44.7, which illustrate that the strength of the substrate–adsorbate interaction—in particular for lying-down molecules on different substrates—varies considerably and that the complex interaction mechanisms result in a rich phenomenology of adsorption geometries.

RT, room temperature; LT, low temperature.

An overview of bonding distances determined with the XSW technique on different noble metal substrates is presented in Table 44.1 (summary as of 2010).

44.4.1
PTCDA/Ag(111), Cu(111), and Au(111)

PTCDA (3,4,9,10-perylene-tetracarboxylic acid dianhydride) has become the best-studied system in this field; see, for example, Refs. [23–32]. There are precise data on three different substrates, that is, Ag(111), Cu(111), and Au(111). A strong

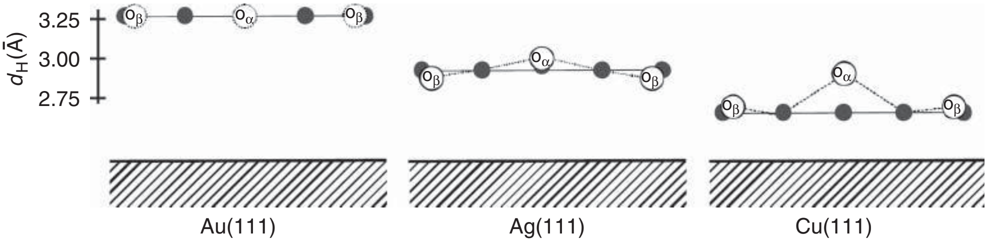

Figure 44.8 Different bonding distances and adsorption geometries of PTCDA on Au(111), Ag(111), and Cu(111) as measured by XSW. On copper, both oxygen species—distinguishable because of a chemical shift in the photoemission spectra—are located above the carbon plane. On silver, however, the carboxylic oxygen atoms are bent toward the surface. The position of the oxygen atoms on Au(111) was not measured with XSW. (From Ref. [27] with permission.)

interaction with the substrate ('chemisorption') is found for Ag(111) and Cu(111), with a bonding distance of 2.86 ± 0.01 Å and 2.61 ± 0.02 Å, respectively. Yet, a much weaker interaction is found for PTCDA on Au(111) with 3.27 ± 0.02 Å. The close correlation of these findings with the electronic properties of PTCDA on the different substrates is discussed in Ref. [27].

The XSW results of PTCDA/Ag(111) obtained in the monolayer regime agree with surface diffraction data [33] obtained from multilayer films of PTCDA. This indicates that the growth of further layers does not influence the first layer and the XSW measurements of d_0 discussed here are indeed relevant beyond the monolayer coverage. Moreover, a substrate-dependent distortion of the C=O bonds is found: for PTCDA on Ag(111) the carboxylic oxygen atoms are located below the molecular plane ($d_0 = 2.68$ Å), but for PTCDA on Cu(111) these atoms are above the plane ($d_0 = 2.73$ Å) (Figure 44.8). Theoretical efforts based mainly on density functional theory are being made to explain these findings, but are still hampered by the necessarily tedious computations.

44.4.2
NTCDA/Ag(111)

Recent XSW experiments demonstrate that the adsorption geometry of NTCDA (1,4,5,8-naphthalene tetracarboxylic dianhydride) on Ag(111) is similar to the one found for the larger PTCDA molecule [34, 35]. A slightly weaker substrate–adsorbate interaction results in a carbon distance of $d_0 = 2.997 \pm 0.016$ Å to the Ag(111) lattice. Therefore, the adsorption of NTCDA might be regarded as relatively strong (chemisorption). A nonplanar adsorption geometry is also reported for NTCDA. In essence, the distortion of the C=O bonds in NTCDA is similar to the case of PTCDA on Ag(111) in which the carboxylic oxygen atoms are located below the molecular plane. As no XSW data for Cu(111) or Au(111) are presently available, a substrate-dependent distortion of NTCDA—as found for PTCDA—has not yet been established.

44.4.3

F_{16}CuPc/Ag(111) and Cu(111)

The XSW results obtained on F_{16}CuPc (copper hexadecafluorophthalocyanine) show that perfluorinated copper-phthalocyanine molecules adsorb in a lying down, but significantly distorted configuration on Cu(111) and Ag(111) surfaces [36]. While on copper (silver) the central carbon rings reside 2.61 ± 0.05 Å (3.25 ± 0.05 Å) above the substrate, the outer fluorine atoms are located 0.27 Å (0.20 Å) further away from the surface. These results on F_{16}CuPc are in remarkable contrast to those on PTCDA on Cu(111) and Ag(111) mentioned earlier. First, a much larger difference between the adsorption distances d_0 on copper and silver is found. Second, the type of molecular distortion, that is, an upward bending of the C–F bonds in F_{16}CuPc, is the same on copper and silver despite the obviously weaker interaction of F_{16}CuPc with the Ag(111) surface. As for PTCDA, a thorough explanation for the nonplanar adsorption structure of the molecules is still missing. Yet, it is suggested that the results can be discussed in terms of the outer carbon atoms in F_{16}CuPc undergoing a partial rehybridization ($sp^2 \rightarrow sp^3$) with a concomitant change of the bonding angles. For details, see Ref. [36].

44.4.4

SnPc/Ag(111)

The adsorption geometry and orientation of the nonplanar phthalocyanine molecule SnPc (tin phthalocyanine) has been measured by XSW [37–39]. Depending on the preparation Conditions, SnPc monolayers exhibit different superstructures and molecular conformations on the Ag(111) surface. The existence of an incommensurate room-temperature (RT) phase with an average carbon bonding distance of 3.17 Å (Sn-down orientation) and a commensurate low-temperatures phase with a carbon bonding distance of 2.93 Å (mixed Sn-down and Sn-up orientation) was established [37]. Moreover, it is reported that for a monolayer of SnPc prepared via desorption of a multilayer film [37], the carbon atoms are bent toward the surface, whereas for deposition at 300 °C substrate temperature [38] the carbon atoms are bent away from the surface with $d = 3.61$ Å.

44.4.5

PEN/Cu(111) and PFP/Cu(111)

The adsorption geometry of pentacene (PEN) and perfluorinated pentacene (PFP) on Cu(111) has been studied using the XSW technique und other complementary techniques [40]. The element-specific structural information derived from the C(1s)and F(1s) photoelectron signals reveals the different bonding mechanism of both molecules (Figure 44.9).

While PEN interacts strongly with the copper substrate and adsorbs with an average bonding distance of only 2.34 ± 0.02 Å, the carbon core of the PFP molecule is located at 2.98 ± 0.07 Å. Despite the relatively weak interaction of PFP

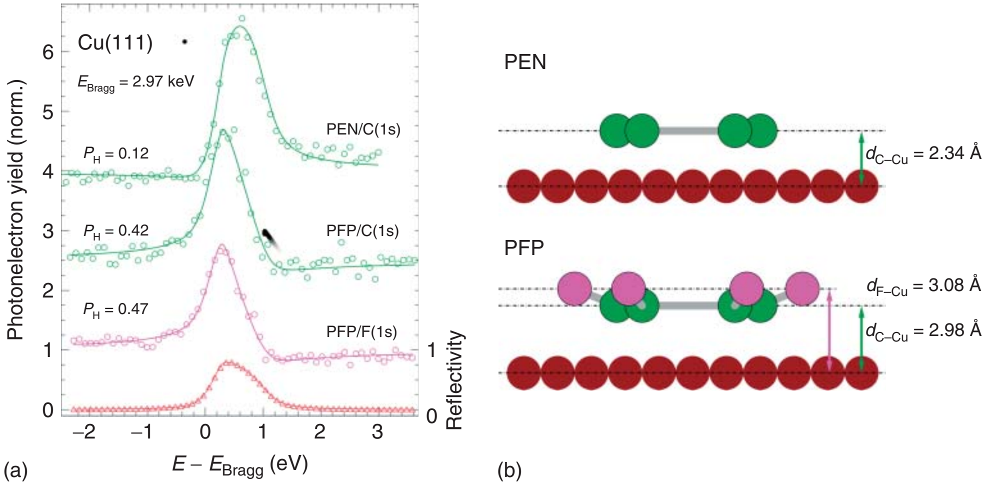

Figure 44.9 (a) X-ray standing wave scans obtained on submonolayers of PEN and PFP on Cu(111). The symbols represent the photoelectron yield (circles) and substrate reflectivity (triangles) data measured for both adsorbate systems. The solid lines show least-square fits based on the dynamical diffraction theory, which provide the coherent position P_H and coherent fraction f_H for each element. The coherent position thus reveals the adsorption distance d_0 of PEN and PFP, whereas the coherent fraction ($0 < f_H < 1$) with $f_H = 0.55$ for PEN/C1s and $f_H = 0.41$ for PFP/C1s and PFP/F1s, is related to disorder in the adsorbate system. (b) Schematic conformation of PEN (top) and PFP (bottom) on Cu(111) derived from XSW measurements, indicating the different average positions of the F and C atoms. (From Ref. [40] with permission.)

with the substrate, the molecules experience a mild distortion upon adsorption, with the fluorine atoms being slightly above the molecular plane at 3.08 ± 0.04 Å. On the basis of the XSW results, the influence of the intramolecular dipole on the charge transfer across the interface has been discussed in detail [40].

44.4.6
Other Systems

Besides these relatively large organic molecules with conjugated π-electron systems, there have been several XSW studies on smaller organic molecules on metal subtrates. For example, F_4TCNQ (tetrafluorotetracyanoquinodimethane) on Cu(111) [41], where a nitrogen bonding distance of 2.7 ± 0.1 Å is found, methanethiol on Pt(111) [42], where a Pt–S bonding distance of 1.67 Å is found, and tetrahydrofuran on Cu(111) [43], where a Cu–O bonding distance of 2.39 Å is found.

Photoelectron Spectroscopy Applications to Materials Science

Maria Benedetta Casu and Thomas Chassé

45.1

Introduction

The interaction of electromagnetic radiation with matter is the basis of several spectroscopies.

Whenever electromagnetic radiation encounters matter, three events may occur: the radiation can be reflected, can propagate through matter, or can be absorbed. In particular, photons and matter interaction generates several phenomena, among others, the photoelectric effect, the Compton scattering, and, in addition, two processes with very small energy transfer: Thomson (elastic) scattering on a “free” electron, that is, the redirection of low-energy photon without change in energy, and the Rayleigh (coherent) scattering that results from a combined (coherent) action of an atom as a whole. In the photoelectric effect, electrons are emitted from matter (metals and nonmetallic solids, liquids, or gases) as a consequence of their absorption of energy from electromagnetic radiation with a frequency greater than a critical threshold frequency. The emitted electrons that may be referred to as *photoelectrons* have kinetic energy E_{kin} determined by the Einstein relationship [1]

$$E_{\mathrm{kin}} = h\nu - E_{\mathrm{b}} \tag{45.1}$$

where $h\nu$ is the energy of the incident radiation and E_{b} the binding energy of the emitted electrons. Equation (45.1) indicates that radiation will be absorbed for incident energies larger than the binding energy of the electrons in the system (Figure 45.1).

Historically, Heinrich Hertz, in the 1880s during his studies on electromagnetic waves, noticed that metals in electrical systems when exposed to light reacted with a spark. In 1899, Joseph John Thomson found that light could be deflected by an electric field. He found that cathodes could emit rays or better “matter” and those emitted particles were lighter than the mass of the lightest atom, hydrogen. He concluded that the rays were composed of very light negatively charged particles, which he called *corpuscles*: he discovered the electrons. Finally, in 1905, Albert Einstein explained the real nature of the photoelectric effect, that is, a transfer of

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

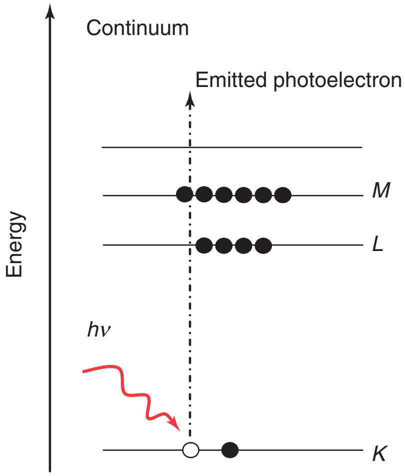

Figure 45.1 Schematic view of the photoelectron effect.

energy between a photon and an electron in an atom, resulting in the emission of the electron itself, with the concepts of quanta, proposed by Max Planck in 1900. Einstein was awarded the Nobel Prize in 1921 for his explanation.

In this chapter, we report some basic concepts that represent the background of the photon electron spectroscopy and its use in investigating surfaces and adsorbates. In doing so, we refer to the classical work of Hüfner [2], Briggs and Seah [3], and Cardona and Ley [4]. Other specific references are also given in the following paragraphs.

Photoelectron Spectroscopy: Basic Principles

Looking at Eq. (45.1), we can immediately derive some basic considerations on the photoelectric effect: there will be an emitted electron only when $h\nu > E_b$, that is, one has to expect that the effect has a threshold defined by the system, as each electron has a different binding energy due to its environment. Thus, for incident photon energy below E_b, no effect is possible. Keeping $h\nu$ as a fixed parameter, the kinetic energy of the emitted photoelectron is higher, the lower its binding energy, and vice versa. If we assume that the electron is emitted from an atom, the photoemission event is not influenced by different isotopes of the same element. This is due to the fact that although isotopes have different numbers of neutrons, they have the same nuclear charge and their difference does not influence the binding energy of the electrons.

How can we define the binding energy of the photoemitted electron?

In principle, E_b is defined as the difference between the energy $E_f(n-1)$ of the $(n-1)$ electron final state and the energy $E_i(n)$ of the n electron initial state:

$$E_b = E_f(n-1) - E_i(n) \tag{45.2}$$

If no rearrangement of the system took place, this difference would be identical to the negative binding energy of the electron in its orbital, ε_k. This approximation (with frozen orbitals) is the basis of the so-called Koopmans' theorem [5]. This energy can be calculated within a Harthree–Fock method. However, during emission of the photoelectron, a core hole is created and the system reacts to shield and minimizes the energy of its ionized state. The energy reduction caused by this rearrangement is called *relaxation energy*. In addition to the relaxation, electron correlation ($\delta\varepsilon_{\mathrm{corr}}$) and relativistic effects ($\delta\varepsilon_{\mathrm{rel}}$) are also neglected by the Koopmans' theorem. Consequently, in general, E_{b} is given by

$$E_{\mathrm{b}} = -\varepsilon_k - E_{\mathrm{r}}(k) - \delta\varepsilon_{\mathrm{corr}} - \delta\varepsilon_{\mathrm{rel}} \tag{45.3}$$

It is worth mentioning that the correlation and the relativistic corrections are very small and this is the reason why they can be neglected.

As mentioned in the introduction, the photoemission process has to be described with a quantum mechanical approach. On the other hand, a semiclassical model, the three-step model [6], gives the opportunity to interpret the photoemission events in a simpler but effective way.

In the three-step model, the photoemission process is broken up into three sequential steps: the optical excitation of the electron inside the bulk, the diffusion of the electron to the surface, and its transmission through the surface into the vacuum. Only those electrons that have enough kinetic energy along the direction normal to the surface are able to overcome the surface potential barrier and to escape. The remaining electrons are totally reflected, back to the bulk.

Depending on the photon energy, it is usual to distinguish between two measurement regimes: ultraviolet photoelectron spectroscopy (UPS) when $h\nu$ is lower than 100 eV and X-ray photoelectron spectroscopy (XPS) for values above 100 eV. X-rays have enough energy to ionize atoms by emission from both valence electrons and core electrons, while UPS gives detailed information on electrons coming from the valence band.

In the UPS regime, the photon momentum p is related to the photon frequency ν via the relationship $p = \hbar k$ with wave vector $\mathbf{k}$. In UPS, p is negligible and the photoexcited electrons have the same momentum in the initial and in the final state; it means that direct transitions occur. UPS spectra show energy and intensity variations depending on the incident energy, and this gives the opportunity to map out the energy band structure of well-ordered materials.

45.2.1
UPS Regime

As mentioned, the kinetic energy of the emitted electrons is given by Einstein's relationship (Eq. (45.1)). In a metal, the maximum kinetic energy, $E_{\mathrm{kin}}^{\mathrm{max}}$, that one electron escaping from the emitter can have is

$$E_{\mathrm{kin}}^{\mathrm{max}} = h\nu - \Phi_{\mathrm{m}} \tag{45.4}$$

where Φ_{m} is the work function of the metal (Figure 45.2).

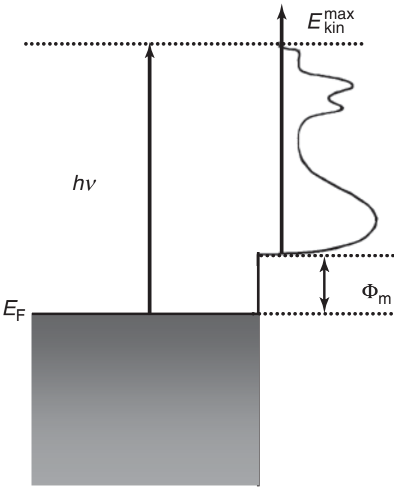

Figure 45.2 Photoemission from a metal.

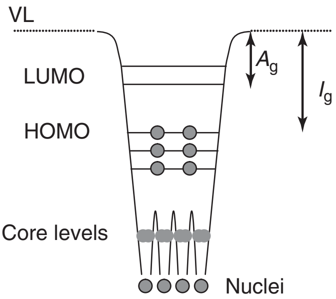

Figure 45.3 Potential well of a polyatomic molecule.

In a polyatomic molecule, the effective potential well seen by an electron is formed by the atomic nuclei and the other electrons. The deep atomic orbitals are still localized in the atomic potential well but the upper ones interact, forming delocalized molecular orbitals (MOs). The edge of the potential well is the vacuum level, VL, above which the electron can escape from the molecule or the chain. In a molecule, the separation from the highest occupied molecular orbital (HOMO) to the VL is the gas-phase ionization potential, I_g, and between the lowest unoccupied molecular orbital (LUMO) and the VL is the electron affinity, A_g (Figure 45.3). Thus, by using UPS, it is possible to determine the ionization potential of a molecule, analogously to the work function in the case of a metal.

UPS gives valuable information when investigating semiconductors also. For example, the ionization potential, I_P, and the electron affinity, E_A, of an organic semiconductor are still defined as in a molecule, but their values are different because (i) of the solid state effects, (ii) of the crystalline periodic potential, if the organic semiconductor is well ordered, and (iii) of the overlapping of the wave functions [7].

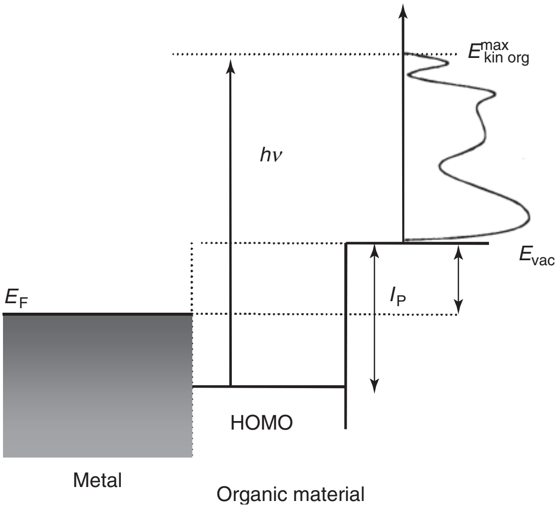

Figure 45.4 UPS at the interface organic/metal: $h\nu$, incident photon energy; E_F, Fermi level of the metal; I_P, ionization potential; HOMO, highest occupied molecular orbital; $E^{max}_{kin\ org}$, maximum kinetic energy of the photoelectron emitted from the organic material; and E_{vac}, VL of the organic layer.

Keeping this picture in mind, the photoelectrons of an organic adsorbate deposited on a metal surface come from the organic layer. The photoelectrons with highest kinetic energy, $E^{max}_{kin\ org}$, originate from the HOMO (Eq. (45.4)). Consequently, it is possible to obtain the ionization potential, I_P, of the organic layer as

$$I_P = h\nu - E^{max}_{kin\ org} \tag{45.5}$$

Several other physical parameters can be obtained from the UPS spectra such as the alignment of the HOMO of the organic layer with respect to the Fermi level, E_F, of the metal; the VL energy shift of the organic layer at the interface metal/organic with respect to the VL of the metal; and also the energy, ε^F_{vac}, of the VL of the organic layer relative to the E_F [8] (Figure 45.4 and Figure 45.5).

This means that UPS is a very powerful technique to study the interfacial electronic structure and the energy alignment at the organic/metal and organic/organic interfaces [9, 10].

A further interesting aspect of UPS that we like to mention in this chapter is the fact that UPS spectra are strongly dependent on energy dispersion of valence and conduction states and they give direct information about the resulting 2D band structure of surface states, the 2D band structure of adsorbates, as well as bulk band structure. In particular, when a well-ordered system is investigated with this technique, the spectra are very sensitive to the variation of the incident energy and to the variation of the angle of incidence, α, the takeoff angle, θ, and the azimuth angle, φ (Figure 45.6). Therefore, angle-resolved

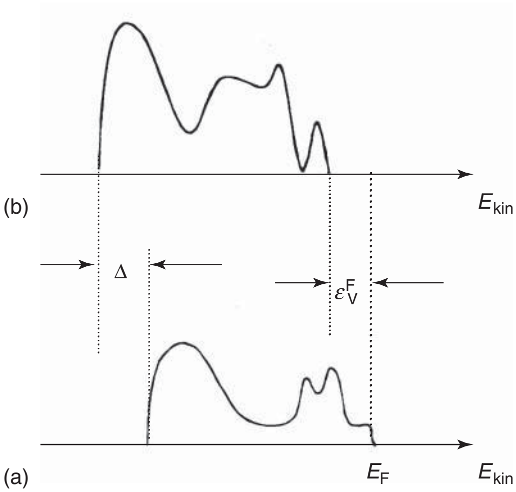

Figure 45.5 Comparison between the UPS spectra (a) from a metal and (b) from the deposited organic material. The abscissa is the kinetic energy of the emitted photoelectrons; the origin is fixed in an arbitrary point. E_F is the metal Fermi energy, Δ is the vacuum level shift at the interface, and ε_V^F is the energy alignment of the HOMO relative to E_F.

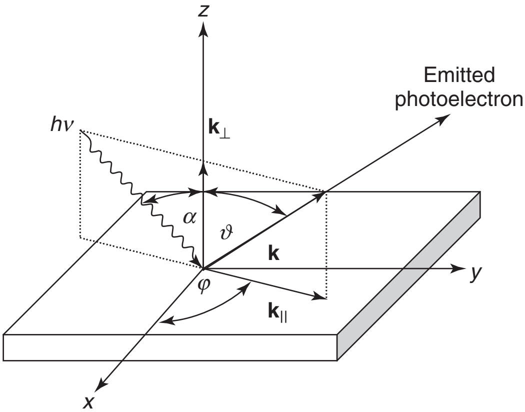

Figure 45.6 Geometry of an UPS experiment: α, angle of incidence; θ, takeoff angle; φ, azimuth angle; $h\nu$, incident photon energy; $\mathbf{k}$, wave vector of the emitted photoelectrons; and $\mathbf{k}_\perp$ and $\mathbf{k}_{||}$ are the components of $\mathbf{k}$, perpendicular and parallel, respectively, to the surface of the sample.

ultraviolet photoelectron spectroscopy (ARUPS) allows determining the energy band dispersion relation $E(\mathbf{k})$ between the energy E and the wave vector $\mathbf{k}$ of the photoelectrons [11].

To obtain the $\mathbf{k}$-resolved band structure, the peaks from the recorded spectra are related to $\mathbf{k}$-conserving transitions from occupied (E_{in}) to unoccupied bands (E_{fin})

of the material, satisfying the equation

$$E_{\text{fin}} = E_{\text{in}} \pm h\nu \tag{45.6}$$

in which direct transitions are assumed.

The measured quantity is the kinetic energy of the photoelectrons, E_{kin}, detected for a given energy and fixed angles α, θ, and ϕ, relatively to the substrate normal of the sample:

$$E_{\text{fin}} = E_{\text{kin}} + \Phi \tag{45.7}$$

where Φ is the work function of the system.

The kinetic energy and the momentum of the electron in the vacuum are related according to

$$E_{\text{kin}} = \frac{\hbar^2}{2m_{\text{e}}}(\mathbf{k}_{\perp}^2 + \mathbf{k}_{||}^2) \tag{45.8}$$

where $\mathbf{k}_{\perp}$ and $\mathbf{k}_{||}$ are the components of the momentum of the electron, perpendicular and parallel, respectively, to the surface.

In a photoemission process, only the component of the wave vector parallel to the surface is conserved because the translation symmetry is broken by the surface; therefore, this component will be given by the following equation:

$$\mathbf{k}_{||} = \left(\frac{2m_{\text{e}}}{\hbar^2}E_{\text{kin}}\right)^{1/2} \sin\theta \tag{45.9}$$

To determine $\mathbf{k}_{\perp}$ the free-electron model has been widely used [11–13]. In this model, the dispersion relation of the final state is assumed to be

$$E_{\text{fin}} = \frac{\hbar^2}{2m_{\text{e}}}(\mathbf{k} + \mathbf{G})^2 + E_0 \tag{45.10}$$

where $\mathbf{G}$ is a reciprocal lattice vector, $E_{\text{v}} - E_0$ is the inner potential, $V_0 = E_{\text{v}} - E_0 = |E_0| + \Phi$, that is, the potential well depth where the energies are measured with respect to the Fermi level.

In normal emission $\mathbf{k}_{||} = 0$, therefore, the momentum normal to the surface is given by

$$\mathbf{k}_{\perp}^2 = \frac{2m_{\text{e}}}{\hbar^2}(E_{\text{inc}} - E_{\text{b}} + V_0) \tag{45.11}$$

By means of Eqs. (45.9) and (45.11), it is possible to map out the complete band structure of materials.

Already in the 1990s, ARUPS was used to investigate the electronic structure and the energy dispersion of surface states [11], as well as bonding of adsorbed hydrocarbons, the orientation and symmetry of the adsorbate on the surface, the influence of lateral interactions, and the formation of two-dimensional adsorbate band structures. Several examples of energy band structure of simple hydrocarbon molecules such as benzene, ethylene, and acetylene deposited, for example, on Ni(110), Ni(111), Ru(001), and the reconstructed Pt(110)1 × 2 surface have been experimentally determined by Steinrück [14]. Ueno *et al.* [13] also investigated a variety of

adsorbates determining, among others, the valence-band energy dispersion of thin films of pentatriacontan-18-one [$CH_3(CH_2)_{16}CO(CH_2)CH_3$] on copper, comparing the results with theoretical calculations.

A recent application of the potential of ARUPS in band mapping is represented by graphene. Graphene is a strictly two-dimensional material that exhibits exceptionally high crystal and electronic quality, and has already revealed a world of new properties and potential applications [15]. It is a one-atom-thick planar sheet of sp^2-bonded carbon atoms that are packed in a honeycomb crystal lattice. Graphene can be recognized as the mother of all graphitic forms. From the theoretical point of view, most of its electronic properties were well known since 1947, when a calculation of the graphene band structure was performed on the basis of tight banding approximation [16]. This calculation already showed the dynamics of the electrons in such a single, one-atom-thick sheet of carbon atoms. However, there was no experimental evidence that 2D systems could ever exist as self-standing crystals, as it was believed that strictly 2D crystals were thermodynamically unstable: the nascent 2D crystallites would try to minimize their surface energy and morph into 3D structures. In graphene, the thermodynamic stability is reached by gentle crumpling in 3D. In 2004, Novoselov *et al.* [17] were able, by using a peeling technique, with adhesive tape to isolate a single layer of graphene. This was the fundamental step that allowed to prove all characteristics of this fascinating material, and that also led to Geim and Novoselov winning the Nobel Prize in Physics in 2010 [18]. This discovery literally propelled the curiosity of the scientists on graphene including the possibility of experimentally determining its band structure. This result was achieved in 2008 by Emtsev *et al.* [19] using ARUPS (Figure 45.7). Their experiment clearly shows the unusual band structure of a graphene single layer with its linear dispersion close to the Dirac points, without band gap, due to the fact that electrons in graphene behave as massless Dirac fermions [15–17, 19].

45.2.2
XPS Regime

As previously discussed, the binding energy of the emitted photoelectrons depends on the final and on the initial states. The effects of both natures are visible in the XPS spectra and they will be described in the following, starting with the initial state effects.

XPS spectra are characterized by high-intensity features that belong to core-level photoemission effects. Figure 45.8a shows the survey spectrum, that is, a wide scan, of a monolayer of hexadecanethiol (HDT). Alkanethiols are well known to form self-assembling monolayers (SAMs) on substrates such as gold, silver, and copper because of the strong affinity that the sulfur atoms show for these metals. They are molecules with an alkyl chain, $(\mathrm{C{-}C})_n$ chain, as the backbone, a tail group, and an S–H head group. They are extensively investigated because of their possible applications in optoelectronics and sensors [20]. In this case, HDT has been deposited on a semiconductor surface, that is, indium phosphide [21]. The spectrum has been excited by using Al Kα radiation ($h\nu = 1486.6\,\mathrm{eV}$). Several peaks may be attributed to either the In or P atoms of the substrate, and carbon and sulfur peaks of the film are also recognizable, in chemical agreement with the substrate + adsorbate system. It is clearly visible how the main lines have their binding energy position exactly where it has to be expected because of their element specificity. The peak assignment can be performed by using the tables of electron-binding energies for the elements in their natural form [22] or in a particular bond [23]. Thus, one can identify the main lines due to In 3s, In 3p, In 3d, In 4d, and P 2s and P 2p, which are contributions coming from the substrate, and the lines due to C 1s and S 2p due to the adsorbate. Looking at the survey spectrum at the energy positions of the main XPS lines, their binding energy represents the strength of the interaction between the electron and the atomic nucleus; consequently, they

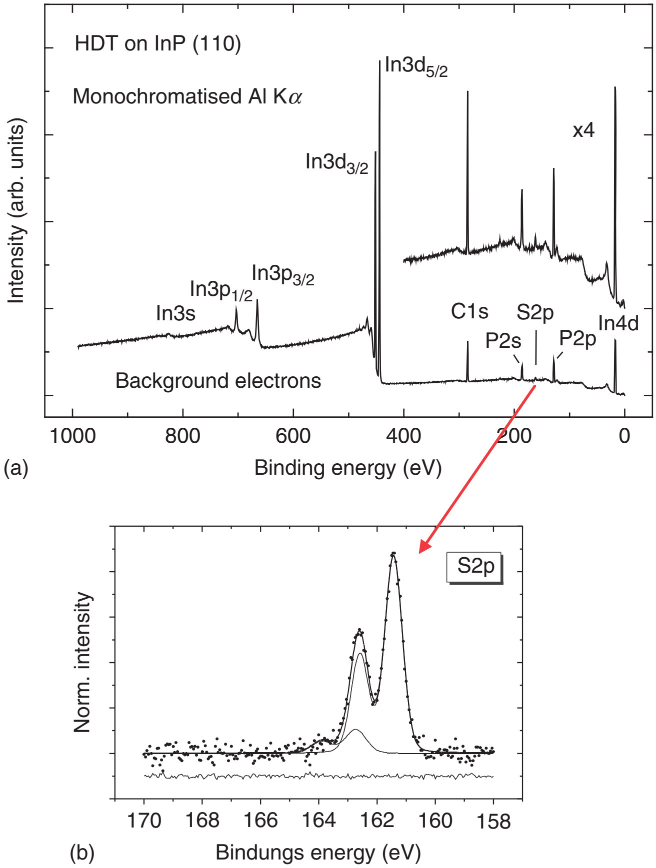

Figure 45.8 Hexadecanethiol (HDT) on InP (110). (a) Survey spectrum. (b) S 2p highly resolved core-level photoemission spectra.

follow the energy of the orbital and, for example, the binding energy of the 3s states is higher than the binding energy of the 3p states. In addition, the binding energy increases with the atomic number Z (i.e., the number of protons found in the nucleus of an atom and therefore identical to the charge number of the nucleus); thus, the main line assigned to 3s, 3p, 3d states of the In atoms have higher energy than the relative binding energies of the 2s and 2p core levels in P atoms.

Further examining the spectrum in Figure 45.8a, another relevant aspect of XPS spectra is visible: the background. The background has a typical step shape with higher intensity for higher binding energies (left of the main peak). This is due to the inelastic scattering processes that are caused by electrons that have lost a part of their energy because of inelastic collisions in the solid, but they have still enough energy to escape the surface. Continuous values of the energy are possible from zero kinetic energy to the photoemission peak for a given kinetic energy because the collision events have energies that are continuous themselves.

A survey spectrum is very useful to immediately characterize a system, to check whether extraneous atoms, due to unexpected chemical species, for example, are present. Figure 45.8a does not evidence any impurity, leading to the conclusion that the HDT monolayer is contamination-free.

However, additional information can be obtained from highly resolved spectra. Figure 45.8b shows the highly resolved S 2p core-level photoemission spectrum. The feature that seemed to be unique in the survey spectrum in Figure 45.8a in reality shows a more complex structure. This effect is again an initial state effect and it is due to the spin–orbit splitting, that is, the interaction of the electron spin with its momentum [24]. The 1s orbitals do not show any spin–orbit splitting and, in general, they appear as a singlet in XPS.

The electronic cloud around an atom is sensitively influenced by the electronegativity of the neighbor atoms. This is mirrored in the XPS spectra that show a difference, a shift toward higher energies, known as *chemical shift*, in the binding energy of the emitted photoelectrons involved in the bond between a more electronegative atom and a core electropositive atom, for example, in the case of functional groups and oxidation states. This effect is visible in XPS spectra of complex anions, alkali, alkaline earth compounds [25], and metal oxides. A case system is the Ti 2p core-level spectrum for metallic Ti and for TiO_2 [23]. The binding energy for Ti $2p_{1/2}$ and $2p_{3/2}$ are 460 and 454 eV, respectively. Owing to the presence of oxygen, which withdraws the electrons, titanium assumes an oxidation state 4+; consequently, the Ti 2p relaxes to higher binding energies, that is, 464.3 and 458.8 eV, respectively [23].

Till now, we have examined only initial state effects, but, as mentioned, XPS spectra show also features that are due to final state effects. Here, we briefly analyze these aspects. According to the Koopmans' theorem, we should expect the main lines having their binding energies exactly as if the electrons were in a system as the nonexcited one, but with one electron less (frozen orbital approximation). However, we cannot observe this state of the system because the system immediately reacts, screening the core hole. The binding energy is shifted toward the higher energy range. Analogously, we cannot observe the system in a fully relaxed state, that is, in the ground state of the ionized system because the photoemission event is faster than the full relaxation. Thus, we observe a series of complementary features at higher binding energies in the spectra, which depend on various excited states of the systems: (i) excitations of electron to bound state (shake-up satellite), (ii) excitations of electron to unbound (continuum) states (shake-off satellite), and (iii) excitations of hole states (shake-down satellite).

A particular final state effect is visible in spectra of metallic systems. It is well known how electrons in a metal behave as a Fermi gas, owing to the properties of the metallic bond and the strong delocalization of the electrons in metals [24]. The collective oscillations of the free-electron gas give rise to plasmons, that is, to quanta of a plasma oscillation. Plasmons, for example, are clearly visible not only in the XPS spectra of simple metals such as Na and Mg [2, 26, 27] and Al but also in semiconductors.

45.3
Photoemission Measurements and Data Analysis

Surface analysis of solid samples using electron spectroscopies are typically performed in ultrahigh vacuum (UHV) conditions at base pressures of about 10^{-10} mbar. Because of the very strong interaction cross sections of the electrons with matter, any interactions of the emitted electrons with molecules from the residual gas need to be avoided on their path from the samples toward the detecting unit, in order to record sufficiently intense electron spectra. In addition, both the photon sources (X-ray tubes or UV (ultraviolet) lamps) and electron detectors require better than high vacuum conditions to operate properly for long times. Further, an estimate using kinetic gas theory gives easily that even at 10^{-6} mbar within 1–3 s, about one monolayer is adsorbed from the residual gas due to the huge number of hits from the gas phase to the surface, provided any hit results in an adsorbate atom/molecule. But any recontamination of carefully prepared samples by hits from residual gas molecules needs to be carefully avoided during measurements, as will happen in time if the partial pressures are not sufficiently low enough. Therefore, dedicated stainless steel chamber systems equipped with two-or three-level pumping systems and, of course, adequate handling of the systems is strictly required.

As outlined in the previous chapters, during a photoemission experiment the photoelectrons coming from a sample, due to the excitation with an appropriate incident radiation, are collected. We can divide the required setup for a photoemission experiment into two blocks: source, and measuring chamber with analyzer and sample.

UPS measuring units are usually equipped with standard UV light sources such as He discharge lamps (He I = 21.2 eV and He II = 40.8 eV).

X-ray laboratory sources are obtained by focusing a beam of high-energy electrons (usually with energy above 10 keV) onto a target. In this way, core holes are created in the target (anode) that emits fluorescence X-rays. They represent the source of the radiation for the experiment. Several materials are used as an anode: Mg, Al, Si, Zr, Ag, Ti, and Cr. Their characteristic energies are given in Table 45.1. As a specific line is used because of the order of magnitude of its intensity (in principle, the background emission could also be used), each anode provides its

Table 45.1 Most common X-ray lines with their relative energy and line width.

Line	Energy (eV)	Line width (eV)
Na Kα	1041.0	0.70
Mg Kα	1253.6	0.70
Al Kα	1486.6	0.85
Zr Lα	2042.4	1.7
Ti Kα	4510.0	2.0
Cu Kα	8048.0	2.6

own fixed energy for the X-rays. The most used anode materials are Mg and Al, very often also in combination in the same setup. However, the obtained emission is not perfectly monochromatic; also, satellite background emission, high-energy electrons, Bremsstrahlung, and heat will reach the sample (the electron energy is mostly converted into heat; this is the reason a water cooling system is required for the X-ray source). Thus, an X-ray transparent window (usually Al for Mg and Al anodes) is placed in front of the X-ray source. A further optimization procedure is the use of a monochromator. This is very often found in combination with an Al anode and it is based on quartz crystals. The con of this system is the obvious reduction in the intensity that can be compensated for by using efficient detection methods.

We like to mention that in recent years a considerable improvement on the photoemission experiment came from the use of synchrotron radiation. Synchrotron light is intense, bright, and polarized. It covers a very broad spectral range if the emission is produced with a bending magnet; on the other hand, the emission from periodic arrays of magnets inserted in the linear parts of the electron storage rings occurs over a very narrow and tunable spectral band. Using an appropriate monochromator, the desired spectral range can be selected for the experiment. Because of all these important characteristics, a synchrotron source is, in principle, an ideal photon emitter [28]. The measuring line, or more commonly in a synchrotron, the so-called beamline, is of course structurally determined by the source. The main identifying part, which very often also gives the name to the beamline, is the monochromator, with gratings or crystals. It is used to select a narrow spectral bandwidth from the continuum of the radiation coming from the synchrotron ring, to modulate the flux, to scan the incident energy, and sometimes to focus the beam on the sample. More often, mirrors properly chosen and placed fulfill this task. In a synchrotron as well as in a beamline, the UHV is necessary to let the particles move at relativistic speed in the accelerator. The development of the modern electron storage rings (from third generation on) has had a real impact and importance in photoelectron spectroscopy. We do not further address this topic and we suggest that the readers refer to the existent literature [29, 30].

The analyzer usually has three sections: an electronic lens, a dispersive part, and a detector (usually a channeltron: channeltron is the trade name of one of the most commonly sold multipliers) (Figure 45.9). Its energy resolution depends on their geometry. The lens has to collect the emitted photoelectrons: this can be done by choosing the angular resolution, the spatial resolution, or maximizing the number of collected electrons; for example, it is possible to switch between detection from large or small areas as well as large or small acceptance angles. The dispersive part analyzes the electrons depending on their kinetic energy. It consists of two cylindrical or hemispherical deflection plates, kept at a certain voltage, that determine the energy of the electrons pulled into the electron multiplier. Electron spectra are preferably measured using constant analyzer pass energy of the electrons, which results in a constant energy resolution but an energy-dependent transmission. An electron multiplier is a vacuum-tube structure that

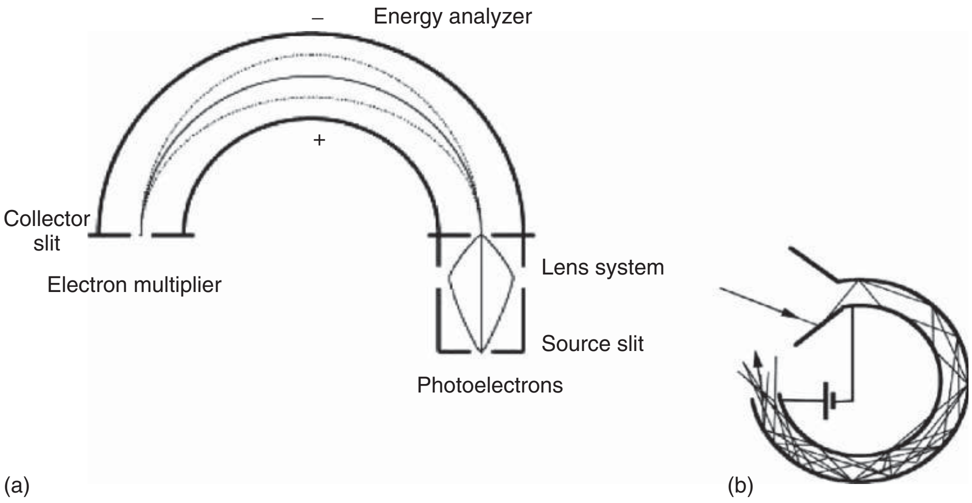

Figure 45.9 A schematic view of (a) an analyzer and (b) a multiplier.

multiplies incident charges, by using secondary emission. Electron bombarding a metal can induce the emission of a few electrons (1–3). Applying a potential between this metal and a second plate accelerates the emitted electrons to the next metal plate and induces secondary emission of further more electrons. This can be done as many times as necessary to amplify the signal, resulting in an avalanche of electrons collected by an anode. The electrons are detected by stacks of channeltron-type electron multipliers (typically 5–9) or position-sensitive channel plate detectors.

Here, we like to mention the surface sensitivity of photoelectron spectroscopy. Surface sensitivity in a technique is given by the relationship between kinetic energy of the photoemitted electrons and their inelastic mean free path (IMFP). The *IMFP* is defined as the average distance traveled by an electron between inelastic collisions. It depends on the kinetic energy according to a general behavior that is similar for all materials, the so-called universal curve [22]. The surface sensitivity is determined by the depth perpendicular to the surface from which the electrons escape, which is proportional to the IMFP via the cosines of the emission angle of the electrons relative to the surface normal. Thus, the surface sensitivity of an experiment can be accordingly varied: the IMFP has a minimum at around 50 eV, corresponding to a few Angstrom. For kinetic energies up to 2000 eV, its value is 70 Å large [22]. Thus, for example, in synchrotron, XPS experiments with different surface sensitivity can be carried on, taking advantage of the tuning of incident photon energy [31].

Another useful concept related with the surface sensitivity is the information depth. The information depth is the maximum depth, in the direction normal to the surface, from which the information is obtained. The number of emitted electrons trough matter with no energy loss decreases obeying the Lambert-Beer:

$$I = I_0 \exp(-d/\lambda \cos\theta) \tag{45.12}$$

where I and I_0 is the intensity of the emitted photoelectrons at d and $d = 0$ (i.e., the surface), λ the inelastic mean free path, and θ the angle between the normal to the surface, and the emitted photoelectrons. From simple numerical consideration, Equation (45.12) leads to the fact that 95% of the electrons comes from $d = 3\lambda$. This is the informatiom depth at which 95% of the electrons is emitted.

In a photoemission experiment, samples have also to fulfill important requirements: in particular, they must be conductive to avoid charging effects. The charging effects lead to artifacts in the spectra such as shift in the energy of the features, distorted peaks, and new peaks. However, insulators can also be investigated by photoelectron spectroscopy, provided that the positive charges are neutralized, for example, with an electron gun or with an electric field.

In addition, to measure the kinetic energy/binding energy of the photoemitted electrons, the sample is put in electrical contact with the spectrometer and grounded. This means that the Fermi edge of the two systems, sample, and spectrometer are aligned. To measure the binding energy, it is now necessary to overcome the work function of the spectrometer. It is possible to take Einstein relationship (Eq. (45.1)) into account, modified as follows:

$$E_B^F = h\nu - E_{kin} - \Phi_{sp} \tag{45.13}$$

where E_B^F indicates that the binding energy is referred to as the *Fermi level*, and Φ_{sp} is the work function of the spectrometer. This implies the necessity to determine this parameter. This can be done using a known sample with well-defined main lines, for example, gold or silver, and modulating the spectrometer settings in order to exactly match their binding energy. Once the spectrometer is calibrated, in principle, the calibration can be taken as fixed. However, changes in the UHV level, use of gases, and various preparations can change its work function; thus, a systematic calibration and check are a good laboratory practice.

Very often, in UPS, it is necessary to measure the work function of the sample, for example, to determine the energy-level alignment between a metal substrate and an organic adsorbate (Figure 45.5). This can be done by negatively biasing the samples with respect to the analyzer. This raises the energy levels and it overpasses the work function of the analyzer because the bias voltage adds to the photoelectron kinetic energy relatively to the analyzer itself, giving the opportunity to clearly measure the secondary electron cutoff. The work function is consequently determined by the excitation energy minus the width of the photoelectron spectrum.

Data analysis represents a very important issue, in XPS as well as in UPS. In both cases, information on occupied states (core levels and valence states, respectively) can be obtained by comparing experiments with calculations. This is a standard procedure that has been extensively applied, for example, to organic materials, when the first UPS investigations of this class of materials were performed. The first approach has been to use single-molecule calculations and compare the data of the simulated spectra with the experiments. Very little was known at that time about small molecules and polymer thin films; thus, this was certainly a successful method to gain as much information as possible on the new systems [32]. Nowadays, the necessity of model calculations that take into account intermolecular interactions, solid-state interactions, and a periodic potential have brought new challenges that have still to be completely addressed by theoreticians in this fields, in contrast to band structure calculation and optical absorption where brilliant results have been already obtained [33].

From a quantification point of view, XPS can provide information on the stoichiometry of the investigated films as well as on the atomic density of the elements on which the system is based. The area of the main lines, together with their relative satellites for a given element, is proportional to the percentage of the same element in the chemical formula of the investigated system. In highly resolved XPS spectra, the rich fine structure allows fitting the lines including contributions for different atomic sites of the same element that, owing to a different chemical environment, are expected to show differences in their binding energies [34, 35].

The fitting curves can be described with a Voigt profile, that is, a convolution of a Gaussian and a Lorenzian profile. This is due to the fact that different contributions influence the line shape of the XPS main features: intrinsic lifetime broadening leads to a Lorenzian profile, while experimental contributions and various inhomogenieties have a Gaussian profile. The lifetime of the core hole is determined basically by the Heisenberg uncertainty principle and consequently the intrinsic peak width. For example, the Lorenzian width for the C 1s orbital is around 80 meV, and for the O 1s orbital it is around 100 meV in organic materials [35]. The setup gives a contribution assumed to have a Gaussian lineshape due to the resolution of the analyzer, the not perfect monochromaticity of the X-ray, and inhomogeneities of different nature.

A background subtraction must be also taken into account before performing an appropriate fit procedure of the XPS curves. The most used method was developed by Shirley [36] in 1972. This method considers the background due to inelastically scattered electrons, it is assumed to arise only from the scattering of electrons of higher kinetic energy and it is proportional to the integrated photoelectron intensity of the higher kinetic energy. Later, Tougaard [37] described the transport of electrons after excitation with equations based on a convolution of the recorded data with an energy-loss probability distribution. Each material has its own characteristic loss function [38].

Regarding the atomic density, we can observe that the intensity of the signal for a given photon energy is proportional to the photon flux Φ_0, the photoionization cross section σ, the number of photoemitting atoms n, the transmission of the spectrometer T, and the detection efficiency A, according to the following formula

$$I(h\nu, E) = \Phi_0 \cdot \sigma(h\nu) \cdot n \cdot A \cdot \lambda(E) \cdot T(E) \tag{45.14}$$

where λ is the IMFP. The photoionization cross section, σ, represents the probability of the ionization of a subshell. It measures the ‘‘overlap’’ of the initial and the final state wavefunctions [22].

Adopting a ratio procedure, for example, for two elements 1 and 2, as following:

$$\frac{I_1}{I_2} = \frac{n_1 \cdot \sigma_1 \lambda_1 \cdot T_1}{n_2 \cdot \sigma_2 \lambda_2 \cdot T_2} \tag{45.15}$$

it is possible to determine the atom fraction for a certain element:

$$\frac{n_1}{n_2} = \frac{I_1/S_1}{I_2/S_2} \tag{45.16}$$

according to Eq. (45.16), and generalizing:

$$x_1 = \frac{n_1}{\sum_i n_i} \tag{45.17}$$

where S is the atomic density factor defined as $S_i = \sigma_i \lambda_i T_i$.

The differential ionization cross section, $\mathrm{d}\sigma/\mathrm{d}\Omega$, for isolated atoms using nonpolarized photons is given in the traditional dipole approximation as

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega} = \frac{\sigma}{4\pi}\left[1 - \frac{\beta}{4}\left(3\cos^2\theta - 1\right)\right] \tag{45.18}$$

where β is the asymmetry parameter, σ is the total photoionization cross section for a given subshell, θ is the angle between the photon and photoelectron propagation directions, and $\mathrm{d}\Omega$ is an element of the solid angle [39, 40]. More recent studies include quadrupole terms and these lead to a significantly different angular distribution [39].

The above-mentioned formalism is derived under the assumption that the photoelectron trajectories are linear from the depth of emission to the surface. In reality, photoelectrons may undergo elastic interactions with atoms of the solid and, as a result, the photoelectron trajectories are generally nonlinear and this formalism is not adequate anymore.

The effects of elastic scattering of the signal electrons in XPS can be accounted for by the introduction of two correction parameters, Q_x and β_{eff} [40], into the equation commonly used for quantitative analyses of homogeneous materials. Two formulae describe each parameter. One of these formulae is a function of the single-scattering albedo and the photoelectron emission angle, and is useful for emission angles between 0° and 80°. The other simpler formula is a function only of the single-scattering albedo and is useful for emission angles between 0°and 50° [40]. Hence, angle-resolved XPS reveals to be a nondestructive method for the determination of simple concentration depth profiles in perfectly flat surfaces [41].

Observing Eqs. (45.15–45.17), the necessity to know the value of λ for individual material in order to address a quantitative analysis of the XPS spectra is clear. The algorithm proposed by Tanuma, Powell, and Penn (TPP) have been applied to many solids, including organic and inorganic materials as well as elements. In particular, they also developed the so-called TPP-2M [42–47] equation to determine the IMFP according to the Bethe equation:

$$\lambda(\text{Å}) = \frac{E}{E_{\mathrm{p}}^2[\beta \ln(\gamma E) - CE^{-1} + DE^{-2}]}(\text{Å}) \tag{45.19}$$

$$E_p(\text{eV}) = 28.8\left(\frac{N_v\rho}{M}\right)^{1/2}(\text{eV}) \tag{45.20}$$

where E_p is the free-electron plasmon energy, N_v the number of valence electrons per atom/molecule, ρ the density, and M the atomic/molecular weight. The values of the parameters β, γ, C, and D have been determined for many materials [42–47]. By comparison with values of the IMFP experimentally obtained, it has been demonstrated that the TPP-2M equation constitutes a useful predictive equation for estimating λ in materials [48].

Seah [3] also contributed in a substantial way to address this aspect of quantification in XPS, developing, in addition, also the necessary equations to determine the thickness of adsorbates using the XPS signal.

45.4
Applications

In the following, we report some photoelectron experiments from the existing literature in order to show the potential of this technique, and how it can be used to answer questions ranging from basic research to solve problems also relevant in technology.

45.4.1
Ultraviolet Photoelectron Spectroscopy: Basic Research and Its Relevance in Technology

Already at the beginning of the 1940s, it was clear that the work function depends on the different crystallographic faces of the crystals of the same element [49]. The difference in values ranges from a few tenths of a volt to 1 V [49]. For example, for gold the calculated work function is 6.01, 6.16, and 5.40 eV, for the fcc (face-centered cubic) crystallographic directions (111), (100), and (110), respectively [50]. Analogously, it has recently been shown that thin films of well-organized molecules are also characterized by different ionization potentials depending on the different molecular orientation that the molecules themselves may assume in the film [51].

Figure 45.10 shows the experimental and the theoretical photoelectron spectra of α,ω-dihexyl-sexithiophene (DH6T). DH6T is a small organic molecule used in organic electronics; thus, it is important to know in a very accurate way its ionization potential in thin films because of device engineering. The figure indicates a shift of the binding energy of the molecular levels comparing a lying monolayer, and a second standing layer. Duhm *et al.* [51] have shown that the difference of 0.6 eV is due to a difference in the ionization potential in the two cases. By using photoelectron spectroscopy combined with density functional theory (DFT) calculations, they have demonstrated that the ionization potential changes are linked to the existence of a surface dipole built into the molecular layers, due to details of the molecular electronic structure. In particular, its magnitude depends on the orientation of molecules relative to the surface of an ordered assembly.

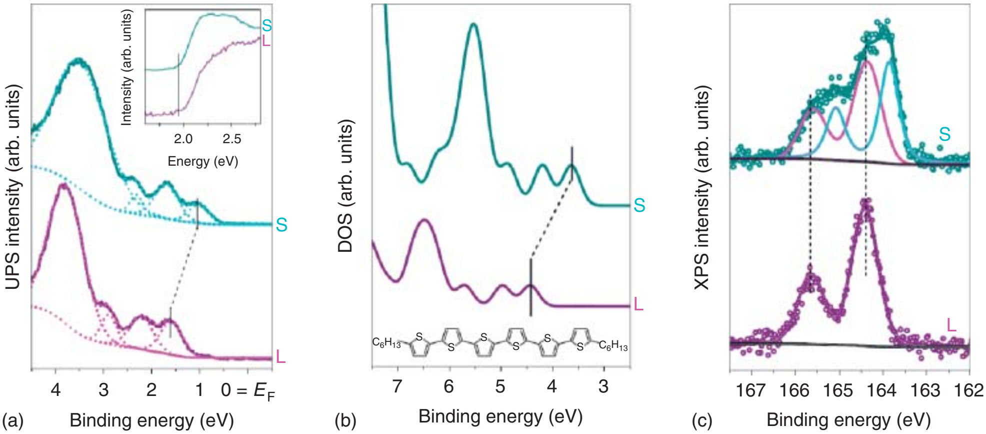

Figure 45.10 (a) Photoemission spectra of DH6T on Ag(111). Experimental UPS spectra of 4 Å of DH6T (purple), and 40 Å of DH6T (cyan). The dotted lines are a fit. The inset shows the secondary-electron cutoffs. (b) Density functional theory calculation of the density of states of a single layer of lying (purple) and standing (cyan) DH6T molecules. The inset shows the chemical structure of DH6T. (c) Experimental XPS S 2p spectra for 4 Å (purple), and 30 Å (cyan) of DH6T. L indicates a lying monolayer, and S a second standing layer. (Reprinted with permission from Macmillan Publishers Ltd [51] copyright 2008.)

As molecular orientation in organic thin films is influenced not only by the molecule–substrate interaction but also by several parameters such as preparation conditions [52, 53], topography [54], and morphology of the substrate [55, 56], including patterning [57], it is possible to design films with a certain molecular orientation to obtain the desired level of alignment to achieve the necessary optimization of working devices.

45.4.2
XPS as a Tool to Investigate Buried Interfaces

Organic small molecules have been extensively investigated in recent years because of the fascinating opportunities related to their use in electronics, ranging from flexible, stretchable displays to transparent ones, via new lighting concepts, where lamp structures or walls are the light-emitting objects themselves. As briefly mentioned earlier, to use the molecules in a device, it is necessary to deposit molecules onto a substrate. The orientation of the molecules must be known to determine the electronic properties at the interface, and consequently the device performances.

The family of phthalocyanines (Pcs) is one of the most promising candidates for a variety of applications [58–60] owing to their electronic and optical properties and their variability in functional group substitution. Anisotropic electrical transport properties are often observed in these materials, caused by the preferred molecular orientation [61–63]. A very high degree of orientation in evaporated films was observed on several substrates [64–68], even on relatively ill-defined technically relevant substrates [69].

Biswas *et al.* [70], by using near-edge X-ray absorption fine structure (NEXAFS), investigated copper phthalocyanines (CuPcs) deposited on gold foil. They found lying CuPc molecules in the first layer on top of the polycrystalline gold substrate. However, the NEXAFS dichroism was not evident for thicker films. This can be interpreted either as a rearrangement of the molecules during film growth or as a sum of signals from differently oriented, lying, and standing molecules. XPS investigations with different surface sensitivities have been performed to clarify this point. The C 1s photoemission spectrum of CuPc in Figure 45.11 shows two main features, one is derived from the benzene substructure (C1) and another from the atoms of the pyrrole substructure neighbored to nitrogen (C2). They can be used to distinguish standing and lying molecules within the uppermost layer. In the former case, the C2 atoms are located deeper inside the film compared to the C1, so the corresponding surface-sensitive photoemission signal of C2 atoms is weakened compared to the C1 signal from the outer parts of the molecule. In the latter case, C2 electrons from different parts of the lying molecule are not particularly attenuated, and the photoemission signal represents the stoichiometric ratio.

Figure 45.11 presents also the resulting C1–C2 ratios, calculated as (C1a + C1b + S1a + S1b)/(C2 + S2), as a function of the excitation energy for all

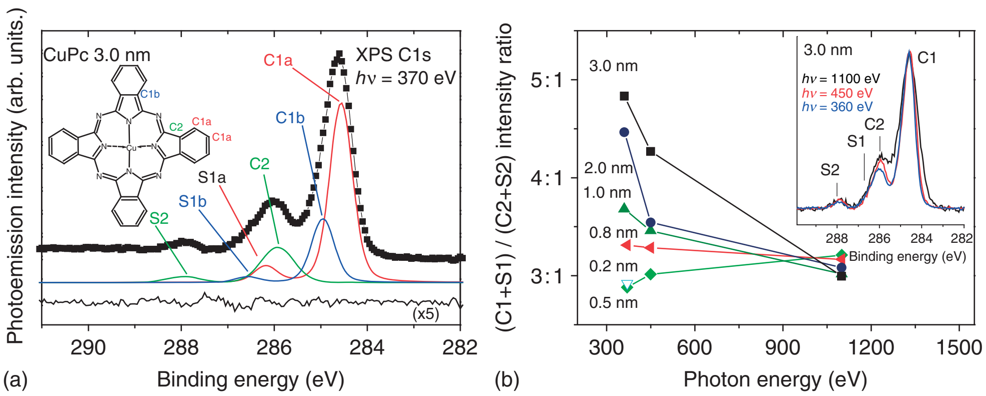

Figure 45.11 (a) Numeric peak fit of the C1s photoemission spectrum of the copper phthalocyanine films (3.0 nm thick film measured with an excitation energy of 370 eV). The spectrum is described by three components and the corresponding shake-up satellites, distinguishing the benzene components C1a and C1b and the pyrrole component C2. (b) The component ratios of the investigated copper phthalocyanine films show a distinct trend: for the film thicknesses of 1.0, 2.0, and 3.0 nm, they deviate from the 3 : 1 stoichiometric ratio, when the data are taken with lower excitation energies (enhanced surface sensitivity). This gives evidence for the overall standing orientation in the topmost molecules. In contrast, the signal ratio remains constant at each photon energy for film thicknesses below 1 nm, as expected for lying molecules. The lines are guides for the eye. As an example of a changing C1–C2 intensity ratio, the spectra for the 3.0 nm thick film are shown in the inset.

investigated films. The inset shows a direct comparison of the spectra for a 3.0 nm thick film for different photon energies. The spectra taken at 1100 eV are the least surface sensitive and the intensity ratios are in agreement with the stoichiometry for all investigated film thicknesses. As expected for lying molecules, the C1–C2 ratios for the film thicknesses below 1 nm also are about 3 : 1, reflecting the stoichiometric value. For the 1.0 nm thick film, the C1–C2 ratio only slightly depends on the excitation energy. A clear deviation from 3 : 1 can be seen for surface-sensitive spectra at 360 eV of the 2.0 and 3.0 nm thick films. The ratios of 4.5 : 1 and 4.8 : 1 for 2.0 and 3.0 nm, respectively, are close to the value of 4.9 : 1, that was found earlier for a 7.6 nm film of standing zinc Pc molecules under more surface-sensitive conditions [71]. Thus, it could be concluded that standing molecules form the topmost layer of the 2 and 3 nm thick films. From the disappearance of the anisotropy of the NEXAFS data, about half of the total film consists of lying molecules, that is, about three layers of lying molecules are covered by about one layer of standing molecules.

This example shows how XPS, coupled with the opportunity to use synchrotron radiation, that is, to tune the surface sensitivity of the experiment, delivers information on buried interfaces without destroying the investigated systems.

45.4.3
XPS as a Tool to Investigate Growth Modes

A model study of film growth typically involves deposition of a controlled amount of atoms/molecules onto a well-characterized crystalline substrate at a defined set of growth conditions. The precisely defined growth conditions, coverage, and deposition rates in such studies make it possible to decipher the rules governing the evolution of the growth front, and to explore ways of tailoring film morphology to obtain specific characteristics.

Essentially three basic growth modes can be observed: (i) island (or Volmer–Weber), (ii) layer-by-layer (or Frank–van der Merwe), and (iii) layer plus island (or Stranski–Krastanov) growth [72, 73].

Island growth occurs when the smallest stable cluster nucleates and grows in three dimensions to form an island. The molecules are more strongly bound to each other than to the substrate. The opposite characteristics are shown during the layer-by-layer growth: the smallest stable nucleus develops in two dimensions, resulting in the formation of planar layers. The molecules are more strongly bound to the substrate than to each other. The second layer grows on top of the first experienced, a slightly weaker bond with the substrate. The layer-by-layer mode will be sustained, provided the decrease in bonding energy is continuous toward the bulk-crystal value. The layer plus islands is an intermediate mechanism that can be seen as a combination of the previous two modes [72, 73].

Thickness-dependent XPS investigations offer the opportunity to identify the growth mode of an adsorbate on a given substrate. By monitoring the XPS signal attenuation of the substrate during growth, it is possible to identify which growth mode occurs.

For layer-by-layer growth, the substrate signal goes to zero as the overlayer buries the substrate. The intensity decrease is strictly linear up to the completion of the next full monolayer for ideal layer-by-layer growth. However, the envelope function for the overlayer peak intensities over an extended thickness range shows an exponential decay, with a characteristic decay length determined by the IMFP. In contrast, the intensity decay signal with increasing amount of material will be much slower with the nominal thickness of the film for a 3D growth mode. Its details will depend on the details of island shape and densities, which develop on the surface and are hard to generalize. An intermediate behavior is shown by the layer plus island growth [73, 74].

During the past decade, remarkable research efforts in the field of III nitrides have been achieved. GaN and related materials have attracted a lot of interest for applications in high-power electronics such as light-emitting diodes (LEDs) or high-mobility field-effect transistors [75–81]. In addition, the combination of wurtzite polytypes of AlN, GaN, and InN with band gaps of 6.2, 3.4, and ~0.8 eV allowed the development and commercialization of several devices, such as green and blue LEDs with exceptional efficiencies and brightness for a variety of applications [79]. Further potential applications of III-nitride-based alloys in spintronics and magneto-optics were recently suggested [82–84]. Different deposition techniques, such as metal-organic chemical vapor deposition (MOCVD), hydride vapor phase epitaxy, and plasma-assisted molecular beam epitaxy (PAMBE), have been applied to achieve a heteroepitaxial growth of III-nitride films [85]. However, the lack of matching substrates still limits the quality of the nitride films, especially with regard to GaN. Recently, Sidorenko *et al.* [86] have compared epitaxial growth of GaN films on 6H-SiC(0001)-($\sqrt{3} \times \sqrt{3})R30^\circ$ – Ga and on (0001)-sapphire. Predeposited Ga layers were nitrided by ion-beam-assisted molecular beam epitaxy. On SiC, the initially deposited Ga covers the substrate surface completely, while on sapphire only Ga droplets are present. The different distribution of the predeposited Ga affects the morphology of GaN significantly. The system was investigated with different techniques; in particular, XPS measurements revealed that metallic Ga resides also on top of the GaN films during the growth.

In Figure 45.12, a comparison of Ga 3d and Ga 2p3/2 core-level peak areas at successive stages of the GaN ion beam assisted molecular beam epitaxy (IBA-MBE) experiment are shown for GaN on SiC.

The data represent the surface coverage of the $\sqrt{3}$ structure by Ga, which corresponds to 1/3 ML of Ga. The experimental intensity ratio I(Ga 2p3/2)/I(Ga 3d) is about 5, which is close to the ratio of the corresponding IMFP values of 4.0, the largest value to be expected. The obtained value corresponds very well to the fact that all Ga is laterally distributed in the topmost layer of the sample. After Ga metal deposition, both the Ga 2p3/2 and Ga 3d peak intensities increase because of the additional Ga on the surface, but they remain significantly smaller than 1. The intensity ratio decreases from 5 to 2.5, but this latter value is still much larger than 1, expected for bulk GaN or islands thicker than the information depth. Thus, the Ga metal does not only reside in thick metallic droplets on the surface. Apparently, beside the droplets the metal distributes into a Ga layer, wetting the

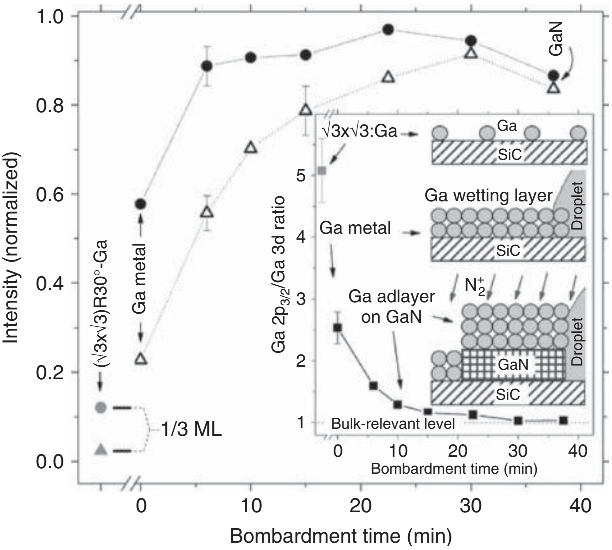

Figure 45.12 GaN on SiC: comparison of Ga 3d (triangles) and Ga 2p3/2 (circles) core-level peak areas at successive stages of the GaN IBA-MBE experiment. The areas are normalized related to the thick GaN film. Gray data points represent the surface. Black data points correspond to successive ion bombardment steps of the 30 nm Ga metal layer, bombardment times $t = 0$–37 min. All lines and arrows are guides for the eye. Inset: plot of the Ga 2p3/2/Ga 3d peak area ratio, related to the main panel. The dashed horizontal line indicates the area ratio expected for a bulklike homogeneous sample. From the detailed analysis of the peak intensities, a growth model is proposed, as illustrated in the inset. Top: as-prepared surface with 1/3 ML of Ga adatoms. Middle: deposited metal Ga film, which forms droplets and a wetting layer of about 2 ML. Bottom: during GaN growth (not completed ion bombardment) the film exhibits a mixture of GaN islands, covered by a Ga metal adlayer and Ga metal droplets. (Reprinted with permission from [86]. Copyright 2007, American Institute of Physics.)

SiC surface. The XPS data in Figure 45.12 allow estimating the thickness of this substrate wetting layer to be ~1.5–2.0 ML. During the initial steps of the GaN growth, a further increase in both Ga 2p3/2 and 3d intensities with the nitrogen bombardment time is observed, despite the fact that no further Ga was deposited. This can be explained by a redistribution of Ga from the droplets toward the growing GaN film, as mentioned earlier. The Ga 2p3/2 intensity approaches a saturation level 1 rather quickly. At this stage, the Ga/GaN film has reached a certain lateral extension on the substrate surface and its thickness exceeds the Ga 2p3/2 information depth, evidently. The increase in the corresponding Ga 3d intensity follows gradually, in this manner indicating the further increase in the GaN film thickness. This growth in thickness is also supported by the approach of the Ga peak intensity ratio toward 1. The slight intensity decrease after the final nitridation step has to be related to the consumption of the metallic Ga, which possesses higher Ga atom density compared to GaN. The final intensities are smaller than 1, which has to be explained by the incomplete surface coverage by the grown GaN film. The interpretation was also corroborated by atomic force and scanning transmission microscopy investigations.

In summary, the detailed analysis of the XPS intensities makes it possible to identify a laterally homogeneous film (Ga wetting layer on SiC) and additional droplets, which are apparently concentrated on a particular stacking termination, and a Ga adlayer resides on top of the GaN film during the growth process.

This experiment shows how by using XPS a reach characterization of growth modes is possible, with specific insights also in complicated growth regimes.

45.4.4

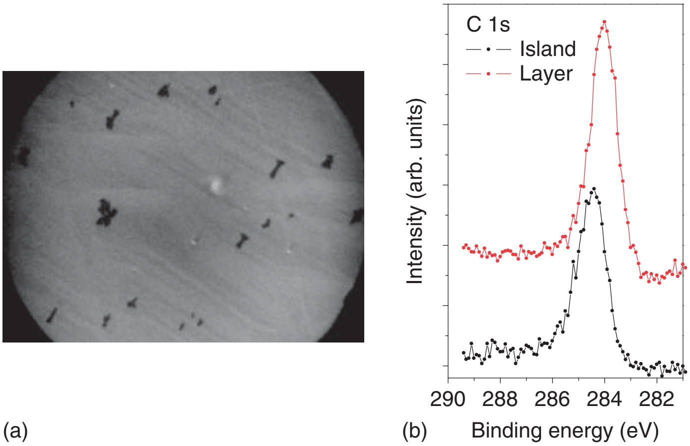
Laterally Resolved XPS as a Tool to Reveal New Aspects in Physics and Chemistry of Thin Film

In the previous paragraphs, we have shown how XPS is a very powerful technique to investigate a large range of effects related to the chemistry, the physics, and the growth modes of materials. However, standard XPS averages over the sample area illuminated by the incident light. If there is the opportunity to couple such information also with high lateral resolution, it is clear how such a technique may reveal aspects not yet investigated of materials.

A way to reach high lateral resolution in XPS is the use of a photoelectron emission microscopy (PEEM) [87]. The excitation is usually produced by UV light, synchrotron radiation, or X-ray sources. The illumination of the specimen with X-rays excites a broad electron spectrum consisting of the primary unscattered or elastically scattered photoelectrons, inelastically scattered electrons (secondary electrons), and Auger electrons. These instruments can reach lateral resolution of a few nanometers, and provide a unique combination of complementary imaging and diffraction methods with structural, chemical, and magnetic sensitivity. They allow a multitechnique investigation, in real time and *in situ*, of surfaces, interfaces, thin films, nanostructures, and the processes thereby occurring.

We have used PEEM to investigate thin films of diindenoperylene (DIP) deposited on Au(111) [88]. DIP is a perylene-based molecule that shows a high-hole mobility already in thin films, good film-forming properties, and thermal stability [89–94]. All these aspects suggest that it is a promising molecule for electronic applications.

The opportunity to use synchrotron radiation as a light source for a PEEM allows the simultaneous investigation of morphology, structure, and electronic characteristics. Figure 45.13 shows an *in situ* observation of DIP growth on Au(111) by using UV-PEEM (ultraviolet photoelectron emission microscopy) (Hg-lamp, $h\nu = 4.9\,\text{eV}$). The PEEM images show bright and dark regions. The work function of gold is higher than the photon energy of the Hg lamp; therefore, there is no contribution from the substrate (no PEEM intensity is shown by the substrate) [95]. However, the work function decreases to 4.35 eV within the first three layers [94], allowing the photoelectrons to escape and the consequent observation of a bright PEEM signal. With increasing film thickness, this contribution is attenuated by elastic and inelastic scattering of the photoelectrons that gives rise to dark regions [92, 95]. A layer-by-layer mechanism characterizes the initial growth (bright



(a)

(b)

Figure 45.13 (a,b) UV-PEEM image of a nominal 53 Å thick DIP films showing islands on a Au(111) surface. The field of view is 25.0 × 18.7 μm. C 1s core-level spectra of the DIP film are shown in the image, obtained from an image stack integrated in the binding energy range between 281 and 289 eV, for an island and the monolayer on top of the gold substrate.

region) followed by island nucleation (dark regions), that is, the growth follows the Stranski–Krastanov mode (layer plus islands) [72, 73]. Investigating the C 1s core levels by PEEM, the spectra are obtained from an image stack taken in the binding energy range between 281 and 289 eV ($h\nu = 350$ eV) and analyzed for an island and for the monolayer on top of the gold substrate (Figure 45.13a). A strong peak at 284.4 eV dominates the spectrum of the island. Because of the molecular symmetry (the free DIP molecule belongs to the D_{2h} point group), the C 1s core-level features are expected to be composed of at least nine contributions, one for each different nonequivalent carbon site. Owing to their similar binding energy and the finite resolution of our experiment, their separation and energy determination by curve fitting would be quite speculative, and it will not be addressed in this context. Comparing the signal of the C 1s core levels of the island and the monolayer, a 0.4 eV shift toward the higher binding energy is clearly observable. This effect is analogous to the shift found comparing monolayer and multilayer with standard XPS [54]. It is due to the substrate-enhanced efficiency of the screening effect of the C 1s core hole in the monolayer. Because of the strength of spectromicroscopy, we are able to demonstrate that this screening effect actually depends on selectable different thickness in a given film, for which both preparation conditions and experimental setup are exactly identical.

We could observe several phenomena [88], such as different screening of the core hole, or different full width at half maximum of the XPS lines that have been previously shown comparing different samples consisting of monolayer and multilayer. On the contrary, we have shown their occurrence comparing islands versus monolayer in the same film. This could be done because of the high lateral resolution of the experiment (~30 nm) that allows speaking about nano-XPS.

45.4.5
X-Ray Photoelectron Diffraction (XPD) as a Tool to Investigate Structural Properties

Here, we briefly introduce an important application of the core-level spectroscopies, that is, photoelectron diffraction (PED). The appearance of PED was proposed by Liebsch [96] in 1974. PED is a phenomenon that occurs in angle-resolved core-level photoemission from ordered, crystalline samples. The directly emitted component of the photoelectron wave function from an emitting atom superimposes coherently with components of the same wave function, which are elastically scattered by the surrounding atoms. This interference leads to a modulation of the measured photoelectron intensity as a function of (i) emission angle or (ii) photoelectron energy. These modulations contain information on the relative positions of the emitter and the neighbored scatterers. Thus, the local geometrical structure of the investigated systems can be deduced from such experimental information (Figure 45.14). Diffraction patterns are specific to the local environments of the emitting atoms and in case of significant chemical shifts also for particular chemical species.

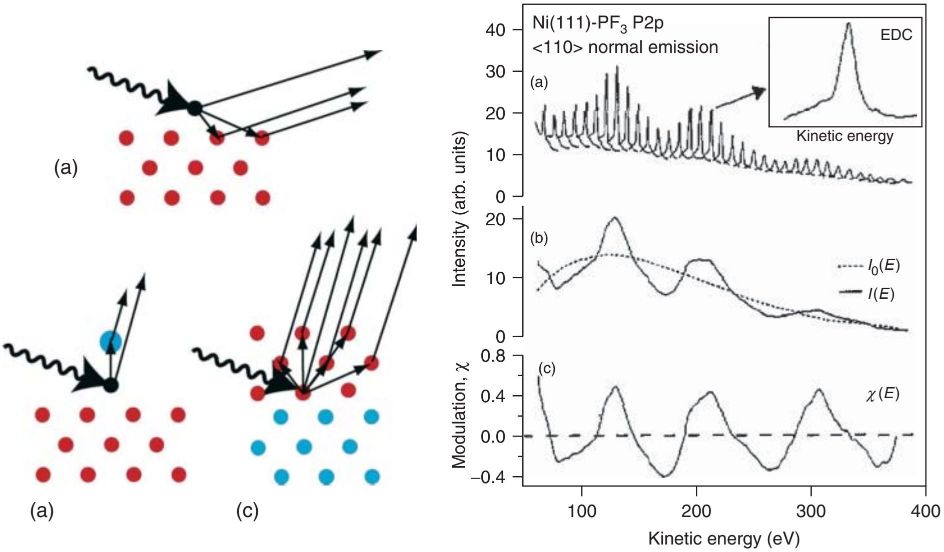


Figure 45.14 Left panel: Schematic diagrams showing some of the near-forward scattering paths in three different applications of XPD: (a) adsorbate site determination using grazing emission geometries; (b) intramolecular scattering in a simple diatomic adsorbate; (c) epitaxial growth characterization. The P 2p level in the molecule PF$_3$ adsorbed on a Ni(111) surface is used as an example. Inset: a single P 2p electron energy distribution curve at $h\nu = 346$ eV. (a) Group plot of the raw energy distribution curves but showing only every third curve. (b) Integrated intensity of the P 2p energy distribution curves together with the sp line function used to normalize to the average value. (c) Resulting modulation function, $X(E)$. (Reprinted with permission from [98]. Copyright 1994, IOP Publishing Ltd.)

Extensive studies by Bradshaw and Woodruff [98–103] have demonstrated that energy-scanned PED may be applied to determine surface and adsorbate geometries. As shown in Figure 45.14, core-level intensities $I(E)$ are measured dependending on the electron kinetic energy E by varying the photon energy and referred to a *smoothly varying background* $I_0(E)$. The systematic comparison of the experimentally derived anisotropy $\chi(E) = (I(E) - I_0(E))/I_0(E)$ with a related quantity from multiple scattering cluster calculations (MSCCs) in the framework of R-factor analysis gives access to the structural parameters of atomic and small molecular adsorbate systems. Recently, this technique has also been extended to investigation of larger adsorbed molecules on surfaces, as nonplanar vanadyl phthalocyanine (VOPc) molecules on Au(111) single crystals [103]. The results showed that the molecular plane of VOPc is essentially parallel to Au(111) and the off-plane V=O vanadyl bond points away from the surface. The V=O bond length of 1.60 ± 0.04 Å determined by comparison to MSCC is close to the molecular value, but the V atom is found almost coplanar with the surrounding N atoms in the adsorbed molecule in clear contrast to the off-plane location of V in crystalline VOPc molecular solid. This indicates a significant interaction between the V atoms in adsorbed VOPc monolayers with the Au(111) surface, in this manner also supporting the notion that bonding of large near-planar molecules to metal surfaces can lead to modification of the internal conformation of the molecules.

In X-ray photoelectron diffraction (XPD) experiments, angular distribution curves (ADCs) of the intensity are measured in dependence on polar or azimuthal angles of photoemission. Owing to the higher energy of the laboratory X-ray sources, the information depth is typically larger in XPD rather than in a related PED experiment and therefore the method has been used to investigate structure of bulk samples and thin films in addition to LEED (low-energy electron diffraction) and STM (scanning tunneling microscopy). In particular, growth of metals on metals, for example, Cu on Ni(001) [98], or oxide film growth, for example, MnO on Ag(001) [104], have been investigated. In Figure 45.15, an angular distribution pattern (ADP) and an ADC curve taken from MnO(001) bulk (lattice constant $a = 445$ pm) are compared to an experimental ADC and simulations for a MnO film on lattice-mismatched Ag(001) ($a = 409$ pm). High-intensity features along low-index directions may be related forward scattering peaks, essentially, but satisfactory quantitative agreement between experiment and theory can only be achieved by taking multiple scattering into account. In this manner, geometric parameters and thus information on strained films and structural relaxations in dependence on film thickness may be obtained by XPD [104] (Figure 45.15).

45.4.6
Molecular Orbital Densities from Photoemission Spectra of Organic Molecules

A recent method that couples ARUPS with theoretical calculations in order to also gain information on MOs not directly accessible with conventional fitting techniques has been developed by *Puschnig et al*. They studied the interface of perylene-tetracarboxylicacid-dianhydride (PTCDA) deposited on Ag(110) by

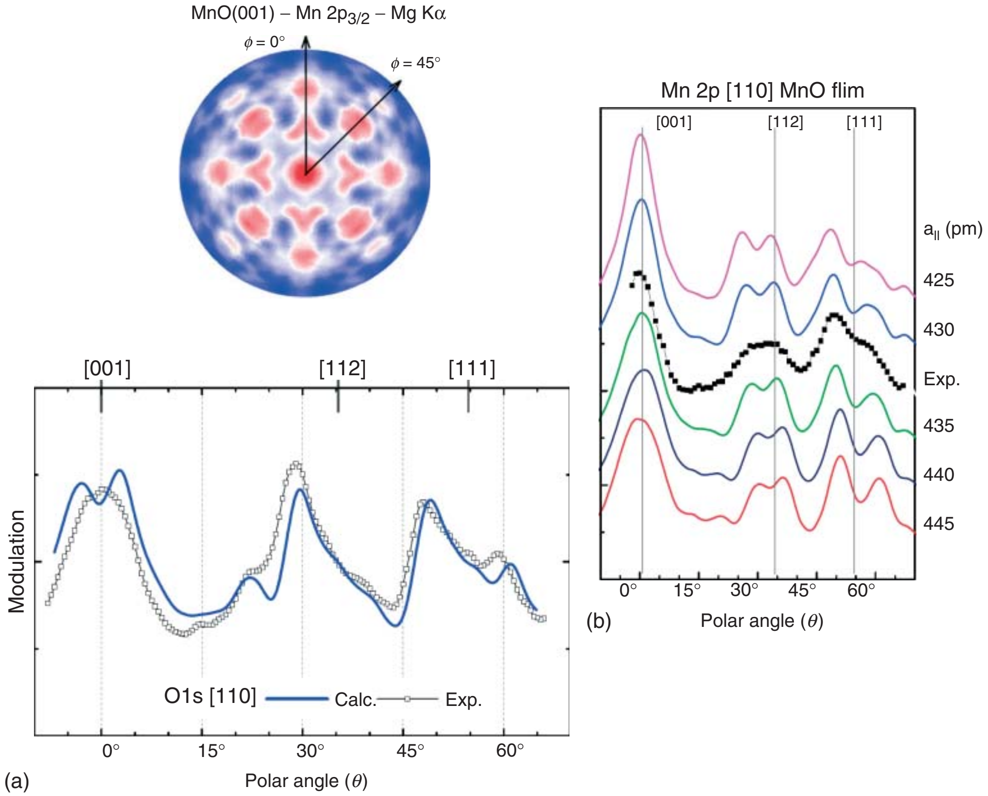

Figure 45.15 (a) Experimental 2π scans of Mn 2p of MnO(001) single crystal excited by Mg Kα-radiation together with the comparison of experimental and theoretical polar scan ADCs of O 1s photoelectrons of MnO(001) single crystal along the [110] direction. (b) Calculated polar scan ADCs of 6 ML MnO film in dependence on the degree of tetragonal distortion. The calculated spectra are compared to experimental results of a 6.5 ML thick film. (Reprinted with permission from Ref. [104]. Copyright 2011, Elsevier.)

ARUPS [105]. They measured the signal intensity from a constant initial-energy state in the full half-space above the sample surface, obtaining a set of data that contain a complete momentum- and energy-resolved density of state (DOS) of the sample in the measured binding energy range.

Analyzing the data in a plane-wave approximation for the final state in the photoemission process, they have assigned the emissions to specific molecular states. For the assignment, they have valuated the tomographic cross section through the momentum-resolved data set and searched for momentum space patterns that are characteristic of the corresponding MOs. In this approximation, the ARUPS intensity distribution from a molecular state corresponds to the respective Fourier transform of the MO. The combination of the simulated momentum maps and the tomographic data allows the deconvolution of the energy distribution

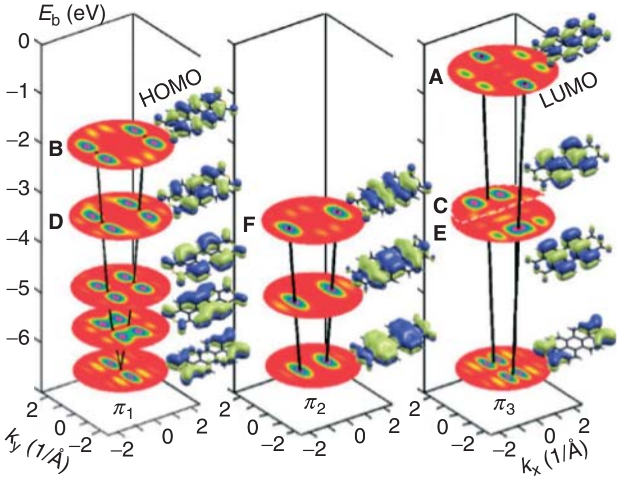

Figure 45.16 Molecular orbitals of free PTCDA together with the corresponding calculated (*kx*,*ky*) maps of 12 PTCDA π orbitals in a binding energy window between −7 and 0 eV. They are grouped into three bands: $\pi 1$ (left panel) dispersing along the *kx* direction and representing orbitals with an *xz* nodal plane, $\pi 2$ (middle panel) dispersing along *kx* with no node in the *xz* plane, and $\pi 3$ (right panel) dispersing along *ky* with an increasing number of nodal planes perpendicular to *y*. (Reprinted with permission from Ref. [105]. Published by the American Physical Society. Copyright under Creative Commons Attribution 3.0 License.)

curves (EDCs) into contributions from a single molecular state beyond the intrinsic limit of the line broadening and of the instrumental resolution. This is possible because the deconvolution is carried in the k-space using the full momentum space information of the MO.

The π-MOs of the free PTCDA molecule can be classified according to their symmetry and momentum distribution [106]. Figure 45.16 shows this classification based on the nodal structure of the MO. The first group is characterized by an *xz* nodal plane through the long molecular axis *x*. The second group has no nodes in the *xz* plane. The third group shows an increasing number of nodal planes in the *xz* plane. These moment patterns are the base for the search for the MO in the data set.

This model was proved to be appropriate for a number of different molecules [106–109] and may be considered useful to extract even more information from ARUPS experiments, providing an orbital-by-orbital characterization of large adsorbates, allowing also the estimation of the effects of bonding on individual orbitals.

45.5
Conclusions and Future

The aim of this chapter has been to demonstrate by a number of representative examples the power of photoemission spectroscopy. Photoemission experiments deliver a wealth of information on a large number of different aspects connected with the characterization of a system, ranging from core-level states to chemical environment, from interface effects and bonding to growth.

The detailed understanding of complex materials requires the use of state-of-the-art experimental techniques that provide information on electronics, structure, and morphology of the materials. The advent of third-generation synchrotron sources has immensely increased the possibilities offered by photoemission because of the high-energy resolution reached. The increasing miniaturization of components furthermore demands the use of techniques with spatial resolution down to the nanometer range. Thus, a good way of satisfying both requirements is to combine the distinctive properties of standard UPS/XPS with those of electron microscopy as in photoemission electron microscopy, which opens even further ways to the use of photoemission and to the investigations of not yet revealed phenomena.

Another aspect of XPS, less inherent to surfaces but that it is presently matter of a very rapid development, is high-energy XPS. It allows the extension of the probing depth typical of standard XPS giving the opportunity to apply XPS to various materials with nanolayered structures and nanoparticles. A straightforward way of extending the probing depth is to raise the photon energy for excitation. The recent progress of X-ray undulators at third- generation synchrotron light sources, as mentioned, delivers high photon flux as well as high flux density. These sources compensate for the decreases in cross section and analyzer transmission, problems to deal with in high energy, and make high-energy XPS accessible. The larger escape depth of photoelectrons with higher kinetic energy facilitates studies of electronic structures and/or chemical states of bulk materials, interfaces, and nanoscale buried layers, as the contribution to the detection of signal from the surface region is small [110].

There are fields where the use of XPS could deliver important information, but the related phenomena do not take place in UHV. Environmental and atmospheric chemistry, catalysis, and biomaterials require higher pressure. Thus, high-pressure XPS in the millibar range has become an important tool within the past years to explore particular phenomena as water deposition on several substrates [111, 112] or catalytically active phases [113]. Also, in this case, the application of this technique at a synchrotron radiation facility has an important role, and future applications will confirm the importance of using high-energy XPS also coupled with high-resolution XPS.

Last but not least, very recently the advent of lasers that emit pulses in the attosecond timescale allowed measuring the time delays between different photoemission processes generated by the same ultrashort light pulse. Photoemission from atoms is assumed to occur instantly in response to incident radiation: Schultze *et al.* [114, 115] found a delay of 21 as in the emission of electrons from the 2p orbitals of neon atoms with respect to those released from the 2s orbital by the same light pulse. Small differences in the timing of photoemission from different quantum states give the opportunity for modeling many-electron dynamics. This finding not only allows further studies of the timing of photoemission but also provides a new way to investigate electron interactions in atoms.

Miniaturized Optical Sensors for Medical Diagnostics

Seong-Soo Kim and Boris Mizaikoff

46.1
Introduction

The interactions between photons and molecules are among the most widely researched areas in physics, chemistry, and biology. Photons interact with molecular constituents in different ways depending on their energies. Photons with higher energies, that is, shorter wavelengths, excite predominantly electronic transitions within molecules, which is utilized in ultraviolet/visible/near-infrared (UV/Vis/NIR) absorption and fluorescence spectroscopy.

Photons with lower energies, that is, longer wavelength, do not provide sufficient energy for exciting transitions between electronic states, thus addressing energetically much closer spaced vibrational and rotational molecular states. In particular, electromagnetic (EM) radiation in the mid-infrared (MIR; 3–20 μm) spectral range provides photon energies compatible with the excitation of fundamental–vibrational and mixed rotational–vibrational modes spectroscopically addressable for molecules with a resulting net change of the permanent dipole moment. The interaction of MIR photons specifically with organic molecules gives rise to sharp transition in contrast to most interactions in the UV/Vis/NIR regime, thereby providing a particularly high discriminatory potential when analyzing complex mixtures. Within the MIR regime, the so-called fingerprint range, where each molecule is characterized by highly distinctive spectral patterns, provides a preferable spectroscopic window for detecting individual molecular species.

Although there is no strict definition for the analytically most useful spectral bands, EM radiation within a wavelength range of 20–100 μm is considered the far-infrared (FIR) regime, while the wavelength range of 100 μm (3 THz) to 1 mm (0.3 THz) is referred to as *terahertz (THz) radiation*. Compared to the aforementioned spectral ranges, the THz regime is to date the least researched area in terms of miniaturized optical diagnostic device technology, as relevant components such as, for example, appropriate light sources, radiation guiding media, and optical detectors have only recently emerged. Most recently, THz radiation has attracted increasing interest because of its potential for interaction with macromolecules via vibrational modes. Hence, it appears feasible to study macromolecules such

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

as, for example, DNA or proteins, which have numerous vibrational modes, with low-energy radiation. As THz photons have typical photon energies of a few millielectronvolts, the analysis of, for example, protein folding, receptor binding, or the label-free detection of DNA hybridization appears within reach.

Raman spectroscopy provides another important optical platform amenable to medical diagnostics. While Raman spectroscopy typically relies on optical excitation of molecules in the UV/Vis/NIR spectral range, the relaxation from higher energy states results in molecular vibrations apparent at much longer wavelengths (in particular, within the spectral regime typical for MIR absorption spectroscopy) because of inelastic scattering. However, despite the inherent merit of significantly less interference by water and water vapor, the Raman process suffers from its optical inefficiency compared to, for example, MIR absorption spectroscopy. The analytical efficiency of Raman techniques may considerably be improved by taking advantage of signal enhancement effects arising at the surface of corrugated (noble) metal layers or particles, also referred to as *surface-enhanced Raman spectroscopy* (*SERS*).

While each fundamental optical process involving photon–molecule interactions has its own merits and weaknesses for detecting molecular constituents including inorganic compounds, small organic molecules, or macromolecules such as, for example, DNA or proteins, it is evident that this wide variety of optical sensing techniques provides complementary analytical information rather than competitive device platforms. Given their versatility, optical spectroscopic techniques are already applied in areas including industrial process monitoring, pharmaceutical development, biomedical research, and so on. However, for the development of diagnostic instrumentation in medical applications it is of primary importance to understand the relationship between the *in vivo* or *in vitro* analyzed chemical/biochemical reactions and molecular patterns, and the physiological or disease status characterized by such data. Any disease is characterized by a complex sequence of metabolic reactions, physiological reactions, and pathogenic reactions that involve a wide variety of *in situ* synthesized or transformed chemical/biochemical constituents. Hence, a ‘‘biomarker’’ may be considered a specific constituent (i.e., indicator) that is found only in a certain metabolic, pathogenic, or pharmacologically relevant reaction or environment and characterizes a certain biological status of the investigated organism. Given the complexity of most disease pathologies or the response of an organism to therapeutic treatment, usually several biomarkers or entire panels of biomarkers are required for a status determination. Therefore, the analysis of such biomarkers – ideally *in situ* and within their native environment – provides valuable information on the condition of a biological system. Consequently, diagnosing the status of physiological processes, metabolism, or disease/therapy progression is ideally enabled by monitoring corresponding biomarkers *in vivo* (e.g., the human body), or after appropriate sampling of representative matrices from the organism (e.g., blood, interstitial fluid, biopsy, etc.). Of particular interest is the analysis of biomarkers in excretions that may be noninvasively collected such as, for example, exhaled breath (EB) or breath condensate, urine, perspiration, saliva, or similar matrices.

From a practical point of view, miniaturization of optical devices and sensing system facilitates their clinical utility and daily operation, in particular, if *in vivo* applications are targeted. During the past few decades, engineering progress including, for example, novel light sources covering a wide spectral range, component and device fabrication processes taking advantage of microelectronic and microelectromechanical fabrication techniques, advances in integrated optical detectors, and so on has enabled the miniaturization of laboratory-style optical instrumentation toward biomedically more applicable optical device and sensor technology. Selected examples and recent developments will highlight the current state-of-the-art and future potential of miniaturized optical diagnostics in this field.

46.2
UV/Vis/NIR Plasmonic Sensors

While conventional absorption and fluorescence spectroscopy measurement schemes are well established in biosensing and imaging applications related to medical diagnostics, methods based on plasmonic sensing schemes utilizing metal nanostructures or thin metal films have recently attracted considerable interest because of the high sensitivity and selectivity achievable in the UV/Vis/NIR spectral range. A variety of plasmonic sensing schemes take advantage of nanostructures for detecting biomarkers; however, common to these techniques is the consequent utilization of plasmon resonance effects.

Surface plasmons result from efficient coupling between free electrons within the conduction band of metals, and incident EM radiation in a coherent manner. Generally, two types of surface plasmon resonances (SPRs) may be discriminated: (i) propagating surface plasmon polaritons (SPPs) and (ii) localized surface plasmon resonances (LSPRs). SPPs are excited at the surface of thin metal films

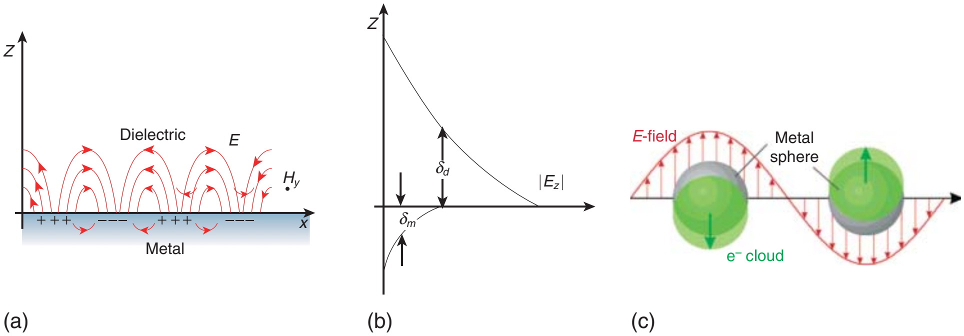

Figure 46.1 Two types of surface plasmon resonance (SPR): (a,b) surface plasmon polaritons (SPPs) and (c) localized surface plasmon resonances (LSPRs). SPR represents a coherent interaction between an electromagnetic field and charges at a metal–dielectric interface. The field lines in (a) represent the electromagnetic field (TM mode). (b) The electric field strength along the normal direction to the interface [1]. (c) LSPRs by the collective oscillation of the electron cloud at a metal sphere under the influence of an external electromagnetic field [2].

surrounded by dielectric media if the appropriate resonance conditions are satisfied, which are illustrated in Figure 46.1a,b. SPPs may propagate up to a few hundreds of micrometers along the metal/dielectric interface. In contrast, LSPR are nonpropagating plasmon excitations generated at metal nanostructures such as, for example, metallic nanoparticles (NPs), nanoshells, or nanoholes, which are surrounded by dielectric media, as shown in Figure 46.1c. In both cases, any change of the dielectric constant in the surrounding dielectrics results in a change of the plasmon resonance conditions, which may be detected by measurable experimental parameters such as, for example, change of intensity, wavelength, and coupling angle. Both types of plasmonic sensors are highly sensitive toward minute changes of the dielectric constant resulting from the presence of a target analyte near the metal/dielectric interface. However, the specificity of such plasmonic biosensors usually exclusively results from appropriate molecular recognition (bio)chemistry immobilized at the surface of or near the metal/dielectric interface for target molecule recognition such as, for example, antibody–antigen, ssDNA–ssDNA, or similar recognition events. Examples for appropriate antibody–antigen binding schemes are shown in Figure 46.2.

To date, SPP biosensor technologies have further evolved than LSPR biosensors, which are still at an early stage of research. Typically, SPP biosensors utilize prism couplers, grating couplers, or waveguide couplers based on optical fibers or channel waveguides [3]. Although SPP biosensors based on prism coupling are the most sensitive optical configuration, systems using optical fibers have advantages in terms of device miniaturization [3]. Optical fiber SPR biosensors usually exploit single-mode fibers with one side surface planar polished and coated with a thin metal film. The fundamental mode of the optical fiber is designed to couple to the SPP excitation mode with the biorecognition element immobilized at the metal surface.

Bench-top style SPR biosensors utilizing SPPs are commercially available, and are already frequently applied in biomedical and clinical analysis. For example, Besselink *et al.* [4] have reported the successful detection of prostate-specific antigen (PSA), a biomarker for prostate cancer, in PBS buffer using a commercial SPR sensor system based on SPPs.

Wittekindt *et al.* [5] have used SPP biosensors to detect antibodies against herpes simplex virus type I and type II from human sera. Wei *et al.* [6] have demonstrated the detection of troponin (cTn I), a biomarker for cardiac muscle injury, in serum. As an example of viable immobilization schemes, an avidin layer was prepared by amine coupling chemistry on alkanethiolate deposited as a self-assembled monolayer (SAM). Biotinylated antibodies against cTn I were then immobilized onto the avidin layer. The limits of detection (LOD) in this particular study were determined at 2.5 and 0.25 ng ml^{-1} for the direct and the sandwich format, respectively. The group of Books has used miniaturized optical fiber SPR sensors to detect cTn I with LODs equivalent to 3 ng ml^{-1} [7].

Nanostructured metals with surrounding dielectrics support a different type of plasmonic excitation, which is an active area of research for enhancing the sensitivity and selectivity of SPR-based biosensors [8]. LSPR at NPs significantly

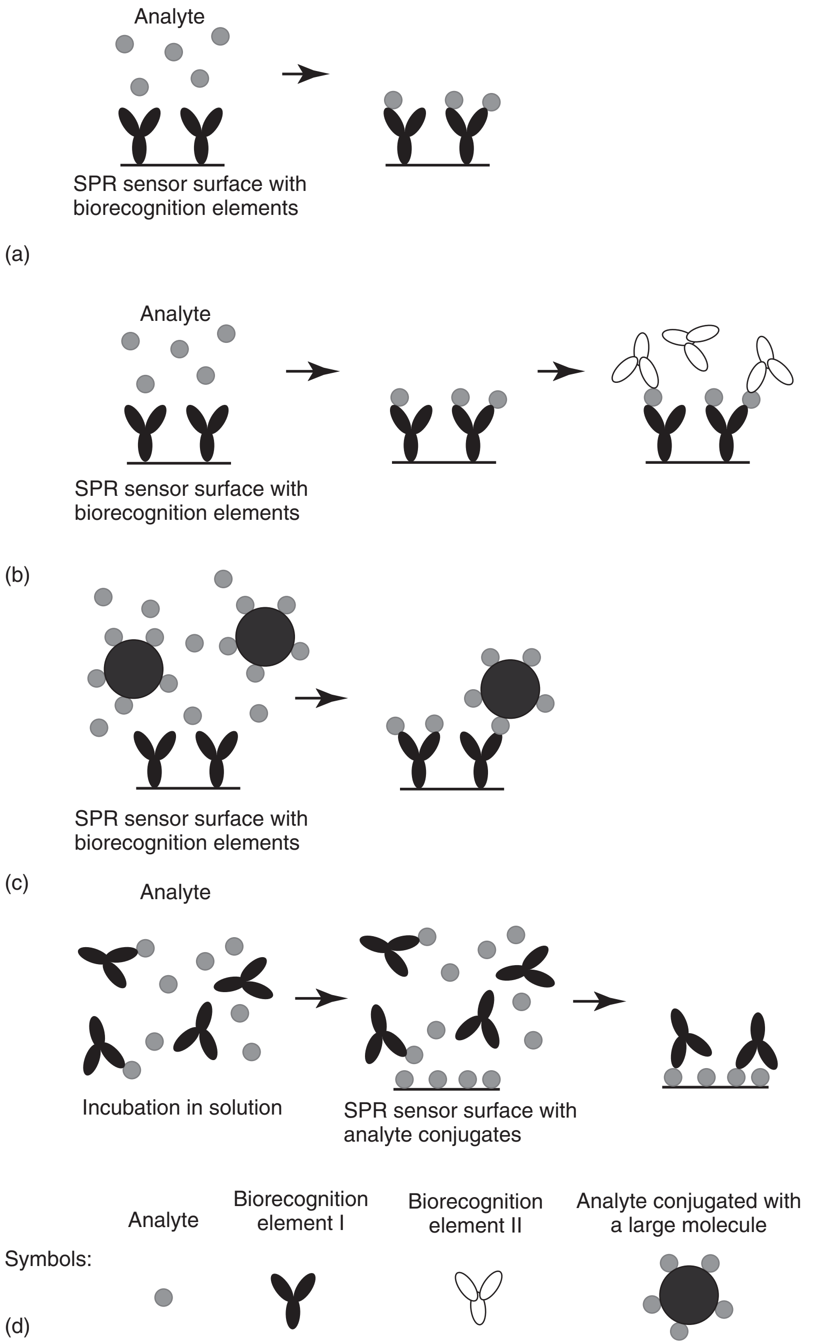

Figure 46.2 Selection of analyte detection schemes applicable in SPR [3]. (a) Direct detection, (b) sandwich detection, (c) competitive detection, and (d) inhibition detection.

enhance light scattering as well as light absorption [8, 9], with several interesting detection schemes based on NPs derived for biosensing applications.

Colorimetric detection schemes based on NP–NP coupling are probably among the most simple, yet effective methods taking advantage of LSPR. Mirkin and his research group [10] have successfully demonstrated a nucleic acid assay with oligonucleotide-functionalized Au NPs. Such oligonucleotide-functionalized Au NPs will aggregate in the presence of the nucleotide as the target analyte. As the distance between the Au NPs decrease as a result of NP aggregation and especially within the range of the LSPR-enhanced electric field, near-field coupling effects dominate, thereby resulting in a redshift of the absorption spectra.

Another highly interesting scheme is the hybridization of SPP biosensors with metal NPs to further enhance the sensitivity. Determining the rather minute changes of the dielectric constant after antigen–antibody binding events is frequently the limiting factor in sensitivity for SPR biosensors based on SPPs, as the change in dielectric constant due to the presence of a few – or small – (bio)molecules may be rather limited. In a hybrid approach, the metal surface of the SPR sensor is modified with an immobilized antibody followed by antigen exposure. To further improve the signal strength, the sensor is then exposed to an antibody-conjugated Au NP solution. The presence of Au NPs near the SPR sensor metal film significantly enhances the dielectric constant change, thereby resulting in higher sensitivity [11]. This method may be applicable for detection in immunoassays, DNA hybridization assays, protein conformation assays, or for analyzing nucleotide polymorphism with rather small sample amounts.

An alternative plasmonic measurement scheme is based on Rayleigh and Raman scattering at metal NPs for sensing and imaging purposes [9, 12–14]. Rayleigh scattering is a purely elastic process, that is, the wavelength of the incident radiation is not altered after scattering. In a Raman process, phonon absorption and generation is involved during scattering, thereby resulting in a wavelength shifting. El-Sayed and his group [9] have used Au NPs conjugated to ligands targeting cancer cell biomarkers for the detection and for imaging cancer cells by taking advantage of very strong Rayleigh scattering. The same methodology was later investigated for even treating cancers by photothermal therapy [9].

Raman spectroscopy is a molecularly highly specific detection technique, with SERS promising significant signal enhancements compensating the low optical efficiency of the Raman. Hence, the enhanced electric field provided by LSPRs at metal NPs significantly improves the Raman coupling efficiency [15–17]. By virtue of the inherent molecular specificity, metal NP-based Raman spectroscopy is complementary to LSPR assays, which has the advantage of high sensitivity and molecular selectivity on the same sensing platform.

A final LSPR biosensing scheme is based on spectral shifting of LSPRs resulting from the dielectric constant change due to the binding event between target biomarkers and appropriate immobilized receptors. While this scheme, similar to colorimetric sensors based on NP–NP coupling, takes advantage of the fact that the LSPR is shifted, one signal is caused by a dielectric constant change due to the biomarker binding event, while the other results from coupling of NPs themselves because of the presence of biomarkers. The group of Van Duyne [18] has developed nanostructured LSPR biosensors to detect amyloid-beta-derived diffusible ligands (ADDLs), a biomarker for Alzheimer's disease, from human brain extracts by LSPR shifting caused by a dielectric change because of the binding event.

46.3
Mid-Infrared Optical Sensors

MIR absorption spectroscopy in the 3–20 μm wavelength regime is characterized by high sensitivity and inherent molecular selectivity, due to sharp optical transitions via efficient direct phonon coupling, and the particular benefit of the ''fingerprint'' region enabling *ad hoc* molecular identification. The unique features of MIR absorption spectroscopy render sensing MIR schemes highly suitable for analyzing multiple analytes, that is, panels of biomarkers, at trace levels with minimal or in the absence of time-consuming sample preparation steps such as, for example, labeling. Mizaikoff and coworkers [19–21] have shown the detection of multiple analytes at trace levels by combining Fourier transform infrared spectroscopy (FT-IR) with hollow-core waveguide sensing modules for gas-phase analytes, or with solid-core fiberoptic or planar waveguides for liquid-phase analysis in many different application scenarios.

MIR absorption spectroscopy appears to be an ideal complementary platform for the detection of biomarkers in medical diagnostics, with the analysis of EB and exhaled breath condensate (EBC) among the most promising clinical fields of application [22]. EB is known to contain more than 1 000 different volatile organic compounds (VOCs) [23–29]. The blood matrix propagates many organic and inorganic compounds as a result of complex metabolic reactions, physiological and pathogenic processes, or pharmacologic responses. Many of these constituents may permeate across the alveolar membrane, thereby ending up in the EB matrix. While the correlation between the VOCs in EB and many distinct disease conditions or physiological reactions is not yet fully understood, some relations between EB composition and certain physiological conditions are already well established. Acetone is among the earliest and most studied VOCs in EB with respect to its potential for diagnostic detection and progression monitoring [30–32].

For example, patients suffering from diabetes show significantly altered acetone levels in their EB, as diabetes mellitus is a metabolic disorder causing higher glucose concentration, and thus, extensive lipolysis [33]. Diabetes increases the concentration of ketones in the blood including, in particular, acetoacetate, 3-β-hydroxybutyrate, and acetone, which result in elevated concentrations of acetone in EB.

As another example, the so-called breath methylated alkane contour (BMAC) appears to have potential as a biomarker for breast cancer [33]. A research team led by Phillips [34] reported breast cancer prediction with 88.2% sensitivity and 73.8% specificity by analyzing BMAC of C4–C20 alkanes and monomethylated alkanes with the aid of fuzzy logic algorithms. Breast cancer causes an increase in oxidative stress, and initiates the expression of polymorphic cytochrome P-450 mixed oxidase enzymes (CYP). Oxidative stress triggers lipid peroxidation of poly-unsaturated fatty acids, thereby resulting in alkanes and methylalkanes, while CYP contributes to the catabolism of these constituents. Therefore, the combined effect of oxidative stress and CYP significantly changes the alkane group profile, which may be of high diagnostic value. The same research group later improved the selectivity and specificity of these studies by additionally analyzing different VOCs with similar methods [35], and identified 2-propanol, 2,3-dihydro-1-phenyl-4(1H)-quinazolinone, 1-phenyl-ethanone, heptanal, and isopropyl myristate as biomarkers of breast cancer, even though their biological functionality is not yet fully understood.

For lung cancer, a diagnostic panel of 22 breath VOCs has been identified, which mainly consists of alkanes, alkane derivatives, and benzene derivatives with high sensitivity and specificity [36]. Furthermore, lung cancer has been diagnosed by detecting different combinations of VOCs, which comprise BMAC, C4–C20 alkanes, and monomethylated alkanes [37].

Furthermore, a variety of VOCs have been used to diagnose respiratory infection and inflammation.

Table 46.1 summarizes a selection of well-known biomarkers found in EB, and the corresponding disease conditions. As VOCs in EB are the ‘‘projection image’’ of constituents also present in the blood matrix, valuable information is provided to noninvasively diagnose the physiological status of the organism.

Recently, a number of efforts have focused on the application of MIR spectroscopy and sensing schemes to human EB analysis for the identification of diseases [26, 38, 39]. The group of Mizaikoff [21] has constructed MIR broadband gas sensing systems based on FT-IR spectrometers, a 1 m long hollow-core waveguide gas cell, and a mercury-cadmium-telluride (MCT) detector, thereby successfully demonstrating simultaneous multianalyte sensing with detection sensitivities of 15.8 ppb for CO_2 and 517 ppb for CH_4. This broadband MIR absorption sensing system requires only ∼1.5 ml of sample for analysis, which is ideally suited for small EB samples. The advantage of the MIR broadband sensing system is the wide spectral coverage, so that most VOCs in EB can be simultaneously addressed. However, the broad spectral band results in limited energy density per wavelength, and thus, limited sensitivity for target analysis.

In order to improve the sensitivity for selected constituents, compact semiconductor MIR lasers are used as light source. While trading in spectral bandwidth and, to a certain extent, multicomponent detection capability, increased sensitivity within a narrow spectral band is gained using narrow bandgap heterostructure semiconductor laser diodes or quantum cascade lasers (QCLs).

Narrow bandgap semiconductor laser diodes are usually made of lead salt materials or IV–VI compound semiconductors, which generate photons by radiative recombination of electrons from the conduction band, and holes from the valence band. The emitted photon wavelength is compatible with the energy gap between the conduction band and the valence band. The operational principle of QCLs is

Table 46.1 Diseases and associated biomarkers commonly found in exhaled breath and exhaled breath condensate.

Disease/health status	Biomarker in EB	Biomarker in EBC
Breast cancer	BMAC, pentane, formaldehyde	—
Lung cancer	BMAC, NO, acetaldehyde	H_2O_2, nitrite
Asthma	NO, CO	H_2O_2, leukotriene E4, isoprostanes, TBARs

quite different from such conventional laser diodes, and had already been suggested by Kazarinov and Suris in the 1960s; experimentally, the first QCL was demonstrated in 1994 by Capasso and his colleagues at the Bell Laboratory [40, 41]. In QCLs, the conduction band consists of several repeating intersubbands, which are engineered by designing appropriate quantum well heterostructures. Electrons in the upper intersubband are forced into the lower intersubband, thereby generating MIR photons whose energy is compatible with the energy difference between the upper and the lower intersubband. As QCLs are usually composed of several cascaded stages, each electron may generate several photons depending on the number of cascades present in the device. Simplified energy band diagrams for bandgap diode lasers and QCL are illustrated in Figure 46.3a,b.

Roller *et al.* [38] have constructed a tunable diode laser absorption spectroscopy (TDLAS) sensing system utilizing IV–VI narrow bandgap MIR diode lasers with an emission wavelength of 5.2 μm combined with a 107 m long multipass White cell to quantitatively detect NO and CO_2 in human breath for the diagnosis of asthmatic conditions in EB, as shown in Figure 46.4. Similar measurement techniques have later been applied in veterinary medicine by analyzing EB from animals. Although narrow bandgap semiconductor laser diodes have shown initial success in EB analysis, and have contributed to the first steps toward miniaturization of MIR sensor systems, they have several disadvantages. They usually require cryogenic temperatures (15–80 K) for operation, and their emitted optical power is usually

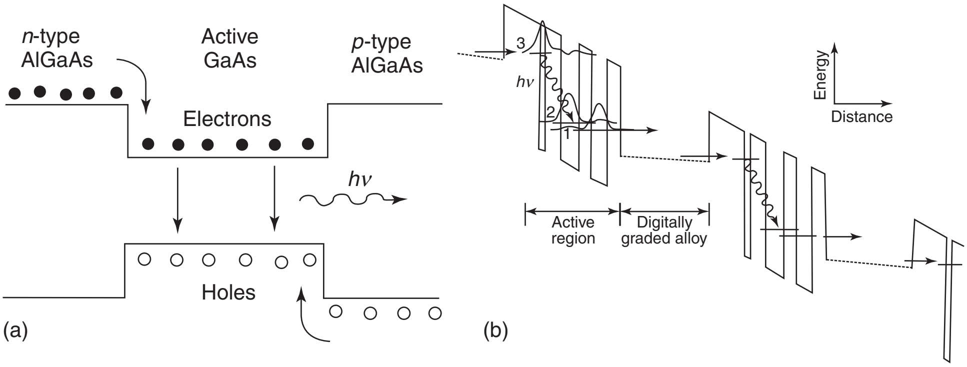

Figure 46.3 Photon generation schemes in conventional bandgap laser diodes (double heterostructure), and in quantum cascade lasers (QCL). (a) In a double heterostructure laser diode, a relatively narrower bandgap layer is sandwiched by a p-type and an n-type layer. The double heterostructure laser diode is under forward bias during operation; the p-type layer supplies holes to the valence band of the active region, while the n-type layer supplies electrons to the conduction band of the active region. Electrons and holes in the active region recombine, resulting in the emission of photons with an energy compatible to the bandgap of the active region. For MIR emission, IV–VI semiconductors are usually applied [42]. (b) In QCLs, the conduction band structure of active regions and injection regions (digitally graded alloy) is schematically shown. The digitally graded alloy region also consists of several quantum wells (superlattice) with the fine structure omitted for simplicity in this diagram. QCL may consist of >20 active regions separated by injection regions. The active region has three coupled quantum wells forming several delocalized electron eigenstates. Optical transitions from level 3 to level 2 release photons within the active region. The electrons in level 1 tunnel through the potential barrier of the injector region, and are transferred to level 3 of the next active region [41]. low, that is, in the range of several milliwatts. Furthermore, their beam quality is not consistent, and because of material limitations, which are governed by the bandgap of the materials and thus difficult to engineer, the entire MIR spectral range is not covered. While the need for cryogenic cooling adds to the technical complexity of the sensing system, the rather low optical output power limits the detection sensitivity of the system and requires either the detection of biomarkers present at acceptable concentration levels, or additional preconcentration schemes. Furthermore, limitations in emission wavelength due to the material restrictions prevent access to certain biomarkers with absorption peaks within these spectral ranges.

Some of the main disadvantages of conventional narrow bandgap semiconductor lasers have recently been overcome by QCLs. Meanwhile, a wide variety of studies have demonstrated superior sensitivity and selectivity in gas sensing applications using QCL light sources in combination with types of gas cells and at different laser tuning ranges. Mizaikoff and coworkers [43] have reported the detection of 30 ppb ethyl chloride from a 1.5 ml sample volume with an integrated MIR sensing system using a 1 m long photonic bandgap optical fiber serving as the waveguide and as the miniaturized sample cell and a QCL with a lasing wavelength of 10.3 μm, as described in Figure 46.5.

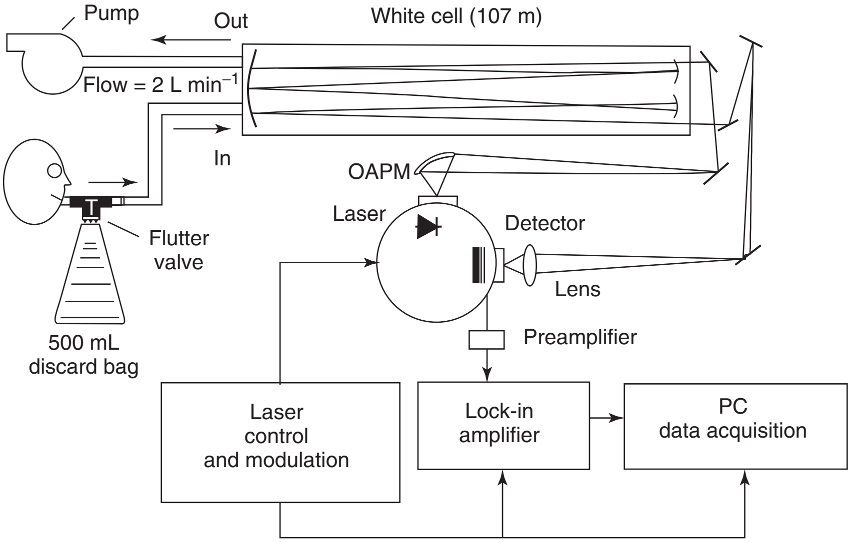

Figure 46.4 Diagram of an exhaled breath (EB) analysis system by Ekips Technologies, Inc. The system consists of a tunable MIR diode laser made from narrow bandgap semiconductor materials, a multipass gas cell in a White configuration, and a cooled detector [38].

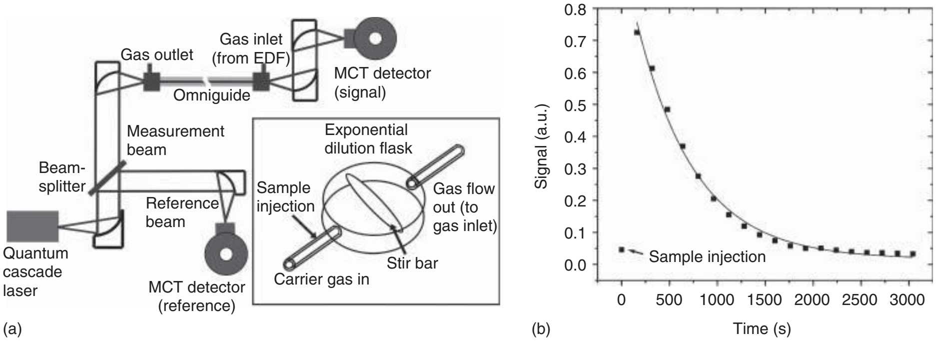

Figure 46.5 (a) Diagram of a gas sensing system comprising a room-temperature-operated QCL with a lasing wavelength of 10.3 μm, and a 1 m long photonic bandgap hollow waveguide with a transmission window matched to the QCL emission [43]. The inset shows an exponential dilution chamber. (Reproduced with permission from [43] copyright © 2005 AIP Publishing LLC.) (b) Experimental results determining the LOD for ethyl chloride at approximately 30 ppb via exponential dilution.

Tittel *et al.* [44] have shown the applicability of tunable laser absorption spectroscopy (TLAS) sensing system to detect approximately 30 ppb carbonyl sulfide (COS), which is a biomarker for failure of the liver function and acute lung transplant rejection. The TLAS sensing system comprises a thermoelectrically cooled QCL lasing at 4.86 μm, and an optical multipass gas cell providing 36 m absorption path length.

QCLs coupled with integrated cavity output spectroscopy (ICOS) sensing systems have detected approximately 3.6 ppb NO, and 15 exhaled human breath samples were tested with this device [45].

While the application of MIR lasers for detecting biomarkers has been proved successfully with regard to sensitivity, it remains critical to match the emission wavelength of the laser with the absorption peak of the target analyte for optimized sensitivity and selectivity. Consequently, the capability of tuning the emission wavelength of the laser deliberately within a certain spectral range is vital for improved selectivity and multicomponent analysis. Therefore, tunable MIR laser diode spectroscopy systems have the potential of serving as miniaturized spectrometers with high sensitivity and adequate discriminatory power for multiple constituents. While the lasing wavelength of semiconductor laser diodes including QCLs usually tunes with temperature or injected current, the tuning ranges thus achieved are limited to a few wavenumbers. An alternative strategy to tuning is to use a parallel array of fixed wavelength MIR semiconductor lasers with different lasing wavelengths, thereby establishing a quasi-broadband coherent MIR radiation source [46, 47]. However, the most effective way to achieve wide tunability is the construction of external-cavity quantum cascade lasers (EC-QCLs), where external-angle-tunable gratings provide wavelength-selective feedback to the coupled QCL [48, 49]. Figure 46.6 shows a diagram of an EC-QCL and its tunable lasing characteristics. In this configuration, continuous tuning over 250 cm^{-1} has been achieved [50]. Young *et al.* [51] have constructed a gas sensing module comprising an EC-QCL and a hollow-core waveguide, thereby achieving multianalyte sensing with excellent sensitivity. It was possible to achieve LODs as low as 4 ppb for ethyl chloride, 7 ppm for dichloromethane, and 11 ppb for trichloromethane by precisely tuning the lasing wavelength of EC-QCL to the Q-branch of each analyte absorption peak.

Another interesting MIR sensing technique is photoacoustic spectroscopy (PAS) coupled with QCLs [52, 53]. PAS takes advantage of a different signal transduction

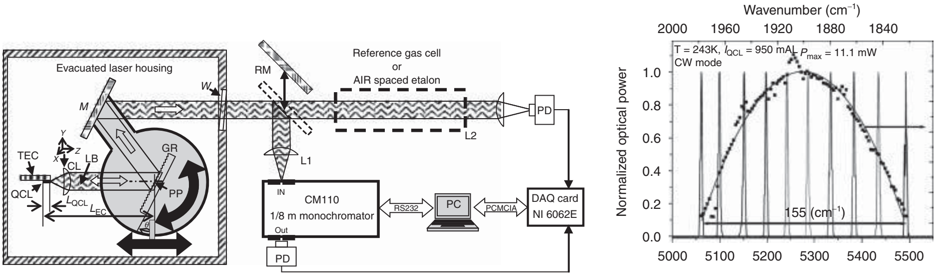

Figure 46.6 (a) Schematic of a typical tunable EC-QCL setup with thermoelectric cooler (TEC), diffraction grating (GR), and pivot point (PP) of the grating rotation [50]. (Reproduced with permission from [50] copyright © 2008 Springer Science & Business Media.) (b) Tuning characteristics of a tunable EC-QCL with a laser emission centered at 5.3 μm; the EC-QCL is operated in cw at 950 mW.

scheme compared to MIR absorption spectroscopic sensing. In PAS, modulated MIR radiation is absorbed by the target analyte similar to conventional absorption spectroscopy. However, instead of directly detecting the remaining intensity of the radiation after absorption, PAS takes advantage of the fact that modulated MIR radiation leads to the periodic excitation of vibrations of the absorbing molecules, thus giving rise to an oscillating pressure wave, if the sample is enclosed in a resonant or nonresonant cell. This modulated pressure change generates an acoustic wave, which may be detected by a microphone(s) or by a quartz tuning fork(s) without the need for an optical detector [42]. There have been several reports about achieving ultralow detection levels of analytes in air at the parts-per-billion (ppb) to parts-per-trillion (ppt) concentrations using this scheme [53–56].

For example, QCL-PAS sensing systems were able to detect ammonia, a biomarker for asthma, to levels of 66 ppb [54]. The introduction of a quartz-tuning-fork-enhanced PAS system has considerably increased the sensitivity, and the degree of miniaturization for such devices [57]. The typical dimensions of a quartz tuning fork are in the range of approximately 1 mm^3, such that the overall device footprint can be as small as approximately 5 mm^3. Therefore, quartz-enhanced photoacoustic sensors (QEPASs) only require small volumes of a gas sample, which is again ideal for EB analysis. A small device footprint is particularly important for handheld diagnostic applications such as, for example, posthospitalization therapeutical progress monitoring, and biohazard exposure monitoring in work places.

While gas cells and hollow-core waveguides serve as excellent transducers for gas phase analytes, solid-core optical fibers, planar waveguides, channel waveguides, or advanced photonic structures such as, for example, disk or ring resonators are the transducers of choice for liquid- or solid-phase analytes. Especially in medical diagnostics, several types of bodily secretions and constituents of the human body exist as forms of liquid and solid. However, the interaction mechanism of transducers is quite different from that of the gas-phase analyte. In the gas cell or hollow-core waveguide, the gas-phase sample and MIR radiation are simultaneously present inside the transducer, such that MIR radiation and target analyte molecules directly interact. Solid-core optical fibers or planar waveguides confine MIR radiation inside the waveguide by forming a guided mode due to total internal reflection (TIR), while the liquid or solid or liquid-phase analytes reside at the surface of the optical waveguide. However, radiation may interact with analytes at or close to the waveguide surface via evanescently guided modes emanating at the waveguide surface, if the internally reflected radiation is incident at the waveguide/adjacent medium interface below the so-called critical angle, and if the refractive index of the adjacent medium is smaller than the refractive index of the waveguide material. Therefore, analyte molecules need to be present within the penetration depth of the evanescent field, which, in the MIR, extends a couple of micrometers into the adjacent medium. Solid-core optical fibers or planar waveguides are composed of MIR transparent materials such as, for example, GaAs, chalcogenide glass, or silver halides [58]. Although such solid-core waveguides are efficient MIR transducers, the sensitivity may be considerably enhanced by coating the waveguide surface with appropriate enrichment membranes or molecular recognition structures. An enrichment membrane may increase the concentration of target analytes compared to the concentration in the native samples by several orders of magnitude, if the partition coefficient favorably facilitates diffusion of the analyte(s) into the enrichment matrix. Such signal enhancement strategies lead to significantly higher detection sensitivity, and may also reduce interferences of other matrix constituents. In particular, for the MIR regime, hydrophobic enrichment membranes reduce water interferences within the evanescent field, thereby further facilitating the detection of trace constituents such as, for example, small organic molecules in the aqueous matrix. Water is among the most prominent interferants in MIR absorption spectroscopy owing to its pronounced dipole moment giving rise to strong MIR absorptions.

Liquid- and solid-phase MIR sensing systems utilizing QCLs as a compact MIR light source and silver halide [20] or GaAs/AlGaAs [59] waveguides as the transducer have successfully detected precipitated solid-phase urea samples at 80.7 μg, and solution concentrations of 10.8 μg of acetic anhydride in 0.01 μl of acetonitrile, as shown in Figure 46.7. These fundamental studies are considered

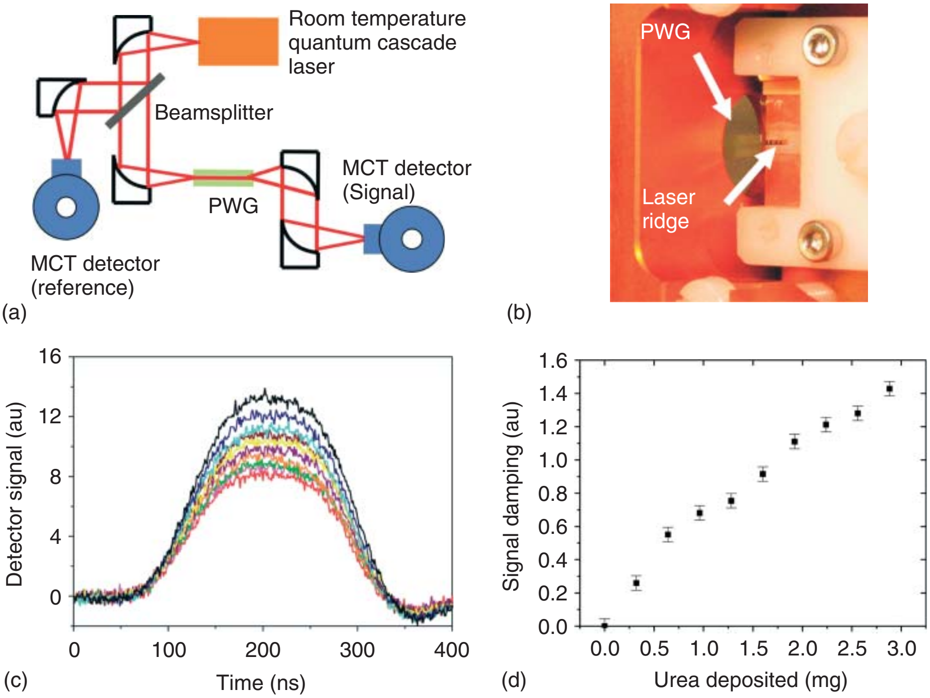

Figure 46.7 (a) Diagram of solid-core waveguide sensing system for liquid- and solid-phase analytes. the first proof-of-concept for MIR absorption spectroscopy sensing systems with sufficient sensitivity applicable to bodily secretions including, for example, EBC, urine, interstitial fluid, or saliva. EB not only contains VOCs but also nonvolatile organic compounds, which provide relevant information on the physiological status of an organism. Such nonvolatile compounds are usually collected as EBC at a cooled surface for further analysis [60, 61]. Usually, patients suffering from asthma, chronic obstructive pulmonary disease (COPD), or cystic fibrosis (CF) show markedly elevated concentrations of H_2O_2, leukotrienes, lipid peroxidation products, and isoprostanes in EBC, which are considered biomarkers of oxidative stress [62, 63]. Nitric oxide metabolites in EBC have also been used as biomarkers for airway inflammation in asthma, CF, COPD, and adult respiratory distress syndrome (ARDS) [64–67]. EBC is less researched than VOCs in EB despite its potential for medical diagnostics, predominantly as analysis methods are comparatively cumbersome. Recently, increased research efforts adopting microfluidics, optofluidics, and advanced photonic structures such as, for example, photonic crystals or microdisk/ring resonators for further miniaturization and enhanced sensing performance may provide a viable solution for direct analysis of EBC constituents utilizing lab-on-chip or monolithically integrated devices [68–71].

For example, the research team of Capasso [69] has achieved a detection sensitivity equivalent to a 170 μm thin absorption cell for a liquid-phase sample with a volume of approximately 10 pl using a sensing platform a few hundreds of micrometers in size. An intracavity absorption spectroscopic device using a narrow ridge microfluidic QCL with a 9 μm laser emission was established, as shown in Figure 46.8a,b.

Loncar *et al*. [70] have developed photonic crystal QCLs combined with an optofluidic structure, which is suitable for miniaturized liquid-phase chemical sensing, as shown in Figure 46.8c,d. Consequently, advanced MIR photonic sensors provide a promising platform for molecularly selective analysis of clinically relevant samples, and are certainly among the most attractive optical sensing techniques once advanced photonic structures are readily available.

46.4
Terahertz Optical Sensors

In the past decade, the THz spectral range has attracted increasing interest for many applications including biological analysis and biomedical diagnostics [72–74]. However, as THz spectroscopy has been less explored compared to any other spectral regime of analytical interest, the relevant device technologies including light sources, waveguides, and detectors are less developed. This also reflects in the expression ‘‘THz gap’’ referring to the difficulty in accessing this spectral regime from a device optics and electronics point of view. However, recent progress in THz technology has significantly revitalized this field and promises the transition of THz spectroscopy from a niche technology to a bioanalytically relevant tool.

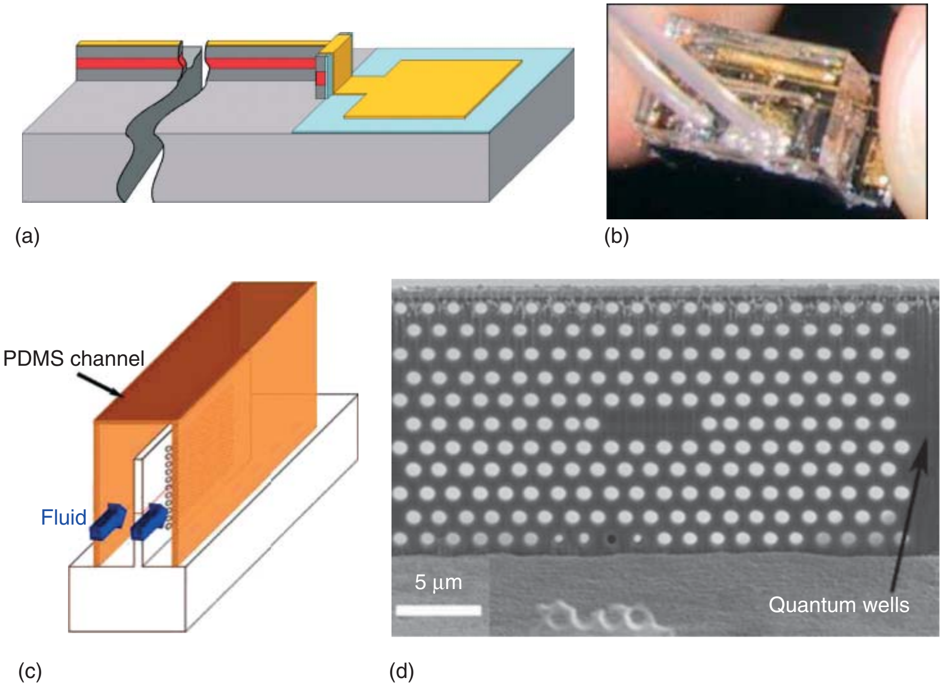

Figure 46.8 Advanced miniaturized photonic sensors. (a) Diagram of a narrow-ridge waveguide QCL for intracavity absorption spectroscopy [69]. (b) Optical image of a QCL intracavity absorption spectroscopic sensor with microfluidic liquid channels connected to tubing [69]. (c) Diagram of a photonic crystal QCL with microfluidic analyte guiding channel [70]. (d) SEM image of a photonic crystal waveguide microfabricated by focused ion beam milling [70].

While there is no strict definition of the THz spectral range, it is usually considered to cover the frequencies from 0.3 THz (1 mm or 10 cm^{-1}) to 3 THz (100 μm or 100 cm^{-1}); however, occasionally the FIR region from 20 to 100 μm is included into the THz regime. With respect to (bio)sensing applications, several research groups have recently applied THz spectroscopy for protein folding, label free detection of DNA hybridization, general disease diagnostics, monitoring of receptor binding events, dental diagnostics, and medical imaging [74–76]. Before discussing details of THz biomedical or medical diagnostic applications, it is essential to highlight the unique nature of THz radiation compared to more commonly applied UV/Vis/NIR or MIR radiation, and the consequences of these unique properties for biomedical applications.

The energy of THz radiation matches well with the phonon energy associated with macromolecules at different conformational states, which implies that useful resonances should be available for molecular studies. Owing to the long wavelength, less scattering and more penetration depth are anticipated with typical spatial resolution of approximately 170 μm at 1 THz. Finally, the photon energy of THz radiation is far below the ionization energy (4 meV at 1 THz), thus ensuring minimal effects on the probed molecules.

Consequently, THz radiation appears particularly suitable for studying biological samples or organisms given the opportunity of addressing a variety of biologically relevant macromolecules including proteins, RNA, and DNA, as THz radiation provides an efficient optical window to monitor conformational or structural changes, or binding events of such macromolecules. However, it should be noted that water vapor and liquid water are highly absorptive in the THz regime, that is, the absorption coefficient of liquid water varies from 100 to 1000 cm^{-1} [72]. Although some of the water absorption peaks are not yet firmly assigned, it is evident that THz radiation is efficiently absorbed via intramolecular vibrational and rotational modes, as well as intermolecular vibrational modes associated with hydrogen bonds [73]. The high absorptivity of THz radiation by water plays an important role in biomedical applications, and renders imaging or tomographical applications for visualizing, for example, the human body rather challenging. However, by taking advantage of the strong absorption of water, it is indeed feasible to image tissues utilizing their water content as contrast mechanism, which is difficult to obtain with other spectroscopic techniques.

For example, THz images utilizing the tissue water content provide a discrimination between, for example, muscle from adipose tissues, and tumors from normal tissues [77]. By virtue of the deep penetration ability, such images may carry information not only from the tissue surface but also from the bulk material. The low energy of THz radiation is ideal for noninvasive diagnostics with minimal risk of ionization.

From the instrumental perspective, there are different schemes for generating THz radiation. Initially, the photoconductive method developed by Auston in 1975 at the Bell Laboratory was predominantly used for THz radiation generation and detection [78, 79]. In this scheme, EM pulses in the THz range are generated during acceleration of electrons in the conduction band of a semiconductor material such as, for example, GaAs. During this process, ultrashort laser pulses with photon energies higher than the bandgap of the semiconductor material are propagated between two electrodes on the semiconductor material, while a DC bias voltage is applied to the electrodes. The applied DC bias voltage accelerates electrons that are photoexcited by the ultrashort laser pulses into the conduction band. A typical setup is shown in Figure 46.9 [74]. This type of THz source may generate broadband radiation up to 5 THz.

Another interesting paradigm is based on nonlinear optical frequency generation such as, for example, different frequency generation (DFG) or optical parametric oscillation (OPO). Both techniques do not directly generate THz radiation, but convert a fundamental pump laser beam in the Vis/NIR range to THz radiation via nonlinear optical processes. Optical crystals without structural inversion symmetry are able to generate EM radiation (ω_1, idler) from a pump beam (ω_3, pump) with or without another input beam (ω_2, signal) utilizing the second order nonlinear optical coefficient $\chi^{(2)}$, which is referred to as *DFG* (with ω_2 external input) or

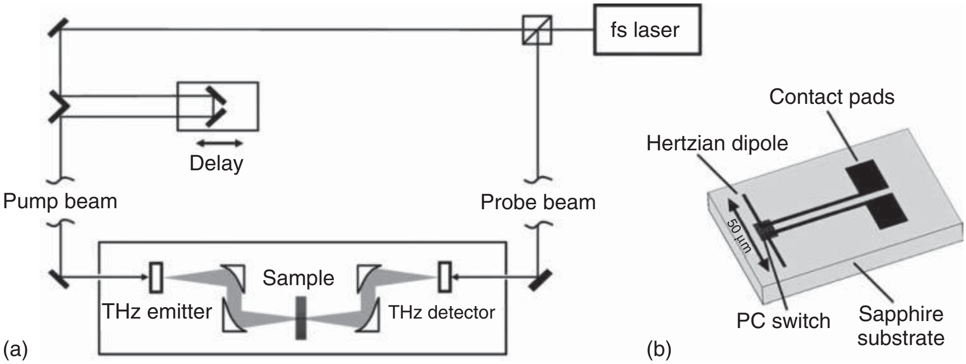

Figure 46.9 (a) Diagram for THz radiation measurement and (b) photoconductive Aston THz switch [74].

OPO (without ω_2 external input), respectively. Typical nonlinear optical crystals are GaAs, $LiNbO_3$, $LiTaO_3$, potassium titanyl phosphate (KTP), or organic nonlinear materials. The relationship among the three involved lightwaves follows energy conservation and momentum conservation:

$$\hbar\omega_1 = \hbar\omega_3 - \hbar\omega_2$$

$$\Delta k = k_1 + k_2 - k_3 = 0$$

$$P(\omega_1 = \omega_3 - \omega_2) = 2\chi^{(2)} E_3 E_2^*$$

The main benefit of frequency down-conversion is the fact that readily available laser light sources with appropriate output power, beam quality, and so on may be applied and converted to the THz regime, where only a few compact high-power coherent light sources are currently available [80, 81].

Another important scheme for direct generation of THz radiation are QCLs, which have been described in the section on MIR optical sensors. QCLs are already considered the most advanced light source for MIR radiation, and may be tailored toward THz emission by reducing the energy gap of the intersubbands. Recently, cw THz emission from QCLs was demonstrated at 66, 87, and 100 μm [82–85]. While QCLs are still predominantly applied in the MIR to FIR radiation regime, recent progress on THz QCLs promises coherent compact semiconductor light sources at these long wavelengths.

Nagel *et al.* [86] recently demonstrated DNA detection with THz biosensors. As THz radiation resonates well with different vibrational modes of the DNA molecular backbone, a potential sensing platform for label-free monitoring of DNA binding is provided. As an advancement, biosensors based on ring resonators with integrated THz waveguides coupled with two photoconductive switches, as shown in Figure 46.10, have demonstrated 5 orders of magnitude higher sensitivity compared to the free space version [74].

Probably the first application of THz radiation for medical diagnostics was the detection of early dental caries by THz imaging [87]. In dental caries, mineral is lost

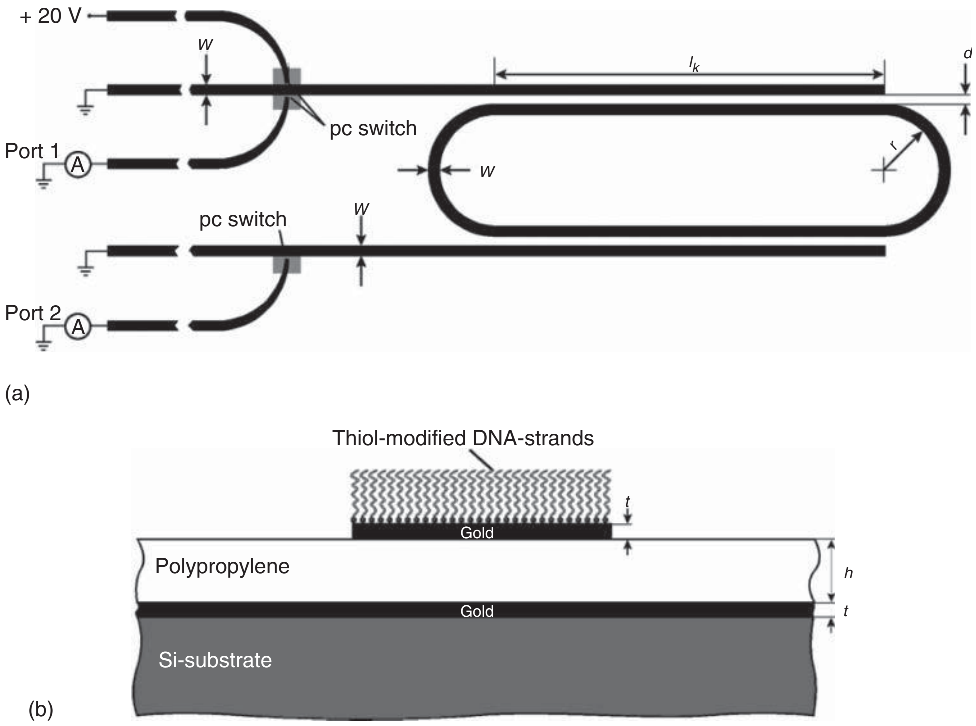

Figure 46.10 Diagram of integrated photonic THz biosensors [74]. (a) Top view of an integrated photonic THz biosensor with racetrack resonator. (b) Cross-sectional view of the device. Top and bottom gold films at the polypropylene layer form thin-film microstrip-style THz guiding structures. The racetrack resonator acts as a filter for THz radiation, which may couple to the detector side only if a resonating mode is formed mediated by the binding event of the target analytes.

from the enamel, which results in a change of the refractive index. THz radiation may noninvasively locate dental caries by imaging using refractive index changes of enamel as a contrast mechanism.

Similar strategies have been applied to investigate the human skin and the human breast for the detection of cancers [88]. Cancer cells and other malignant tissues have different refractive indices and attenuation coefficients compared to healthy tissues, thus providing contrast mechanisms for imaging in the THz regime. Table 46.2 summarizes related results for the THz spectral range. Figure 46.11 compares a visible image and a THz image of the same tissue area containing carcinoma. In this case, a photoconductive emitter was used as the THz light source operated in pulsed mode. Given recent progress in THz QCL technology, similar THz images obtained for a rat brain using a QCL emitting at 3.4 THz indicate the future potential of this technology based on advanced light sources, as shown in Figure 46.12 [89].

Table 46.2 Absorption coefficient (α) and refractive index (n) of healthy and abnormal tissues in the THz spectral regime [73].

	α (mm^{-1})		n	
	0.5 THz	1 THz	0.5 THz	1 THz
Normal skin	11.0	16.8	2.20	2.06
BCC	13.1	19.3	2.26	2.09
Normal breast	10.5	16.4	2.01	1.90
Breast carcinoma	12.5	18.6	2.23	2.08
Breast adipose	1.3	2.2	1.56	1.54
Water	16.3	23.0	2.28	2.09

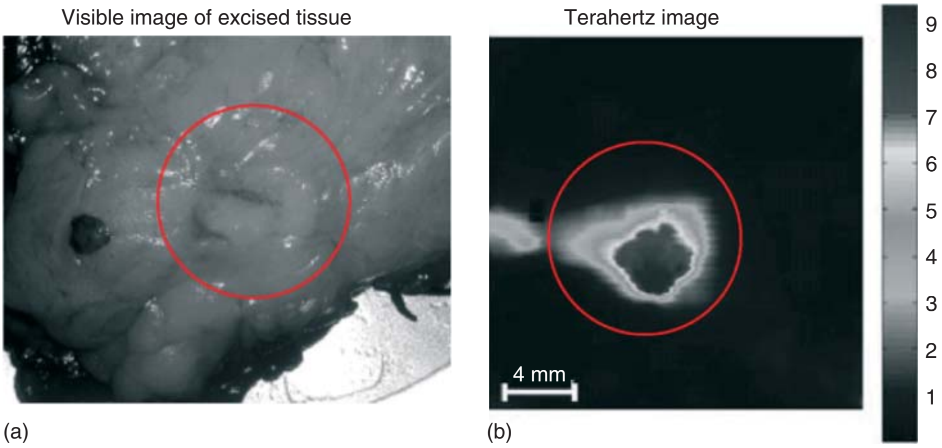

Figure 46.11 (a) Visible image versus (b) THz image of invasive lobular carcinoma (circled area) from a 52-year-old patient [73]. The THz radiation source was a photoconductive Aston switch.

46.5
Conclusions and Outlook

Medical diagnostics are among the fastest growing application areas for optical sensor technologies, especially if miniaturized devices provide access to a wide variety of measurement scenarios. Here, the current status of selected advanced optical sensor technologies has been summarized in reference to the EM spectrum from the UV/Vis/NIR to THz regime. Each spectral range provides individual merits, if appropriate optical sensor technology is applied to address (bio)medically relevant questions. Furthermore, it is evident that the optical sensor technologies presented are at significantly different levels of maturity, thus requiring continuous effort in research and development for transitioning promising laboratory or prototype concepts into the clinical reality.

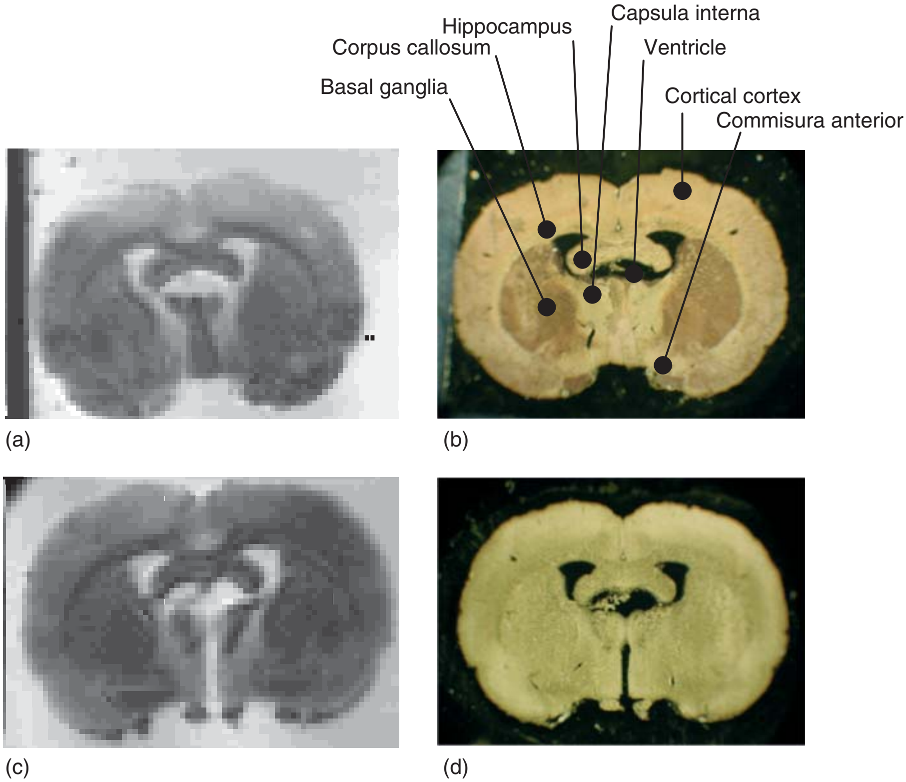

Figure 46.12 Images with (a,b) visible light source and (c,d) THz light source of the frontal section of a rat brain [89]. THz light source was a semiconductor QCL with an emission frequency of 3.4 THz.

While some of the optical (bio) sensor technologies discussed are still at a research stage, SPR-based biosensors using SPPs are already commercially available, and are routinely applied in clinical settings for disease diagnostics. In addition, LSPR biosensors utilizing metal nanostructures have already been proved a successful strategy for detection and imaging of diseases such as, for example, cancers, and Alzheimer's disease. Finally, MIR plasmonics appears to be an emerging novel technology facilitating the combination of inherent molecular selectivity with the benefits of SPR sensing technology [90, 91]. Taking advantage of further signal enhancement via Rayleigh scattering or Raman scattering, it is evident that plasmonic sensors operating in the UV/Vis/NIR spectral range will continue their evolution among the most sensitive optical detection schemes in bioanalytics.

MIR absorption and PAS are among the most promising optical sensing techniques in medical diagnostics because of the inherent molecular selectivity along with high sensitivity [92]. MIR photons directly interact with organic and inorganic molecules via well-structured vibrational and rotational modes, thereby providing the opportunity for close to real-time medical diagnostics without any labeling. In particular, breath analysis appears among the most suitable application areas for MIR optical sensor [93–98]. Recent technological advancements including QCL light sources and thin-film waveguide transducers further accelerate the development of miniaturized MIR sensing techniques toward biomedical applications [99–101].

While the THz spectral regime has only recently attracted interest in bioanalytics and medical diagnostics, rapid progress in light source, detector, and waveguide technology promises an interesting analytical platform for label-free biomolecular analysis. The low photon energy, with no risk of ionization and resonances particularly with biomacromolecules, renders THz radiation an interesting label-free detection scheme for analyzing, for example, conformational changes or binding events of macromolecules such as DNA or proteins. Furthermore, THz imaging applications utilizing water absorptivity within tissues or refractive index changes resulting from tissue compositions as contrast mechanisms maximize the utility of optical sensing and imaging techniques within a possibly broad spectral band.

Tip-Enhanced Near-Field Optical Microscopy

Achim Hartschuh

47.1
Introduction

Fluorescence and Raman spectroscopy are powerful tools for the nondestructive analysis of sample materials providing detailed chemical, structural, and physical information (see Section II of this Handbook). Combined with microscopy, three-dimensional spatial maps with spectroscopic contrast can be constructed. On shrinking the sample dimensions down to the nanometer regime, both spatial resolution and signal detection sensitivity become crucial. However, as conventional microscopes rely on the detection of propagating waves, diffraction limits their spatial resolution to about half the wavelength. The main aim of nano-optics is to extend optical microscopy down to nanometer length scales below the limit imposed by diffraction. Nano-optical concepts are distinguished into far-field and near-field techniques. Far-field techniques rely on the detection of propagating waves at distances from the source larger than the wavelength of light while near-field techniques exploit short-ranged evanescent waves.

Near-field optical microscopy, initiated by the pioneering work of Pohl, Lewis, and others [1, 2] in the late 1980s and beginning of the 1990s, raised high expectations and gave access to nanoscale resolution for the first time. The history of near-field optics is reviewed in articles by Pohl and Novotny [3, 4]. In addition, numerous reviews and books exist describing fundamentals and applications (e.g., [5–10]). Here, we focus on recent developments of a particular type of near-field technique that is based on a laser-illuminated metal tip, termed tip-enhanced near-field optical microscopy (TENOM). TENOM is shown to be *the most powerful tool* for the optical characterization of surfaces not only providing superior spatial resolution down to 10 nm but also enormous signal enhancement.

This chapter is organized as follows: after this short introduction, the basic physical principles of evanescent and propagating waves are outlined. In the following sections the origin of electromagnetic field enhancement at a metal tip and schemes to utilize it for signal enhancement are described. Experimental realizations and recent examples for tip-enhanced Raman scattering (TERS) and tip-enhanced fluorescence (TEF), which highlight the capabilities of the techniques,

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

are reviewed. The summary reviews the main aspects of TENOM and addresses future prospects and remaining challenges.

47.2
Principles of Near-Field Optics

Near-field optics aims at overcoming the diffraction limit of optical imaging [11, 12]. Diffraction results from the formation of the optical far field by propagating waves, described as photons in a particle picture, for which $k_z = \sqrt{4\pi^2/\lambda^2 - k_x^2 - k_y^2}$ is real. Their evanescent counterparts with complex k_z dominate the near field of a radiation source or smaller distances z decaying according to $\exp(-|k_z|z)$. According to Heisenberg's uncertainty principle relating the spread in transverse momentum Δk_x and position Δx of a particle according to $\Delta k_x \Delta x \geq 2\pi$, the spatial resolution corresponding to Δx needs to remain finite. The spread in momentum of a focused beam can be expressed through $\Delta k_x = 2k_{x,\max} = 2|k| n \sin\alpha = 4\pi/\lambda n \sin\alpha$ with n being the refractive index, $\lambda = 2\pi/|k|$ the wavelength of light and the focusing angle α illustrated in Figure 47.1a. The resulting resolution limit of $\Delta x \geq \lambda/2\pi\, NA$ illustrates its dependence on the wavelength and the numerical aperture $\mathrm{NA} = n \sin\alpha$ of the microscope objective. Following Rayleigh's criterion for the spatial resolution the well-known equation $\Delta x = 0.61\lambda/NA$, can be derived [4, 11].

To overcome this limitation, both far-field and near-field concepts have been developed. A comprehensive review of the principles, progress, and prospects of high-resolution, far-field techniques is given in [13]. Near-field optical microscopy achieves high spatial information through interactions between the sample and a pointed probe mediated by the electromagnetic near field. Raster scanning

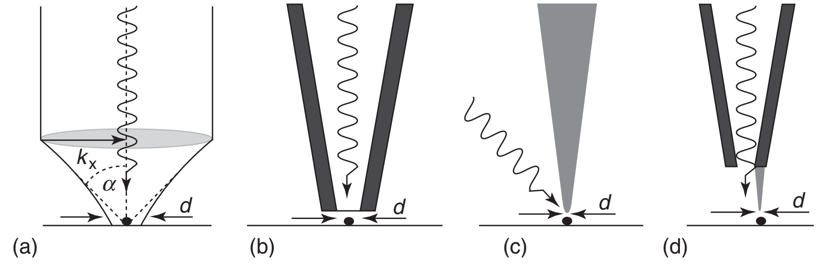

Figure 47.1 Focusing concepts: far-field focusing using a lens (a). The angular frequency range of propagating waves k_x and thus the focus diameter d is limited by the aperture angle α of the lens $k_{x,\max} = 2\pi n/\lambda \sin\alpha$, with n being the refractive index and λ the wavelength of light. (b–d) Near-field optical microscopy exploiting evanescent waves offers subdiffraction resolution limited only by the probe dimension d. In aperture-type scanning, near-field optical microscopy (aperture SNOM (b)), d is given by the aperture diameter. For tip-enhanced near-field optical microscopy (TENOM (c)) combining high spatial resolution and signal amplification, d corresponds to the tip diameter. Tip-on-aperture approach (TOA (d)) combining the advantages of (b,c) (Reprinted from Ref. [9]. Copyright 2008, with permission from Wiley VCH.)

the probe and simultaneous signal detection then allows for image formation. As higher spatial frequencies k_x, k_y are connected to faster exponential decay (see earlier definition of k_z), high-resolution imaging requires nanoscale probe-sample distances. As a consequence, near-field microscopy is limited to surface or subsurface studies or, in other words, the technique provides surface sensitivity. Four different focusing concepts are illustrated in Figure 47.1 including lens-based far-field focusing (Figure 47.1a), the widely used aperture-type approach (aperture scanning near-field optical microscopy(SNOM)) , Figure 47.1b], and tip-enhancement (Figure 47.1c,d) that is at the center of this chapter.

In TENOM, enhanced optical fields in the proximity of a sharp metallic probe are used to locally excite the sample and to extract the emitted light (Figure 47.1c). Shown in Figure 47.1d is the so-called tip-on-aperture (TOA) probe that combines the advantages of aperture-type and TENOM. The use of laser-illuminated metal tips for near-field imaging was suggested by Wessel in 1985 [14]. In general, three different approaches can be distinguished: (1) scattering-type microscopy [15–17] in which the sample response is detected in the far-field at the frequency of the incident light; (2) tip-enhanced nonlinear optical frequency generation and mixing such as second-harmonic generation (SHG) and four-wave mixing (4WM) [6, 18–21]; and (3) tip-enhanced microscopy that utilizes the locally enhanced fields to increase the inelastic spectroscopic response of the system [6, 7, 22–26]. Local signal enhancement not only serves to achieve high spatial resolution but also increases the detection sensitivity enormously. The technique is therefore applicable to weak emitters with low quantum yield and intrinsically weak signals such as Raman scattering. Moreover, the versatility of the technique allows the study of a variety of spectroscopic signals including local time-resolved fluorescence or Raman spectra. In this chapter, we focus on the third approach and refer the interested reader to the references listed for the other two approaches. The next section contains a brief theoretical description of field enhancement at a metal tip and how these fields modify the optical signals.

47.3
Field Enhancement at a Metal Tip

Field enhancement at metal structures is a phenomenon we encounter almost in daily life, forming the principle of a lightning rod, a radio antenna, and the coloring based on metallic nanoparticles. In fact, the three examples also illustrate the different contributions to field enhancement: the electrostatic lightning rod effect is caused by geometric singularities, leading to highly localized surface charge densities that also form the basis for field emission (Figure 47.2a). Surface plasmon resonances of metal particles reflect shape and dielectric properties, causing characteristic extinction spectra (Figure 47.2b). Antenna resonances become relevant if the length of the metal structure matches multiples of half the wavelength of radiation (Figure 47.2c) [26–28]. Antenna and plasmon resonances exhibit distinct wavelength dependencies, with pronounced maxima in

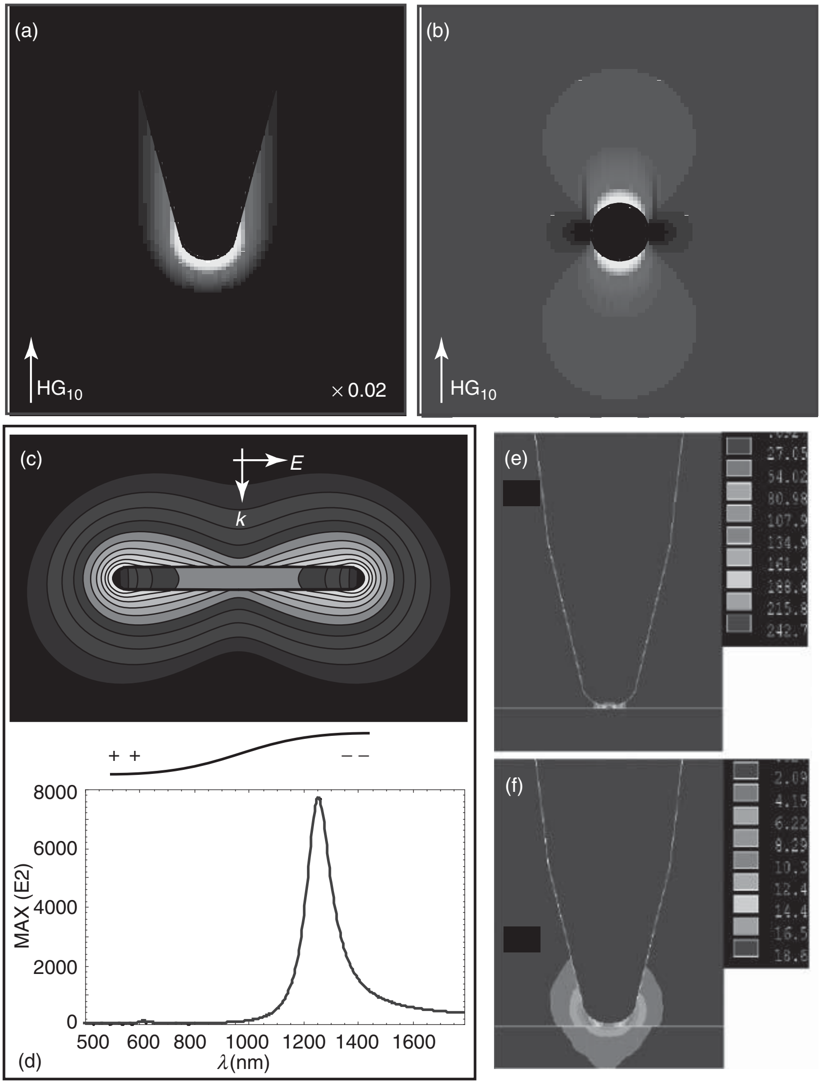

Figure 47.2 Field enhancement at nanostructures results from three different contributions. The quasistatic lightning-rod effect requires a geometric singularity and is observable for semi-infinite pointed probes (a). Surface plasmon resonances result from collective excitations of electrons reflecting both shape and dielectric properties of metal particles (b). In (a,b), calculated field distributions $|E_{local}(\mathbf{r},\omega)|^2$ near a gold tip (a) and sphere (b) located above a glass substrate and irradiated by an on-axis focused HG$_{10}$ laser mode are shown. (Reprinted from Ref. [30]. Copyright 2006, with permission from Annual Reviews. 3.) Antenna resonances occur when the tip length is related to an effective wavelength (c,d). (Reprinted from Ref. [31]. Copyright 2007, with permission from Elsevier.) Electric field enhancement and confinement at a metal tip is strongly increased for metallic (e) as compared to glass substrates (f). ((e,f) Reprinted from Ref. [32]. Copyright 2005, with permission from the American Chemical Society.)

the field intensity tunable through the visible spectral range, while the contribution from the electrostatic lightning rod effect depends on the conductivity of the material at light frequencies typically increasing toward the IR spectral range [27, 29].

Numerous theoretical studies have been presented in the literature, employing a variety of techniques to quantify the contributions from different field enhancement mechanisms and to find the optimum tip structure. The difficulty in describing metallic structures in the optical regime results from the fact that metals do not behave as perfect conductors at these frequencies. This leads to finite skin depth, that is, fields are not confined to surfaces, and ultimately results in deviations from the simple antenna theory. Another consequence is the formation of surface plasmon polaritons at the boundary between metals and dielectrics. The influence of tip shape and material on the field enhancement has been discussed in a series of publications with the aim of finding the optimum tip [31, 33, 34]. For simple tip structures, highest enhancement is predicted theoretically and verified experimentally to occur in the retarded regime, when antenna length is related to an effective wavelength [28, 35]. Results from different numerical techniques need to be compared quantitatively to assess technical difficulties and to maximize the impact of theoretical predictions [36].

From theory and experiments on surface-enhanced Raman scattering (SERS), it is evident that highest enhancement results for two or multiple particle configurations as realized by the combination of spheres, antennas, or in more complex colloidal aggregates [21, 35, 37–43]. Similarly, field enhancement is increased enormously for tips over metal surfaces [32, 44–46] combined with higher localization (Figure 47.2d,e). For samples covered by a thin dielectric layer, on the other hand, field enhancement is expected to drop rapidly [47]. The interaction between tip and sample substrate leads to surface- and distance-dependent spectral shifts of plasmon Resonances, complicating the quantification of field enhancement achieved in a particular configuration [48– 52].

Experiments using tips on metallic substrates revealed that fields are enhanced additionally by sub- or a few nanometer-sized surface features that are hardly observable in atomic force microscopy (AFM) images [51, 53] (see also Figure 47.8). In order to avoid roughness-related artifacts in TERS mapping, atomically smooth metal substrates are necessary for quantitative TERS imaging. For TENOM applications, maximized fields are not sufficient as they also have to be accessible in scanning probe configuration and therefore have to occur at the extremities of the particle or tip [28]. Moreover, the probe dimensions should be small as they directly determine the topographic resolution and the possibility of topographic artifacts resulting from tip–sample distance variations [54, 55].

Resulting field distribution and localized enhancement do not only depend on particle configuration and wavelength but also on the polarization state of the excitation light. To establish a strong field enhancement at tips formed by sharpened wires, the electric field of the exciting laser beam needs to be polarized along the tip axis [27]. Initially, field distributions are calculated for continuous-wave (cw)-excitation by plane waves. In the retarded regime, where light propagation becomes relevant such as in the case of extended antenna structures, tightly focused excitation or excitation with evanescent waves will lead to modified field distributions. Advanced approaches utilize surface plasmon propagation and retardation for field engineering. Chirp- and polarization-controlled laser pulses can be designed, and adaptive subwavelength control of nano-optical fields at metal structures has been recently developed into an efficient tool giving way to the field of ultrafast nano-optics [56–59].

47.4
Tip-Enhancement of Optical Signals

Although the enhanced electromagnetic fields are localized to the tip apex as discussed in the previous section and in Figure 47.2, the image contrast formed by raster scanning the sample does not simply reflect the tip shape. In other words, tip-enhanced optical imaging does not correspond to AFM with optical information. In particular, because Raman scattering and fluorescence are distinct optical processes involving different electronic states of the sample material with a different degree of coherence, the enhancement effects for either type of sample and thus the image contrast is expected to vary.

The enhanced fields at the tip lead to enhanced excitation rates corresponding to an increase in the excitation density provided by the light source. In general, the enhancement of the excitation rate k^{ex} will be identical for Raman scattering and fluorescence if electronic dephasing is not changed. By defining the field enhancement factor f as the ratio between the electric field at the tip $E_{\mathrm{tip}(x)}$ and without tip $E_0(x)$, the excitation rate enhancement is expressed as $k^{\mathrm{ex}}_{\mathrm{tip}}/k^{\mathrm{ex}}_0 = f^2$. In analogy with a radio, which can be used both as receiver and sender, the enhanced fields can also promote radiative decay expressed by the rate k^{rad}. Radiative rate enhancement can be discussed in terms of the Purcell effect and is expressed by Fermi's golden rule in the weak coupling regime [60, 61].

47.4.1
Enhancement of Raman Scattering

In the case of Raman scattering, the total signal depends on the product of the transition rates $k^{\mathrm{ex}}(\lambda^{\mathrm{ex}})k^{\mathrm{rad}}(\lambda^{\mathrm{rad}})$. As a consequence, the total signal enhancement scales with the fourth power of the field enhancement for small differences between the excitation and emission wavelength $\lambda^{ex,rad}$ and assuming that the field enhancement at the tip does not depend sensitively on the wavelength.

$$M_{\mathrm{Raman}} = k^{\mathrm{ex}}_{\mathrm{tip}}/k^{\mathrm{ex}}_0 \cdot k^{\mathrm{rad}}_{\mathrm{tip}}/k^{\mathrm{rad}}_0 \approx f^4 \tag{47.1}$$

For the general case of SERS, Raman enhancement factors are reported reaching up to 12 orders of magnitude for particular multiple particle configurations involving interstitial sites between particles or sharp protrusions on the outside surface [37, 62]. As the signal scales with the fourth power, the already moderate field enhancement, predicted for a single spherical particle to be in the range of $f = 2 - 5$, is sufficient for significant signal enhancement.

47.4.2
Enhancement of Fluorescence

The fluorescence intensity, on the other hand, depends on the excitation rate k^{ex} and the quantum yield η, denoting the fraction of transitions from excited state to ground state that give rise to an emitted photon. The quantum yield is expressed in terms of the radiative rate k^{rad} and the nonradiative rate k^{nonrad} through $\eta = k^{\text{rad}}/(k^{\text{rad}} + k^{\text{nonrad}})$. Accordingly, the fluorescence enhancement due to the presence of the metal tip can be written as

$$M_{\text{Flu}} = (E_{\text{tip}}/E_0)^2(\eta_{\text{tip}}/\eta_0) = f^2(\eta_{\text{tip}}/\eta_0) \tag{47.2}$$

Here, we assume that the system is excited far from saturation. From Eq. (47.2) it is clear that TENOM works most efficiently for samples with small fluorescence quantum yield η_0 and fast cycling rates such as, for example, semiconducting single-walled carbon nanotubes (SWNTs) [63, 64]. For highly fluorescent samples such as dye molecules, the quantum yield η_0 is already close to unity and cannot be enhanced further.

Because of the small separation between emitter and metal tip required for high spatial resolution (below 10 nm in typical experiments) nonradiative transfer of energy from the electronically excited molecule to the metal followed by nonradiative dissipation in the metal has to be taken into account. This process represents an additional nonradiative relaxation channel and reduces the number of detected fluorescence photons. While the theory of energy transfer between molecules and flat metal interfaces is well understood in the framework of phenomenological classical theory [65, 66], nanometer-sized objects are more difficult to quantify. Tip- and particle-induced radiative rate enhancement and quenching have been studied in literature theoretically [42, 61, 67– 70].

Experiments on model systems formed by single-dipole emitters such as molecules and semiconductor nanocrystals and spherical metal particles revealed a distance-dependent interplay between competing enhancement and quenching processes [71–75]. Besides amplifying emission signals, particle-induced radiative rate enhancement can also lead to a substantial spatial and spectral redistribution of the emission [52, 73, 76, 77]. Of major importance for the resulting radiative rate modification is the orientation of the emitter dipole with respect to the antenna structure [73]. While semiconducting tips will cause less efficient quenching [78, 79], they will also provided weaker enhancement because of lower conductivity at optical frequencies.

As signal enhancement and high spatial resolution are the result of near-field interactions between probe and sample as discussed earlier, TENOM spectra can differ substantially from their far-field counterpart. Large wave vectors k, for example, are expected to initiate optical transitions beyond standard dipole approximations assuming constant excitation fields [80–82]. Large field gradients could influence Raman spectra, leading to different selection rules [83]. An improved understanding of near-field optical interactions and phenomena would enable their controlled exploitation, leading to additional and new spectroscopic information.

47.5
Experimental Realization

47.5.1
Near-Field Microscopes

As field enhancement is localized to the tip apex, mechanisms for tip–sample distance control working on the length scale of a few nanometers are required. Experimental implementations are based on normal or shear-force detection used in AFM or current detection as in scanning tunneling microscopy (STM) [84, 85]. A variety of TENOM probes are employed, including sharp gold or silver tips fabricated by electrochemical etching of thin wires and metal-coated AFM probes that are commercially available (e.g., [6, 23, 25]). Alternatively, field-enhancing metal particles are attached to sharpened glass probes (e.g., [86–88]). More elaborate approaches combine etching and focused ion beam (FIB) milling, leading to tailored plasmonic structures such as bow-tie antennas [71, 89, 90].

Illumination schemes can be divided in two classes based on their applicability to nontransparent samples (Figure 47.3). Side illumination allows studying nontransparent samples for which the polarization requirement along the tip axis can be easily fulfilled (Figure 47.3c). In the case of transparent samples, on-axis illumination can benefit from high NA objectives with NA > 1 that decrease the size of the confocal volume contributing to the far-field background as discussed later and that maximize the collection efficiency of the emitted light (Figure 47.3a). The later point is paramount in the case of weakly fluorescence species for which photobleaching at high excitation densities becomes an issue. For on-axis illumination, however, light propagation is parallel to the polarization direction required to excite efficient field enhancement at the tip. This requirement can be fulfilled using higher order laser modes such as the radially polarized doughnut mode [91, 92]. Nontransparent samples can be investigated at high NA, employing parabolic mirror objectives instead of glass objectives (Figure 47.3c) [51, 93–95]. Moreover, parabolic mirrors do not exhibit chromatic aberrations and can be used at all temperatures and ultra-high vacuum (UHV) conditions, making them ideally suited for surface sciences. Their alignment is delicate because already minor deviations lead to substantially altered focal fields and reduced detection sensitivity [93].

To acquire an image, the tip is positioned in the focus of the objective and illuminated by laser light. The optical signal is typically collected through the same objective and detected either using sensitive avalanche photodiodes APDs or CCD-equipped spectrometers after rejecting the fundamental laser light. Raster

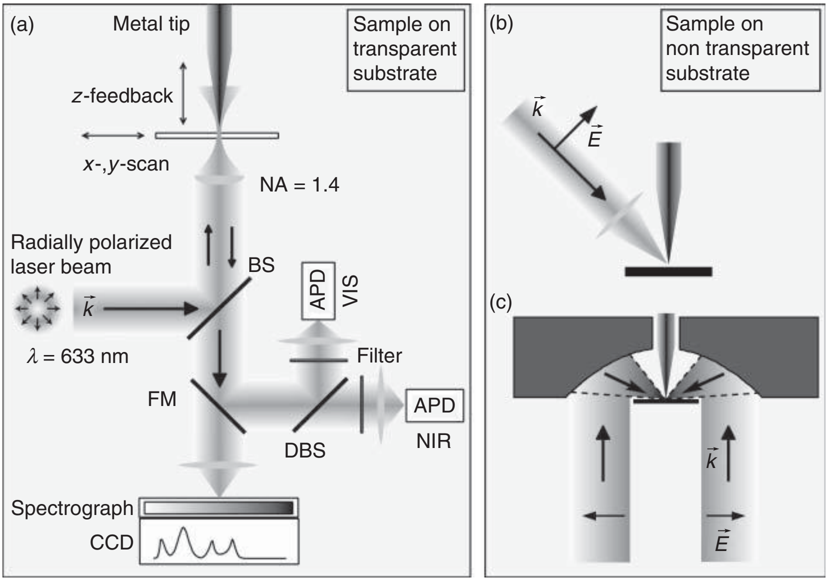

Figure 47.3 (a) Schematic of an experimental setup employing on-axis illumination of a transparent sample used to observe simultaneous Raman scattering and photoluminescence of carbon nanotubes [63]. A sharp metal tip is positioned in a tightly focused radially polarized laser beam. The optical signal is detected after passing the beam splitter (BS) either by two avalanche photodiodes (APDs) for the visual (Vis) and near infrared (NIR) spectral range or by a combination of a spectrograph and a charge-coupled device (CCD). DBS, dichroic beam splitter; FM, flip mirror (b) Side illumination of the tip on top of a nontransparent substrate. (c) Focusing of light using a parabolic mirror with high numerical aperture. To generate a strong field component parallel to the tip axis required for efficient field enhancement, schemes (a,c) utilizes a radially polarized laser mode [51, 91, 92]. (Reprinted from Ref. [9]. Copyright 2008, with permission from Wiley VCH.)

scanning the sample then allows for the simultaneous detection of near-field optical signals and the topography of the sample. Spectroscopic images formed by acquiring spectra at each pixel of the scan provide most detailed information, allowing for true spectroscopic contrast.

47.5.2
Far-Field Background

The configurations discussed so far utilize far-field illumination of the metal tip, and, as mentioned, besides the signal resulting from the near-field interaction between tip and sample, a far-field signal without the tip is detected. This is referred to as *far-field background*. The present configurations therefore rely on a substantial near-field enhancement of the signal as it needs to compete with the far-field background that results from the much larger diffraction-limited sample volume. For high-resolution imaging, the signal results approximately from a circular sample surface area of $\pi(5\text{ nm})^2$, whereas the confocal area is about $\pi(200\text{ nm})^2$ resulting in a surface area ratio of 40000/25. Considering bulk samples and taking into account the finite decay length of the near field of about 10 nm and the longitudinal focal depth of about 500 nm in far-field microscopy, this ratio increases further by a factor of 50. From this discussion it is apparent that TENOM works best for low-dimensional structures such as 1D quantum wires and nanotubes or isolated single emitters such as semiconductor quantum dots and single fluorescent molecules.

Several approaches to minimize or distinguish the background contribution have been developed. The first makes use of the rapid decay of the near-field signal on increasing tip–sample distance. In this approach, a tapping-mode AFM is used to probe the sample while the optical signal is demodulated at the fundamental or higher harmonics of the tapping-mode frequency. This approach also forms the basis of elastic scattering microscopy mentioned previously in Section 47.2. In the case of weakly emitting samples such as single fluorescent molecules, time tagging of the detected photons with respect to the tapping oscillation is used to differentiate between photons generated during small tip–sample distances related to dominating near-field interactions and those detected while the tip–sample distance is increased corresponding to far-field contributions [45, 96, 97]. At present, the corresponding demodulation of CCD-signals is challenging, precluding the acquisition of complete spectra at higher harmonic tapping-mode frequencies.

Different approaches utilize particular probes that avoid far-field excitation of the sample area. The so-called TOA (Figure 47.1d) combines the best of two worlds, namely, high spatial resolution and signal enhancement provided by sharp tips and illumination of the tip with an evanescent wave resulting from a subwavelength aperture [98, 99]. In addition, tip fabrication allows tuning the tip length to match antenna resonances, further maximizing field enhancement [100]. Other schemes make use of surface plasmon propagation [101]. The challenge of coupling propagating light to plasmons can be achieved through grating coupling, in which laser excitation of a grating written by FIB into a tapered gold tip is used to launch surface plasmons propagating to the tip apex [102]. Efficient excitation of propagating plasmons can also be achieved using higher order laser mode coupled into opaque metal-coated tapered glass fibers [69, 103, 104].

In a simplified view, a tip-enhanced near-field optical microscope is built by combining a confocal microscope with a setup for tip–sample distance control, for example, an AFM or a STM. While these microscopic techniques are fully developed, their combination certainly adds substantial complexity and will require careful design modifications to achieve a high degree of user friendliness. Although there is a huge variety of different probes for AFM, including chemically functionalized and magnetic probes, most of the commercially available tips to date cannot be efficiently used for TENOM, being based on semiconductor materials that provide only weak signal enhancement (Section 47.4). At present, the development of well-defined large-scale fabrication processes of metallic or metallized probes with maximized field enhancement factors at high reproducibility is a key issue.

47.6
Tip-Enhanced Fluorescence (TEF)

Confocal microscopes offer detection efficiencies sufficient for fluorescence imaging of single molecules with high fluorescence quantum yield. Here, the signal enhancement provided by the tip is aiming mainly at increasing spatial resolution. In the literature, many examples of TEF microscopy utilizing one- or two-photon excitation exist [22, 63, 72, 73, 96, 99, 100, 105–108]. In the following, selected examples are reviewed to highlight the capabilities of fluorescence-TENOM and to illustrate the discussions in the previous sections.

47.6.1
Single-Molecule Fluorescence Enhancement

Several experiments report on the competition of field enhancement and tip-induced quenching in clearly defined single-molecule experiments (see also Section 47.4). Metallic spheres have been used for which the field distribution can be calculated analytically [72–74, 99, 109]. Figure 47.4a shows the distance-dependent fluorescence signal for a single molecule oriented perpendicular to the substrate plane. Substantial signal enhancement is observed on decreasing the tip–sample distance, while at below about 10 nm fluorescence quenching is observed to dominate. Good agreement between theoretical and experimental curves, including different dipole orientations with respect to the tip-connecting line between dipole and tip, indicate that this effect is well understood and can be accounted for in experiments [110].

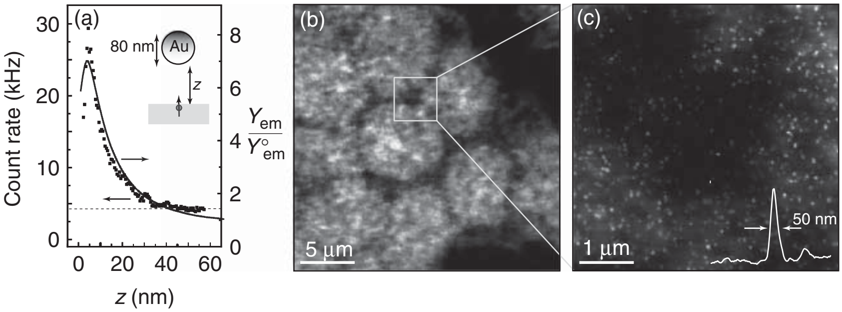

Figure 47.4 (a) Distance dependence of the fluorescence enhancement of a single dye molecule provided by an 80 nm gold nanoparticle antenna. (b) Confocal fluorescence image of individual erythrocyte plasma membranes. (c) Near-field fluorescence image of the area marked in (b) resolving individual PMCA4 proteins. The image was acquired with a 60 nm gold nanoparticle antenna irradiated by a tightly focused, radially polarized laser beam. The inset shows a cross section through one of the fluorescence spots, indicating a resolution of 50 nm. ((b,c)Reprinted from Nano Letters, 2008, 8, 642. Copyright 2008, with permission from the American Chemical Society.)

As Figure 47.4a indicates an optimum tip sample distance for signal enhancement, several experiments used additional inert polymer spacer layers covering the investigate emitter [100, 111]. However, as shown in [47], this is connected to a substantial loss in field enhancement and resolution because of the drop in field strength caused by the dielectric [47]. The different distance dependencies for fluorescence enhancement and quenching indicate that there is an optimum tip–sample distance for fluorescence imaging (Section 47.6).

47.6.2
Imaging of Fluorescently Labelled Biosurfaces

The applicability of TENOM in fluorescence imaging of biological surfaces has been demonstrated in [112]. Figure 47.4c shows near-field fluorescence imaging of erythrocyte plasma membrane.

Figure 47.5 presents fluorescence imaging of single Cy3 dye molecules covalently bound to the termini of short DNA strands [96]. In the present example, efficient far-field background suppression has been achieved by time tagging each detected

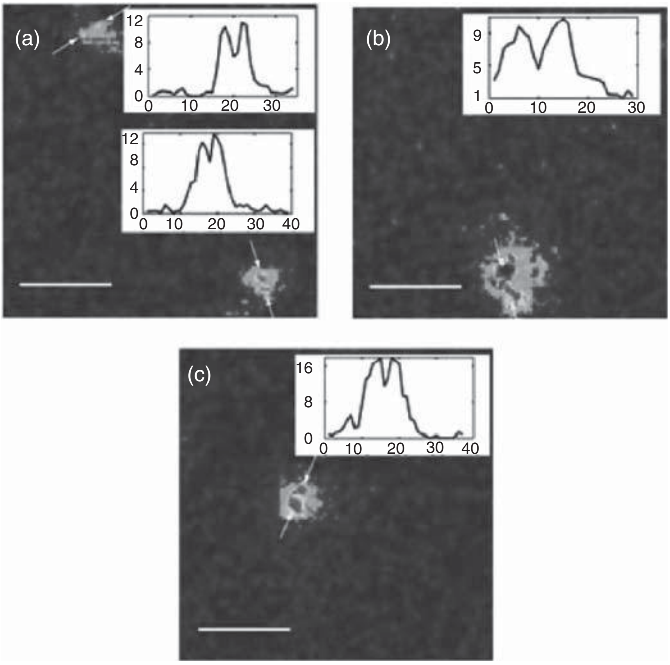

Figure 47.5 (a–c) Near-field images of Cy3 pairs on surface. The signal-to-noise ratio (SNR) is 12.4 and 15.9 for (a), 16.1 for (b), and 20.4 for (c). The insets show the profiles with line cut through the image centers (indicated by arrows), where the horizontal axis is in pixels (1 pixel = 1.95 nm) and the vertical axis is the pixel signal. Scale bars: 50 nm. (Reprinted from Ref. [96]. Copyright 2006, with permission from the American Physical Society.)

photon followed by optimized temporal filtering (Section 47.5). Dye molecules spaced by <10 nm are resolved with high signal-to-noise ratio (SNR). As spectra from highly sensitive CCD cameras cannot be demodulated at typical tapping-mode frequencies in the range of 100 kHz at present, time tagging of photons comes at the cost of reduced spectral information.

Images acquired with a TOA probe of dye-labeled DNA have been presented in [99]. Besides providing high spatial resolution, the radially symmetric field distribution at the tip allows for visualizing the 3D orientation of the transition dipole moment. As the sample is not excited in far field, this approach minimizes the far-field background and simultaneously reduces the irreversible photobleaching bleaching [99, 100].

Besides fluorescent molecules typically used for labeling of biological structures, TENOM is particularly well suited to investigate the photoluminescence (PL) of semiconducting SWNTs [63, 113, 114]. SWNTs are photoluminescent quasi-one-dimensional systems with great promise for applications in photonics, opto- and nanoelectronics [115]. While all SWNTs consist of a hexagonal lattice of carbon atoms rolled up to form a cylinder, their electronic properties vary dramatically depending on the roll-up vector that is expressed by the index tuple (n, m) specifying the nanotube chirality.

Figure 47.6a,b shows the simultaneously acquired topography and PL image of a single nanotube. The PL image is constructed from emission spectra recorded for each position while raster scanning the sample. The PL image shows the intensity within the spectral window ranging from 970 to 1030 nm corresponding to emission from (6, 5) nanotubes [115]. The two spectra detected for the positions marked in (c) are shown in (d,e), respectively. Figure 47.6c shows the spatial dependence of the emission energy, which is seen to vary within a few 10 nm [114]. Energy variations are ascribed to nonuniform wrapping by short DNA segments.

For carbon nanotubes and inorganic nanowires, simultaneous near-field Raman and PL imaging is possible and has been shown in several publications [63, 108, 116, 117]. The enhancement of PL and Raman signals detected simultaneously from the same nanotubes can be used to compare the different enhancement mechanisms [63, 117]. Typically, the observed signal enhancement is stronger in the case of PL. This is somewhat surprising because the Raman signal scales with the fourth power of the field enhancement factor, whereas the PL signal is expected to scale only quadratically. Equations (47.2) and (47.1) indicate that $M_{\text{Flu}} > M_{\text{Raman}}$ is only possible if $(\eta_{\text{tip}}/\eta_0) \geq 1$. Because the quantum yield cannot be larger than unity, $M_{\text{Flu}} > M_{\text{Raman}}$ requires an unperturbed (intrinsic, in the absence of the tip) quantum yield that is very small, that is, $\eta_0 \ll 1$ as in the case of nanotubes. As the nonradiative rate k^{nonrad} is not expected to be decreased by the tip, an increased quantum yield requires substantial enhancement of the radiative rate k^{rad} in the presence of the metal tip, as discussed in Section 47.4.

Predicted by the simple formula discussed in Section 47.4, TEF microscopy is best suited to study weak emitters [63, 64]. The present results demonstrate that TEF is particularly promising for fluorescence imaging of the biosurface in solution. TOA approaches are of major importance because, while reducing the

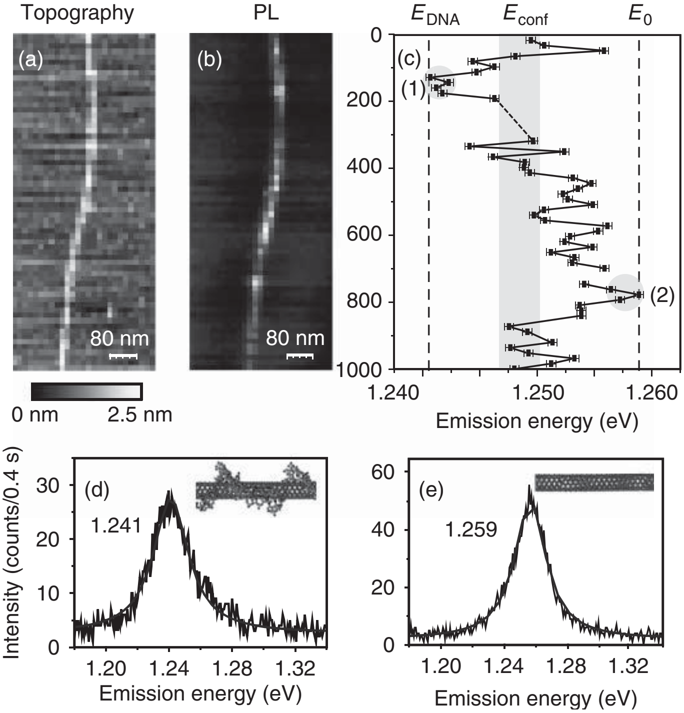

Figure 47.6 Simultaneously recorded topography (a) and near-field PL image (b) of a DNA-wrapped (6,5) nanotube on mica. The PL image was obtained by measuring spectra at each pixel and represents the integrated intensity between 970 nm and 1030 nm covering the emission range of (6,5) nanotubes [115]. For each pixel, the emission spectrum was fitted by a single Lorentzian line shape function to extract the central emission energy that is plotted in (c). Strong energy variations occur on a length scale of about 20 nm, which are assigned to nonhomogeneous wrapping by short DNA strands. PL spectra of wrapped and unwrapped DNA segments detected at positions (1) and (2) along the nanotube are shown in (d,e), respectively [114] Reprinted with permission from Nano Letters, 2008, 8, 2706. Copyright 2008 American Chemical Society.

far-field contribution, they also minimize photobleaching of the emitters caused by long light exposure during raster scanning the sample.

47.7
Tip-Enhanced Raman Scattering (TERS)

Raman scattering probes the unique vibrational spectrum of a sample and directly reflects its chemical composition and molecular structure. A main drawback of Raman scattering is the extremely low scattering cross section, which is typically 10–14 orders of magnitude smaller than the cross section of fluorescence in the case of organic molecules. Clearly, both the high spatial resolution and signal enhancement provided by TENOM are needed for the detection of nanoscale sample volumina. In the following, we review selected examples to illustrate the possibilities, limitations, and perspectives of TERS.

47.7.1
Signal Enhancement and Detection Sensitivity

A comprehensive list of reported enhancement factors achieved in TERS is given in [6], reaching up to 5×10^9 [44]. As discussed in the experimental Section 47.5, the measured relative signal enhancement, the ratio between enhanced near-field signal and background far-field signal, also reflects the different sample areas probed and the field enhancement factors cannot be quantified directly. In the derivation of these ratios, uniform sample properties, that is, uniform coverage for molecular films and uniform signal characteristics along one-dimensional structures, are assumed.

Figure 47.7 demonstrates the signal enhancement experimentally. Raman spectra detected from SWNTs in the presence of the tip and without the tip are shown in Figure 47.7a. In Figure 47.7b the near-field Raman image of SWNTs on glass is Shown, acquired by detecting the intensity of the G band around 1600 cm^{-1} after laser excitation at 785 nm using a radially polarized laser mode while raster scanning the sample. The spatial resolution can be determined from the width of the signal to be about 15 nm. The signal enhancement factor is derived from the present data using the amplitude ratio of enhanced to nonenhanced G-band signal of 3000/100 scaled by the length ratio of the probe nanotube sections of ≈400 nm/15 nm to be about 900 [118].

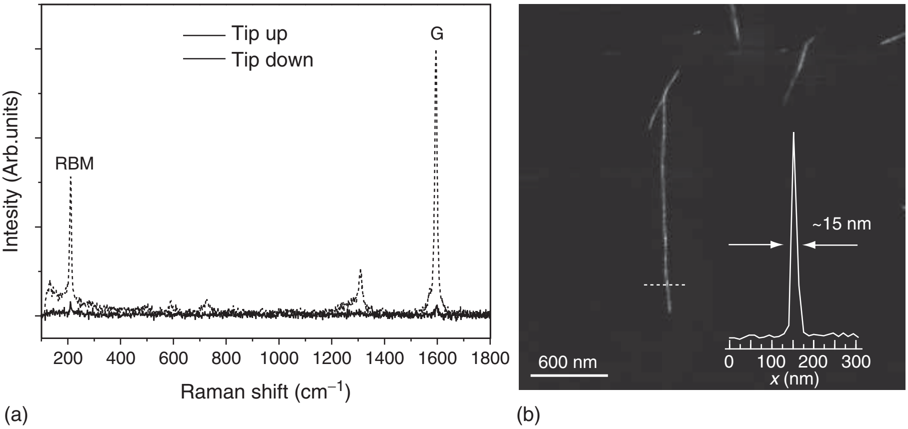

Figure 47.7 Illustration of the signal enhancement provided by a sharp gold tip. (a) Spectra taken at the position of the nanotube with tip (“tip down”, dashed line) and without tip (“Tip up”, solid line). RBM, radial breathing mode. (b) Near-field Raman image (raw data) of single-walled carbon nanotubes on glass, acquired by detecting the intensity of the Raman G band marked in (a) on laser excitation at 785 nm [115]. The cross section shown in the inset features a width of about 15 nm. (Data courtesy of G. Cancado, The Institute of Optics, University of Rochester.)

The sharpest images observed so far for glass substrates feature an optical resolution of about 10 nm, limited by the tip diameter [119]. In general, the measured optical width is smaller than the topographic width by about a factor of 1.3 [25, 119]. While the topographic image of nanometer-sized objects will reproduce the tip shape, the 4th-order dependence of the Raman signal on the field enhancement will render steeper traces (Eq. (47.1)), [117]). Nanoscale Raman spectroscopy probing the structural properties along single carbon nanotubes has been presented in several publications [120–122], clearly demonstrating the enormous capabilities of TENOM.

Corresponding to the time-tagging approach used for fluorescence imaging as described in Section 47.6, confocal background suppression can be achieved in TERS by correlating the detection event with the tapping-mode oscillation [45]. Additional amplification is achieved in tip-enhanced coherent anti-Stokes Raman scattering (TE-CARS) as demonstrated in [123] for DNA networks. High spatial image contrast can also be achieved using other local tip-induced effects not relying on enhanced optical fields. Pressure-induced spectral shifts of Raman bands have been utilized in [124]. In [125], chemical imaging of DNA bases is discussed on the basis of local bond formation with Ag atoms at the tip.

Several publications demonstrate that single-molecule sensitivity can be achieved in tip-enhanced Raman measurements in the case of single dye molecules on metal substrates, providing both additional field and electronic resonance enhancement [44, 126–131]. For extremely high field strength, photochemical modifications of the molecules need to be considered and distinguished in the spectral data [85, 132]. In general, signal fluctuations can also result from temporal fluctuation of the enhancement efficiency caused by physical/chemical changes of the adsorption sites and physical instabilities of the TERS tip during the experiment. Signal losses have also been attributed to tip-induced sample heating, leading to weaker field enhancement by reducing the surface roughness as well as surface diffusion of adsorbates [133].

47.7.2
Chemical Analysis of Surfaces

The chemical analysis of molecular species on surfaces is one of the main driving forces for the development of TERS, holding huge promise for applications in different areas such as catalysis. An example of near-field imaging with chemical contrast is shown in Figure 47.8. A thin layer of benzotriazole (BTA) molecules, a species that does not provide additional resonance enhancement at the laser excitation energy used in the experiment, is imaged on a smooth gold film by a gold tip in the focus of a parabolic mirror objective. Here, the optical signal results from a superposition of Raman scattering from BTA and PL from gold. As described in the section on the fundamentals of field enhancement (Section 47.3), additional signal amplification results from nanoscale protrusions within the metal film, leading to the very bright and highly localized features in the optical image (Figure 47.8a).

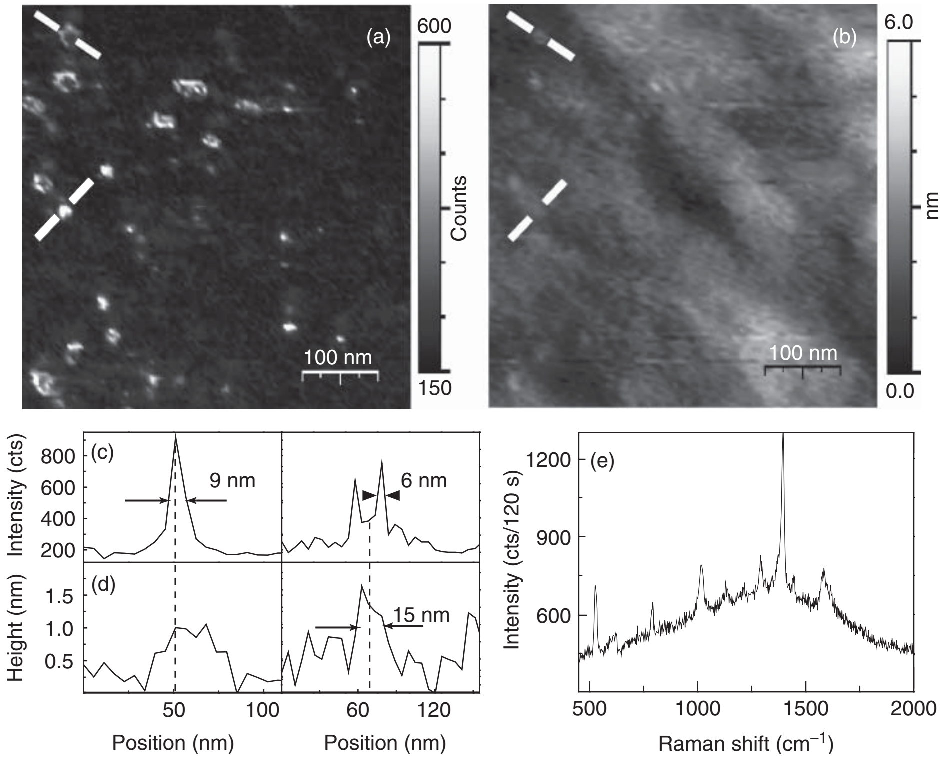

Figure 47.8 (a) Near-field optical image of a smooth Au film covered with a layer of benzotriazole molecules (BTA), which shows the Raman signal of BTA on top of the photoluminescence signal of Au. Simultaneously recorded (b) topography revealing only subnanometer height variation. Strongest near-field enhancement is observed for nanoscale protrusions. (c,d) Intensity height profiles over two small gold islands marked with dashed lines. (e) Raman spectrum detected at one of the bright features in (a). (Reprinted from Ref. [51]. Copyright 2008, with permission from Wiley-VCH Verlag.)

In analogy to TEF imaging (Section 47.6) the detected TERS signal will reflect the mutual orientation of the Raman scattering tensor and the enhanced fields. More specifically, the relative amplitudes of certain Raman lines can be utilized to extract orientational information and to monitor orientational mobility. In the case of chemical binding of the scatterer to the surface, additional Raman lines, line splitting, or shifts that can help to explore the details of the surface chemistry can occur.

47.7.3
Biopolymers and Biosurfaces

DNA bases feature characteristic Raman signatures, and direct optical sequencing of DNA on substrates using TERS is a long-standing dream stimulating the development of the technique. Recent experiments on single RNA strands and picomole quantities of DNA bases indicate that this goal could come within reach [127, 134]. In the past years, several studies using TERS on biological samples were Presented, including ommatidial lens surfaces [135], adenine nanocrystals [136], cytochrome c [137], bacteria [138], and hemoglobin crystals [139], demonstrating the broad applicability of the technique.

47.7.4
Stress Imaging in Semiconductors

As the length scales in semiconductor devices continuously shrink, nanoscale imaging of dedicated stress, for example, in transistor structures is of enormous technological relevance regarding further progress in stress engineering [6, 140, 141]. Stress in silicon causes a spectral shift of the Si–Si Raman peak of about 4 cm^{-1} for 1 GPa of biaxial stress. For realistic (3D) stress states in actual device structures, a shift of about 1 cm^{-1} can be expected. The main challenge for nanoscale Raman measurements results from the far-field to near-field sample volume ratio, making the resulting surface signal variations extremely difficult to extract from the strong confocal background. Moreover, sample heating upon laser excitation also leads to significant Raman shifts in the order of 50 $\mathrm{K/cm}^{-1}$, making the identification of purely stress-induced features difficult [142, 143]. Because of the large reflectivity of silicon, artifacts, in particular for periodic and layered structures, could result [140]. Different schemes based on polarization filtering have been developed for contrast enhancement and background suppression [6, 144, 145], and TERS is very likely to become a useful tool for the investigation of semiconductor surfaces.

47.7.5
Nanoscale Optoelectronic Probing

In the previous examples, tip-enhanced near fields have been used to locally increase the optical response of nano-objects such as Raman scattering and fluorescence. The scheme of tip enhancement or antenna enhancement is, in fact, more general as described in [26] and can, in principle, be used also for probing other sample properties such as local photovoltaic response and electroluminescence efficiency [146]. In [147], antenna-enhanced photocurrent microscopy has been used for the first time for the detection of optical and photocurrent signals with nanoscale spatial resolution and improved detection sensitivity. The enhanced photocurrent signal was shown to result from locally increased absorption by comparing it to the simultaneously obtained Raman signal. The technique was then used to study the direction and decay length of the band bending at the electrical contacts of metallic SWNT devices and to probe local variations in the electronic structure along a single SWNT that cannot be detected by confocal microscopy. These results further underline the wide applicability of the optical antenna concept in nanophotonics, merging the fields of plasmonics and photovoltaics.

47.8
Summary

The results presented in this chapter clearly demonstrate that TENOM has developed into a powerful and versatile tool. With this technique, the highest spatial resolution optical measurements of surfaces have been achieved up to date combined with enormous signal enhancement. In addition, TENOM provides detailed structural information based on the observation of Raman scattering with ultrahigh detection sensitivity. A brief checklist for the applicability of TENOM to the characterization of a particular sample comprises the following points:

1) the surface can be characterized by AFM or STM, providing the basis for tip–sample distance control and the required proximity;
2) the optically active elements (e.g., Raman scatterers, fluorescent molecules) are close to the surface;
3) the sample renders a stable confocal microscopy signal.

Because of the far-field background and the unfavourable near-field to far-field volume ratio, TENOM works particularly well for 0D and 1D structures such as point dipoles or wires. The observation of bulk materials with small spectral contrast, however, remains challenging. Active research currently addresses this issue, and significant improvements also regarding signal enhancement and spatial resolution, eventually reaching a single nanometer, can be expected within the next years.

Compared to far-field techniques, TENOM is likely to retain slightly higher spatial resolution being limited essentially by the tip-apex diameter. For fluorescence imaging of high-quantum yield emitters, far-field techniques however provide much faster acquisition times than scanning-probe-based TENOM at 20 nm resolution. In fact, stimulated emission depletion (STED) microscopy already permits video-rate fluorescence imaging [13].

Because the signal in TENOM results from electromagnetic near-field interactions between a metallic probe and the sample, the detected optical response can differ essentially from the far-field response. In order to exploit this fact for sample characterization and to quantify the near-field optical contrast, tip-induced signal modifications need to be modeled and understood in detail for molecular point dipoles and also for extended crystal-type structures.

To develop into a standard tool and for the broad applicability of TENOM, the controlled, reproducible, and ideally parallel fabrication of tips with a high field enhancement factor needs to be achieved. This will be particularly challenging in the case of background-minimizing probe schemes such as TOA. Compact designs integrating optical microscopy and AFM/STM exist and can be optimized further to yield even more user-friendly microscope systems. Besides providing a tool for unprecedented sample analysis, TENOM is certainly a fascinating research field both with respect to novel physical phenomena and our understanding of near-field optical interactions.

Optical Waveguide Spectroscopy

James S. Wilkinson

Total internal reflection (TIR) elements are well-established components for the optical interrogation of chemical processes at surfaces, with attenuated total reflection (ATR) spectroscopy and total internal reflection fluorescence (TIRF) having a long pedigree and surface plasmon resonance (SPR) finding widespread use in biomolecular research, for example. Key attributes of these devices are that the optical fields are confined to a submicrometer region above the solid surface of the transducer and that the light is delivered to the surface without passing through the bulk of the sample. Optical waveguides take this TIR approach to its most sensitive conclusion by engineering the dimensions and refractive index profile of the waveguide to maximize the interaction of the incident light with the surface integrated optical waveguides to exploit the technological approaches of microelectronics and guided-wave optics to realize optical waveguides performing TIR functions at the surface of an optical chip, allowing miniaturization of sample volumes, integration of multiple optical functions, and robust ‘‘solid-state’’ interconnection. Owing to precise control of local optical velocity and intensity distribution, these waveguides provide strong and well-controlled evanescent interaction of light with chemical species at a surface in a very small sample volume, yielding benefits in terms of sensitivity, speed, or spatial localization. Integrated optical waveguides are able to probe a wide range of optical phenomena, and are compatible with microfluidic systems for sample delivery and with optical fiber for connection to instrumentation. In this chapter, the application of integrated optical waveguides to spectroscopy is described, including a brief introduction to waveguide optimization for spectroscopy, describing the performance of devices implemented to date, and drawing conclusions for the application of these devices in practical applications.

48.1
Introduction

The use of TIR elements for optical spectroscopy at surfaces was proposed and developed by Harrick [1] and Fahrenfort [2] and has since found widespread application. Absorption spectra are obtained from this technique, which is often

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

referred to as *ATR spectroscopy* or *internal reflection spectroscopy* (*IRS*), by reflecting broadband light from the interface between a transparent internal reflection element (IRE) and the sample, resulting in absorption in the evanescent field that extends typically a submicrometer distance into the sample. ATR spectroscopy thus provides spectra for a thin layer (typically 100–500 nm) on the IRE surface, allowing collection of strong spectra from extremely small volumes and from thin films such as monomolecular layers adsorbed at surfaces. Further advantages include reduction of interference from (often scattering) bulk media, determination of absorption spectra of powdered samples without scattering, and external analysis of materials in a closed chamber. Many applications are specifically directed at studying surface layers, so that the IRE surface is part of the system under study, while others simply use the IRE to enhance sensitivity, reduce the effect of scattering, or provide a convenient measurement geometry. It should be recognized that the spectrum of the material at a surface is not necessarily the same as that of the bulk medium and, whether this is a desired effect that is to be observed or a spurious effect to be minimized, it must be taken into account. TIR absorption spectra depend on the extent of the evanescent field in the sample medium, and hence on incident angle; and this also results in the distortion of the spectrum compared with the spectrum of the bulk medium as the extent of the evanescent field is wavelength dependent. However, this dependence is usually readily predicted so that the undistorted spectrum can be determined. The first ATR experiments employed a single reflection, but it was soon realized that using multiple reflections (Figure 48.1) offered a great advantage in terms of the strength of the absorption spectra, or spectral contrast, so that more than 500 reflections are routinely used, by repeated TIR from the sample side and the parallel underside of the IRE as shown in Figure 48.1.

For absorption spectroscopy of thin films, the principal sensitivity advantage of the ATR configuration over transmission spectroscopy comes from these multiple reflections. Multiple IREs are in fact optical waveguides, albeit usually highly multimoded ones. The bouncing rays in an IRE can be described in terms of the superposition of the modes of the IRE, interfering along the length of the structure to produce the resultant reflecting rays. Once the IRE thickness becomes comparable to the wavelength of light, the modal description becomes the more convenient, and Harrick [3] indicates this in his description of a frustrated total

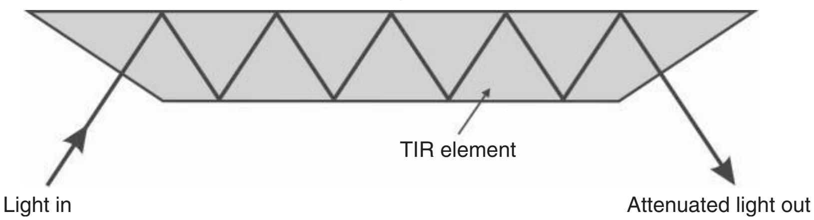

Figure 48.1 Multiple reflection TIR element.

reflection (FTR) optical cavity with enhanced sensitivity and presents a waveguide and prism coupler as an example of IRE geometry.

In 1971, Midwinter [4] presented a theoretical description of the use of optical waveguides for IRS. Noting the similarity between Harrick's FTR cavity and work at the Bell Laboratories on prism coupling into optical waveguides [5], Midwinter asked "if these waveguide techniques could be used with advantage in the examination of internal reflection spectra." Concentrating on designs for minimum distortion of the sample spectrum compared to conventional transmission spectroscopy, he proposed *in situ* use of miniature waveguide probes fabricated by microelectronic techniques, for chemical and biological processes. Polky and Harris [6] studied the theoretical optimization of waveguides for highest sensitivity and described absorption measurements on bulk dye, emphasizing the strong absorption obtained and the effect of adsorption of dye molecules at the surface, and pointing to future applications *in vivo*. The principal differences between these waveguide devices and multiple reflection IREs were that the waveguides would normally consist of a thin film on a solid substrate (Figure 48.2) and that the film would normally be much thinner than an IRE. In a conventional IRE, the number of reflections per unit length is inversely proportional to its thickness. While this ray model breaks down as the thickness becomes comparable to the wavelength, the trend continues so that thin-film waveguides can exhibit the ultimate sensitivity. Taken to its furthest extreme, very thin waveguides, which support only one mode (usually one in each polarization), can be designed to have the highest sensitivity, and also present advantages in stability owing to unique and well-defined surface intensity distribution. In 1974, Mitchell *et al.* [7] demonstrated the application of waveguide spectroscopy to bilirubin measurement in blood samples, emphasizing the minimization of the sample volume and the suppression of scattering and absorption from red blood cells that dominates in bulk transmission spectra, and the selective measurement of the blood plasma.

Optical waveguides for IRS are the natural extension of TIR elements, exhibiting all the same advantages plus ultimate sensitivity, extreme miniaturization, easy integration of multiple sensors and reference sensors, robust fabrication techniques, and the economies of mass-production techniques employed in microelectronics manufacturing. Against these advantages may be traded greater complexity in

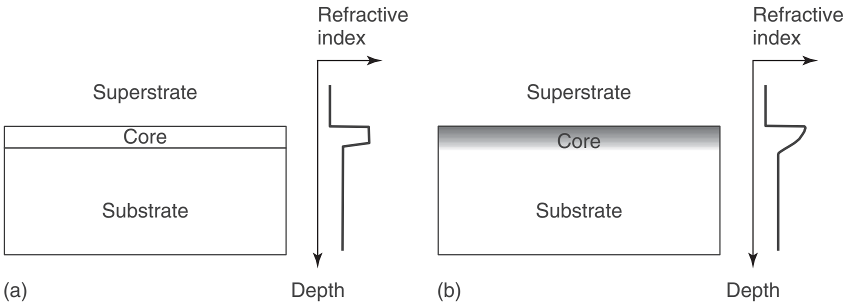

Figure 48.2 Planar waveguides: (a) slab waveguide and (b) graded-index waveguide.

use, particularly connection to instrumentation, and the expense of the fabrication equipment, but the all-pervasive nature of microelectronic devices demonstrates that the additional complexity of microminiaturized devices need be no barrier to successful commercialization.

This introduction has concentrated on the use of IREs for absorption spectroscopy and their natural evolution toward optical waveguide implementations. Since their invention, IREs have been used for a much wider range of broadly spectroscopic applications including TIRF, Raman spectroscopy and surface-enhanced Raman spectroscopy (SERS), SPR, and critical angle refractometry. In this chapter, optical waveguide implementations of these spectroscopic techniques will be discussed, concentrating on truly spectroscopic studies of the sample materials rather than on single-wavelength absorption, fluorescence, and refractive index measurements, despite their great importance in sensing applications, or on studies that interpret changes in waveguide mode velocity ''spectra'' to determine refractive index changes at a single wavelength.

48.2
Integrated Optical Waveguides

The principles of integrated optical waveguide design, fabrication, and operation are briefly reviewed to place the specific configurations and applications to be described in the remainder of this chapter in context and to define important parameters. Detailed descriptions of waveguide principles are given in many excellent textbooks, including those by Adams [8], Ghatak and Thyagarajan [9], Lee [10], and Okamoto [11]. The optimization of waveguides for absorption, index, and fluorescence sensing is well documented [12–15] and, while these studies are directed primarily at single-wavelength sensing, the principles and mathematical descriptions may be applied to broadband spectroscopy.

High-sensitivity waveguide spectroscopy usually requires structures that, for a given power in the waveguide, optimize either the intensity at the waveguide/analyte interface in the case of ultrathin-film spectroscopy or the power in the analyte medium in the case of bulk analyte spectroscopy, leading to significantly different designs. For thin-film spectroscopy, the discrimination between surface effects and bulk effects may need to be maximized, favoring waveguides with rapid evanescent decay into the sample medium [16]. A further important consideration is the efficiency with which power is coupled into the waveguide, which often results in a further trade-off in waveguide design. This may drive the choice of how light is coupled into the waveguide and full optimization requires analysis of the detected optical signal strength, the system noise sources, and the effect of stray light. These aspects, which are strongly dependent on the specific system configuration, are addressed in Section 48.8 on instrumentation. Here, it should simply be borne in mind that optimization of the waveguide element alone is not sufficient, and that the entire system, including drift and noise sources in the optical detection system, must be considered in order to arrive at the highest sensitivity, lowest limit of detection (LoD), or the most cost-effective solution.

The homogeneous planar or slab waveguide is the simplest integrated optical waveguide, consisting of a thin homogeneous film of dielectric material of refractive index n_{co} supported by a substrate of index n_s and overlaid with a superstrate or cladding of index n_{cl}, where $n_{co} > n_s$ and $n_{co} > n_{cl}$, as shown in Figure 48.2a. Most practical slab waveguides are asymmetric, so that $n_s \neq n_{cl}$, and are formed by a wide variety of film deposition techniques such as sputtering, evaporation, or chemical vapor deposition [10].

The graded-index planar waveguide, shown in Figure 48.2b, is similar to the slab waveguide except that one or both discrete dielectric boundaries are replaced by smooth variations in the refractive index profile. In terms of ray optics, TIR is no longer from a discrete boundary; rather, a ray propagating into the lower-index region is turned back into the high-index region by continuous refraction through the index gradient. Graded-index planar waveguides are usually formed by the diffusion of a dopant into a substrate material, for example, by deposition of a thin metallic or dielectric film onto the substrate followed by annealing, or by immersion in a molten source of dopant atoms. The dopant is chosen such that the refractive index of the substrate material increases with increasing dopant concentration.

The planar waveguides described confine light in one dimension and allow it to propagate freely in two dimensions, so that phenomena such as refraction, diffraction, and interference occur in the waveguide plane. In many cases, however, guidance of light in the plane is also required and this is achieved by confining light in two dimensions using channel waveguides. The simplest homogeneous channel waveguide consists of a core of index n_{co} surrounded in two dimensions by media of lower refractive index. It has a geometry similar to a step-index optical fiber except that the cross section of the core is often rectangular rather than circular and it is normally deposited on or buried in a flat substrate as shown in Figure 48.3a,d.

In a basic channel waveguide, propagation of guided modes is along the axis of the channel. However, the additional guidance in the plane of the substrate allows bends and tapers to be introduced into the waveguides and many optical circuit elements such as couplers and power splitters have been realized using the photolithographic techniques developed for the microelectronics industry [11]. Channel waveguides thus allow guidance of light to specific locations on the surface of an optical chip and integration of multiple branches, leading to, for example, the integrated equivalent of dual-beam spectrophotometry.

Homogeneous channel waveguides are usually formed by deposition of a homogeneous slab waveguide on a suitable low-index substrate (or buffer layer) followed by etching of the film to form channels using ion-beam milling, reactive-ion etching, chemical etching, or a combination of these. Outside the core region, the film may be etched fully down to the substrate, in which case a strip waveguide (Figure 48.3a) is formed; alternatively, the film may be only partially removed, in which case a rib waveguide (Figure 48.3b) is formed. Depending on the application, the strip or rib waveguide may then be overlaid with a suitable low-index cladding material as shown in Figure 48.3c. A cladding is used to isolate the waveguide

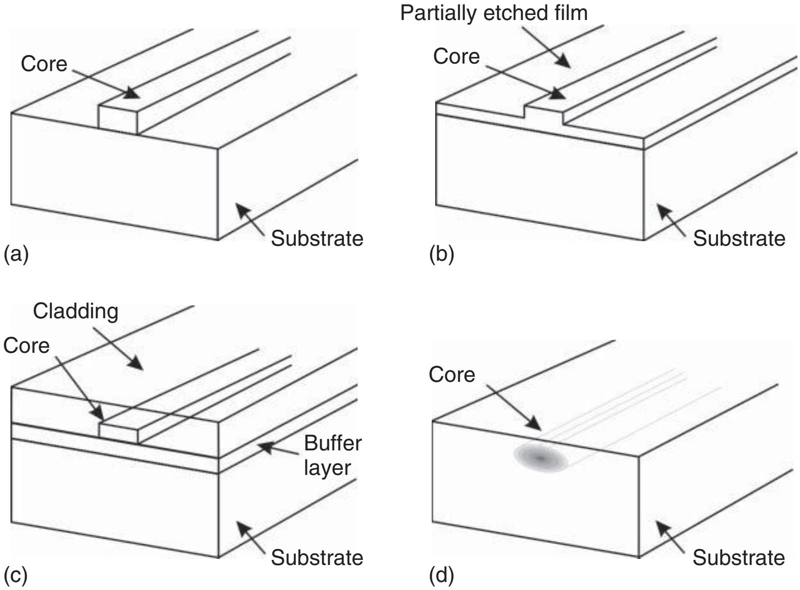

Figure 48.3 Channel waveguides: (a) unclad homogeneous strip waveguide, (b) unclad homogeneous rib waveguide, (c) clad homogeneous strip waveguide, and (d) buried graded-index waveguide.

mode from external influences and to make the mode more symmetrical for ease of coupling light in with an optical fiber. However, in evanescent spectroscopy, the cladding is omitted or reduced in thickness in the measurement region to allow strong evanescent interaction. Figure 48.3c also shows a buffer layer between the substrate and the core layer; this may be appropriate where the substrate does not have the refractive index or transparency required to optimize the waveguide for absorption or refractive index sensitivity. It also relaxes the constraints on the substrate itself, allowing independent optimization for reasons of cost, availability, mechanical properties, or the availability of other features in a convenient substrate material, such as in the case of microfluidic devices in silicon [17].

The graded-index channel waveguide is similar to the homogeneous channel waveguide except that some or all of the discrete dielectric boundaries are replaced by smooth variations in the refractive index profile. Graded-index channel waveguides are usually formed by diffusion from a strip of dielectric or metallic material deposited on a substrate, or by diffusion through a mask deposited on the substrate surface. Unless multistep diffusion processes are used, the discrete dielectric boundary at the substrate surface usually remains, while all other boundaries are graded. Multistep diffusion is usually used to produce a buried waveguide (Figure 48.3d) for the same reasons as homogeneous waveguides are clad. As this reduces the evanescent field at the surface, it is usually not used for applications in waveguide spectroscopy. However, either a cladding or a burial step may be convenient to isolate the waveguide from an analyte (or from a sample cell attached to the waveguide surface) outside the spectroscopic measurement region.

An intriguing special case is the ‘‘zero-mode’’ waveguide that exploits evanescent fields in nanoscale holes in metal films and has been applied to single-molecule studies at high concentrations [18, 19]. The hole is considered to be a metal-clad waveguide below cutoff in which light is confined laterally by the walls of the hole and along the length of the hole by the evanescent decay length (as no mode can propagate). Cutoff occurs for hole diameters $<0.586\ \lambda_m$, where λ_m is the wavelength in the medium filling the hole. In [18], holes of diameters including 43 and 66 nm were opened in an 89 nm thick aluminum film deposited on a fused silica substrate. Illumination through the substrate with light at a free-space wavelength of 488 nm results in an evanescent decay length of order 10–20 nm and thus a probed volume of 10^{-19} to 10^{-20} l, compared with order 10^{-13} l for conventional diffraction-limited optics. This allows measurements to be made on individual molecules at million-fold higher concentrations, allowing single-molecule studies at concentrations relevant to observing normal molecular behavior. These waveguide arrays have been applied to fluorescence correlation spectroscopy (FCS) of single-labeled molecules using a single excitation wavelength and counting fluorescent photons with time as the molecule diffuses into and out of the excitation volume. Applications including diffusion in lipid bilayers and live cells ‘‘exploring’’ zero-mode waveguide structures are described by Moran-Mirabal and Craighead [19]. The vast majority of truly spectroscopic studies using waveguides have applied conventional monomode or multimode dielectric waveguide structures, which will be addressed in the remainder of this chapter.

48.3

Optimization of Dielectric Optical Waveguides for Evanescent Spectroscopy

The key pieces of information required to design or analyze integrated optical waveguides for evanescent spectroscopy are the modal intensity profile at any cross section of the waveguide and the modal velocity v_m, which is most conveniently expressed through the modal effective index $N_m = c/v_m$, where c is the vacuum speed of light. Both the intensity distribution and the velocity are functions of wavelength, resulting in predictable distortion of spectra measured using waveguides. They are found by obtaining wave equations for electromagnetic radiation in the waveguide media and matching tangential components of electric and magnetic fields across the dielectric boundaries, yielding discrete modal solutions effectively corresponding to resonances across the core of the waveguide, as described in several textbooks [8–10]. Chapter 1 of [20] written by the pioneers of waveguide techniques for Raman spectroscopy, JF Rabolt and JD Swalen, provides a very good theoretical introduction to waveguide design and operation with a particular emphasis on surface studies.

Most practical waveguides require numerical techniques to determine their modal distributions and velocities, and there are several good commercial Computer

Aided Design (CAD) packages available to design such waveguides and devices and to convert the designs to photolithographic mask layouts. Here, we discuss only the basic considerations and interrelationships between quantities to aid understanding of waveguide optimization for evanescent spectroscopy. Often, the choice of waveguide *materials* is dominated by pragmatic considerations such as their chemical durability and wavelength transmission windows (polymers; glasses; and crystals, such as silicon, sapphire, and lithium niobate, among many others, may be used to create practical waveguides). The choice of waveguide *design* may sometimes be dominated by the need to couple light in easily, rather than for achieving the maximum possible sensitivity.

The homogeneous slab waveguide shown in Figure 48.2a is a conveniently simple structure with which to illustrate the basic behavior of optical waveguides. In the following discussion, it will be assumed that the refractive index of the substrate is higher than that of the superstrate, $n_s > n_{cl}$, which is usually the case, for example, when the superstrate is air ($n \approx 1.0$) or water ($n \approx 1.33$), and the substrate is, for example, glass ($n \approx 1.5$). The core index must be higher than the substrate index and the core thickness, a, must be great enough to guide at least one mode. For the slab waveguide, this requires that (with m set to zero to correspond to the fundamental mode):

$$a > \frac{\lambda}{2\pi\sqrt{n_{co}^2 - n_s^2}} \left[\tan^{-1}\left\{ \eta \sqrt{\frac{n_s^2 - n_{cl}^2}{n_{co}^2 - n_s^2}} \right\} + m\pi \right] \tag{48.1}$$

where $\eta = 1$ for the transverse electric (TE) polarization (electric field parallel to the dielectric interfaces) and $\eta = (n_{co}/n_{cl})^2$ for the transverse magnetic (TM) polarization (magnetic field parallel to the interfaces). Note that for a symmetrical slab waveguide, where $n_s = n_{cl}$, the cutoff thickness for the fundamental ($m = 0$) mode is zero. In practice, losses and mode size place a lower limit on the practical thickness of symmetrical slab waveguides. The waveguide becomes multimoded where the inequality in Eq. (48.1) is satisfied for $m = 1$; here, we will concentrate on monomode waveguides as these are most suitable for high-performance spectroscopic applications. For a homogeneous slab waveguide, the modes display sinusoidal or cosinusoidal field distributions across the core, with exponentially decaying fields into the superstrate and substrate, as shown for the TE_0 and TE_1 modes in Figure 48.4a. Matching these field solutions at the two boundaries results in discrete modes with well-defined field profiles and effective indices, N_m, which are wavelength dependent. The modal effective indices for a homogeneous slab waveguide with $n_s = 1.51$, $n_c = 1.52$, and $n_{cl} = 1.0$ are plotted against normalized core thickness in Figure 48.4b, where $t_{norm} = a/\lambda$ [21], for the first three TE and TM modes. This clearly shows cutoff, where the fundamental mode is no longer supported, below $t_{norm} \approx 1.25$. The effective index is equal to the substrate index at cutoff and increases toward the refractive index of the core as core thickness increases, as a greater proportion of the power travels in the core and the power in the evanescent fields diminishes for thicker waveguides. To emphasize the

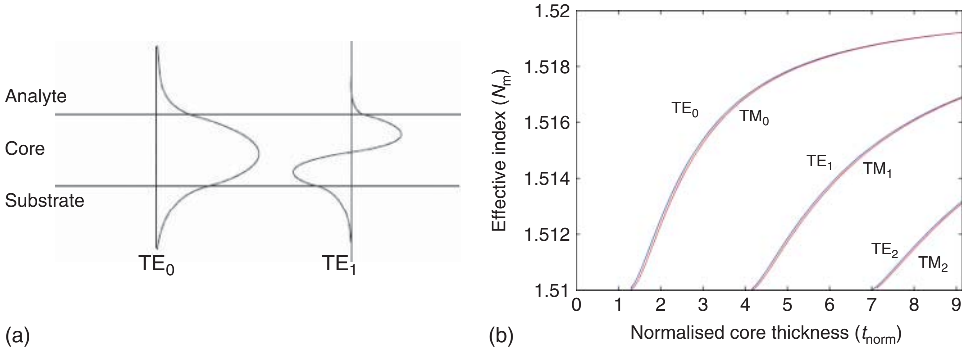

Figure 48.4 (a) Modal field distributions and (b) modal effective indices.

application of waveguides to spectroscopy, the superstrate will be referred to as the *analyte* in what follows.

Each mode travels with a phase velocity given by c/N_m where $n_{co} > N_m > n_s$, and the distance at which the field has decayed into the analyte by $1/e$ of its surface value or at which the intensity has fallen to $1/e^2$ of its surface value is given by

$$d_{cl} = \frac{\lambda}{2\pi\sqrt{N_m^2 - n_{cl}^2}} \tag{48.2}$$

Note that for the common situation of a glass waveguide in water, d_{cl} takes a value close to $\lambda/4$, so that the evanescent field probes a region about one-quarter of a wavelength beyond the dielectric interface. For a higher index waveguide, such as $LiNbO_3$ in water, d_{cl} is closer to $\lambda/10$, so that it is more surface specific. However, while the evanescent decay length in a given medium is dictated by the effective index of the mode, the proportion of modal power in the analyte and the surface intensity depend strongly on the refractive index contrast of the core/substrate interface. The decay distance in the substrate is given by the same expression as Eq. (48.2) with the subscripts "cl" replaced by "*s*." In most situations, this interface has a much weaker refractive index contrast so that the decay length is much longer than in the analyte. For example, a conventional glass or lithium niobate waveguide may have a decay length of several wavelengths in the substrate. This strong asymmetry leads to a rather small proportion of the modal power traveling in the analyte as shown in Figure 48.5, where the analyte fills the space corresponding to $x > 0$. Note from the inset how the surface intensity increases with decreasing core thickness, *over this range of thicknesses*.

Tiefenthaler and Lukosz [15] and Parriaux, Veldhuis *et al.* [12, 13] have reported comprehensively on waveguide optimization for evanescent sensing, which must be addressed distinctly for "bulk" analyte measurements where the analyte fills the evanescent field and "thin-film" measurements where the film to be measured is on the waveguide/analyte interface and is thin compared with the extent of the evanescent field. The *sensitivity* S is defined as the rate of change of the effective index of the mode with changes in the refractive index of the analyte which, for

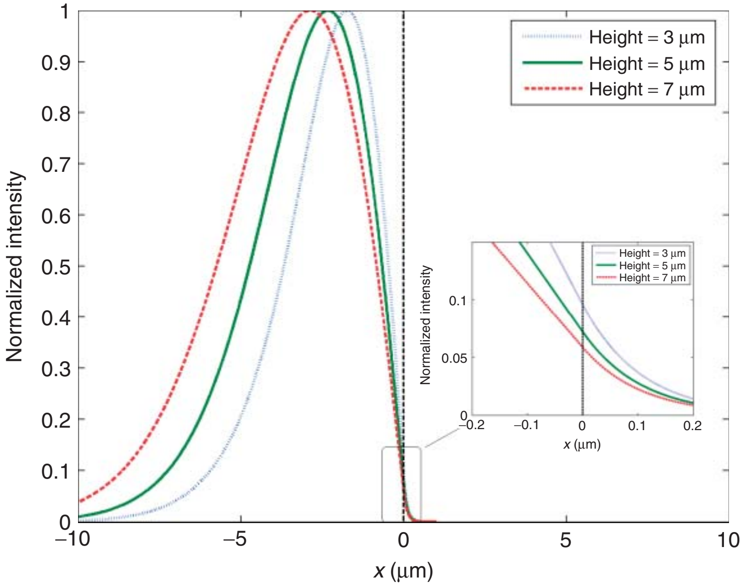

Figure 48.5 Intensity distribution across waveguide core for three core thicknesses. $\lambda = 750\,\text{nm}$, $n_{\text{cl}} = 1.0$, $n_{\text{co}} \approx 1.52$, $n_{\text{s}} = 1.51$.

a bulk analyte is $S = \delta N_{\text{m}}/\delta n_{\text{cl}}$. This applies to sensitivity to the refractive index including sensitivity to absorption, as absorption may be described in terms of the imaginary part of refractive index through the expression:

$$\alpha \cong \frac{2k_0}{2.3}\text{Im}\{n\}$$

where α is the absorption coefficient in the base 10 form of the Beer–Lambert law and k_0 is the free-space wavenumber $(2\pi/\lambda_0)$. It will be assumed that the imaginary part of the analyte index is small compared with the real part, as is usually the case.

48.3.1
Optimization for Bulk Analyte Spectroscopy

To the first order, optimizing the waveguide design for sensitivity to a bulk analyte comes down to maximizing the fraction of modal power carried in the analyte, so that, in general (i) the substrate index should be as low as possible to shift the waveguide mode into the analyte, leading ultimately to "reverse-symmetry" waveguides [22] where the analyte index is higher than the substrate index, and (ii) the waveguide core index should be as high as possible, assuming that its thickness can then be chosen to optimize the waveguide at the wavelength of operation. To clarify this last point, if the core thickness is kept constant, then the evanescent power will *reduce* with increasing core index. However, practical constraints such as available materials, fabrication tolerances, efficiency of coupling light into and out of the waveguides and waveguide losses usually limit the maximum practically useful core index.

An example showing the proportion of power traveling in the analyte against normalized core thickness, for the TE_0 mode in a homogeneous slab waveguide with $n_s = 1.51$, $n_c = 1.52$, and $n_{cl} = 1.33$ (corresponding to a typical glass waveguide in water) is given in Figure 48.6, where $t_{norm} = a/\lambda$ [21]. This clearly shows cutoff, where the fundamental mode is no longer supported, at $t_{norm} \approx 1.25$ and a maximum analyte power at $t_{norm} \approx 1.7$. In other words, *for this set of refractive indices*, the core thickness required for maximum sensitivity to the analyte is close to two free-space wavelengths. For core thicknesses below the optimum, for this asymmetrical waveguide, the modal power is increasingly carried in the substrate. In the case of sensing, which is usually carried out at a single wavelength, the optimization procedure is straightforward. However, in the case of spectroscopy over a wide range of wavelengths, it is clear that the fraction of evanescent power in the analyte can change dramatically with wavelength, distorting the spectra obtained. If this is an important design issue, then choosing a thicker waveguide, and one with a lower core index, will reduce this distortion, at the cost of absolute sensitivity, as pointed out by Midwinter [4] in his original paper. Furthermore, for broadband spectroscopy, the dispersion of all the materials including the analyte must be taken into account. For a more precise optimization for bulk analytes and applying to slab waveguides, the following expression should be used for the sensitivity [15]:

$$S = \frac{n_{cl}}{N_m}\frac{P_{cl}}{P_{tot}}\left\{2\left(\frac{N_m}{n_{cl}}\right)^2 - 1\right\}^q \tag{48.3}$$

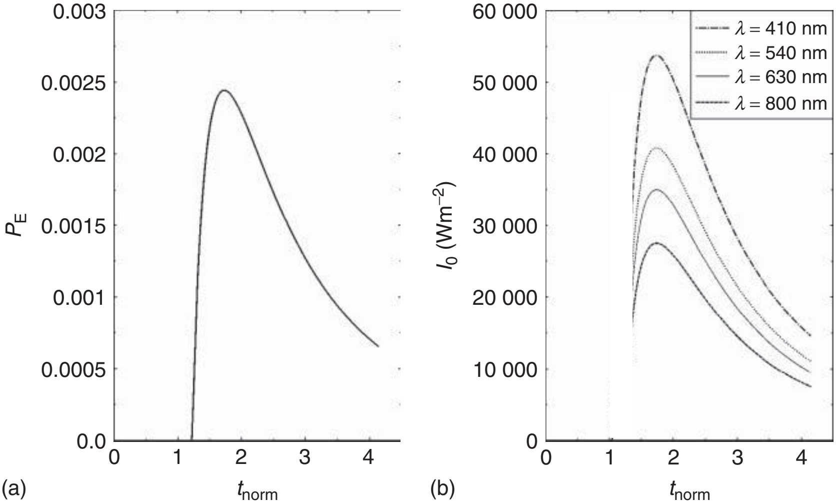

Figure 48.6 (a) Fraction of power in the analyte. (b) Surface intensity. $n_{cl} = 1.33$, $n_{co} = 1.52$, $n_s = 1.51$. (From [21] reprinted with permission.)

where $q=0$ for TE modes and $q=1$ for TM modes. In the case of the TM polarization, this is conveniently rearranged in [13] to yield the following expression:

$$S_{\mathrm{TM}} = \frac{N_{\mathrm{m}}}{n_{\mathrm{cl}}} \left\{ 1 + \frac{\left(N_{\mathrm{m}}^2 - n_{\mathrm{cl}}^2\right)}{N_{\mathrm{m}}^2} \right\} \frac{P_{\mathrm{cl}}}{P_{\mathrm{tot}}} \tag{48.4}$$

It can be seen that in addition to the fraction of modal power in the analyte there are two further factors that must be taken into account. The first is the velocity of the mode relative to the velocity of a wave in the bulk analyte (as described by the term $N_{\mathrm{m}}/n_{\mathrm{cl}}$) and the second is a term correcting for the additional component of electric field along the direction of propagation in the case of the TM polarization [13].

Because the effective index must always be higher than the superstrate index to allow a guided mode to be supported, the first two terms in Eq. (48.3) are always greater than unity, giving a sensitivity advantage to the TM polarization. However, the power fraction term is not the same for the two polarizations and will be optimized at different thicknesses for the two polarizations, so this must be calculated for the specific waveguide design before the relative sensitivities can be finally determined. For the usual case of a waveguide where the substrate has a higher index than the analyte, the optimized sensitivity is greater and the optimum core thickness is larger for the TM polarization, so this is likely to be preferred [12, 13]. While the same arguments apply to channel waveguides as to slab waveguides, precise optimization of the sensitivity usually requires numerical solution of the modal equations.

48.3.2
Optimization for Thin-Film Spectroscopy

Here, we consider the case where a film much thinner than the evanescent field depth, d_{cl}, is present at the waveguide/analyte interface. In this case, the sensitivity to the optical properties of the film is dominated by the optical intensity at the core/analyte interface. This surface intensity is shown in Figure 48.6b, for the waveguide modeled in Figure 48.6a, and where the mode is carrying a power of $1\,\mathrm{W\,m^{-1}}$ of (infinite slab) waveguide width. It can be seen that the surface intensity is maximized for close to the same thickness. As a rough approximation, $1\,\mathrm{W\,m^{-1}}$ (1 Watt per metre of slab waveguide width) in the slab waveguide is equivalent to 5 mW of total power carried in a typical $5\,\mu\mathrm{m}$ wide channel waveguide mode. The peak surface intensity is higher for the shorter wavelengths because the optimized waveguide is thinner and the light is therefore confined more tightly, yielding higher intensity for the same total modal power.

The broad considerations for waveguide design for evanescent spectroscopy have been discussed here. There are many variants depending on the specific spectroscopic application and these are discussed in the sections that follow according to classes of spectroscopic measurement. Many approaches have been taken to reaching a compromise between sensitivity and ease of use, and some of these are discussed in Section 48.8 on instrumentation.

48.4
Absorption Spectroscopy

The majority of measurements of absorption of bulk analytes and thin films have been carried out using lasers at single wavelengths or at a few discrete wavelengths, probably because of the perceived difficulty of coupling broadband light into waveguides. Plowman *et al.* [23] presented an excellent review of waveguide-based spectroscopies up to 1997. Here, a very brief review of the historical development is given followed by a more detailed description of developments since 2000, concentrating on broadband absorption spectroscopy. In 1972, Polky and Harris [6] at the University of Washington made single-wavelength absorption measurements of solutions of methylene blue (MB) using sputtered glass waveguides. They observed enhanced absorption due to adsorption of MB at the waveguide surface and reconciled the measurements with theoretical models. In 1974, extending this work, Mitchell *et al.* [7] conducted single-wavelength measurements of bilirubin in blood plasma samples, emphasizing the suppression of the effects of scattering by erythrocytes using evanescent techniques compared with conventional absorption spectroscopy, the lack of blood sample preparation needed, and the subnanoliter volumes required for waveguide spectroscopy. In 1979, Swalen [24] reviewed the use of waveguides for surface spectroscopy and pointed out that the causal relationship between the imaginary (absorptive) part and the real part of the refractive index of an analyte distorts an absorption spectrum and that simultaneous measurement of the real part of the analyte refractive index (in this case through measuring prism-coupling angles) improves quantification. Measurements were made of monolayers of cadmium arachidate on glass and polyvinyl alcohol (PVA) waveguides, determining the optical anisotropy of the films over the visible spectrum, demonstrating the determination of molecular orientation in monomolecular films, and emphasizing the complementary nature of measurements of refractive index and absorption. In 1990, DeGrandpre *et al.* [25] applied high-index (tantalum pentoxide) planar waveguides to single-wavelength absorption spectroscopy of bromothymol blue in phosphate buffer, achieving a micromolar detection limit. Waveguide spectroscopy with multimoded waveguides may be attractive because of the ease of incoupling more power, but usually results in fluctuations in measured absorption because each mode has a different effective absorption coefficient and the distribution of power between modes tends to fluctuate. However, in 1995, Gnewuch and Renner [26] reported that multimode waveguides with linear refractive index profiles display mode-independent evanescent absorption. In the same year, Kato *et al.* [27] at the National Institute of Materials and Chemical Research in Japan demonstrated broadband (380–650 nm) spectroscopy of a Cu–porphyrin complex in a Langmuir–Blodgett (LB) film on a monomode ion-exchanged glass waveguide. Polarized absorption spectra were obtained, yielding information on bandsplitting due to aggregate formation and on molecular orientation. In 1999, the same group [28] extended this technique further into the UV by using highly multimoded Suprasil (silica) slab waveguides supported on a low-index fluoropolymer, and a pulsed Xenon lamp. In both [27] and [28], broadband light was coupled in by focusing onto an incoupling prism. The UV-visible spectrum of adsorbed cytochrome *c* was measured between 230 and 600 nm. This approach was then exploited for a wide range of surface spectroscopic measurements including absorption spectroscopy of a hemoglobin submonolayer [29], kinetic studies of cytochrome *c* adsorption [30], simultaneous determination of mixed MB and new MB adsorption at a waveguide surface using an artificial neural network approach [31], coadsorption of myoglobin and MB [32], and metal nanoparticle self-assembly on protein-functionalized glass [33]. In 1996, Mendes *et al.* [34] at the University of Arizona measured the absorption spectrum of a hydrated cytochrome *c* monolayer at the surface of a sputtered glass monomode waveguide using broadband light from 500 to 600 nm. The absorption spectrum yields information on ligand binding, oxidation, and protein conformation. Conventional transmission spectroscopy is insufficiently sensitive to achieve absorption measurements on these ∼3 nm thick films, and waveguide spectroscopy achieved an enhancement in absorption of order 10^4, by evanescent absorption along a ∼1 cm long protein film. A broadband (achromatic) input coupler was used to couple light into the 400 nm thick waveguide and an output grating was used to disperse the transmitted light onto a charged-coupled device (CCD) camera, yielding transmission spectra without the need for an external monochromator. More recently, Araci *et al.* [35] have used a silver-diffused waveguide with high sensitivity and improved short-wavelength transmission (∼400 nm) to study the Soret band at 406 nm in a submonolayer film of cytochrome *c*, and employed channel waveguides due to their efficient coupling to lasers and detectors using optical fiber. In a dramatic demonstration of the suppression of scattering in the measurement of absorption spectra of powdered materials without pretreatment, using evanescent spectroscopy, Ogawa *et al.* [36] obtained UV-visible absorption spectra of naphthalene and salicylideneaniline powders placed directly on the waveguide surface. Infrared waveguide spectroscopy was demonstrated by Plunkett *et al.* [37], by using a multimoded germanium slab waveguide on a ZnS substrate with an Fourier transform infrared (FTIR) spectrometer. This extended conventional infrared IREs by reducing the slab thickness to improve sensitivity, necessitating support on a substrate. Absorption spectra of deuterated water were obtained at wavelengths in the range of approximately 2–10 μm, and spectroscopy using the wider range of IR waveguides which are now available [38], is likely to be a significant area for growth. Further extension of waveguide spectroscopy to the Terahertz region has been demonstrated by Zhang and Grischowsky [39], where a parallel-plate metallic waveguide was used to determine the refractive index and absorption of a 20 nm film of water on the internal waveguide walls at frequencies up to 2.5 THz. Terahertz spectroscopy has many potential applications in environmental monitoring, medicine, security, and biomolecular film characterization, and novel Terahertz waveguide materials and configurations for spectroscopy are under intense investigation. Laamiri *et al.* [40] have recently demonstrated evanescent spectroscopy of a film of photoresist using a grating-coupled silicon slab waveguide at frequencies up to 1 THz.

The examples of waveguide absorption spectroscopy described here illustrate the advantages of the technique, in particular for high-sensitivity spectroscopy of ultrathin films, spectroscopy of bulk analytes avoiding the effects of transmission through the medium, particularly scattering, and analysis of surface-specific interactions. Many of the approaches have used readily available low-cost highly multimoded slab waveguides, which differ only slightly from conventional IREs, but the examples cited here emphasize the sensitivity advantages that can be gained as the waveguides become thinner and, ultimately, monomode.

Waveguide technology has primarily been developed for the telecommunications industry so the materials systems have been optimized for operation at wavelengths between 800 and 1600 nm. However, interest in mid-IR waveguiding at wavelengths from 2 to 20 μm is increasing and it is expected that the study of new waveguide systems appropriate for evanescent spectroscopy over a much wider range of wavelengths will continue to expand. There are many glass compositions that support transmission into the IR and which are now being developed for application to mid-IR waveguide spectroscopy. The majority of optical waveguide approaches to mid-IR sensing demonstrated to date have concentrated on silver halide [41] and chalcogenide glasses [42, 43]. The $AgCl_{0.4}Br_{0.6}$ waveguides were excited with a 6 μm quantum cascade laser (QCL) to detect urea and a 10 μm QCL to detect acetic anhydride, and FTIR spectroscopy was also carried out to validate these results. While yielding excellent transmission into the IR, these waveguides were essentially free-standing bulk ATR elements reduced to the thickness of a silicon wafer by hot pressing. This is incompatible with the thin-film processing techniques required for high sensitivity and mass production, and the halides are not ideal in terms of chemical durability. The chalcogenide waveguides first used for mid-IR studies were formed from Germanium-Antimony-Selenide [43] and Germanium-Antimony-Sulfide [42] glasses. For the selenides, a thin-film cladding and waveguides were evaporated on silicon, and human IgG was successfully immobilized on the films, but only external (nonwaveguiding) mid-IR spectra were reported, confirming successful immobilization. The thin-film sulfide waveguides were thermally evaporated directly onto an oxidized silicon wafer; measurements were reported in the NIR for the N−H bond absorption near 1.5 μm from *N*-methylaniline. Microdisk resonators for cavity-enhanced IR absorption have now been integrated and used to measure enhanced absorption of *N*-methylaniline in carbon tetrachloride [38]. Recently, the group at the University of Rennes realized high-quality sulfide waveguides by RF sputtering directly on oxidized silicon and reactive-ion etching and immobilization of avidin [44] has been monitored through NIR spectroscopy. More advanced biochemical systems have recently been studied through mid-IR evanescent absorption spectroscopy, using surface-modified zinc selenide waveguides and an FTIR spectrometer, to detect DNA hybridization through direct observation of vibrational modes [45]. In a further development by the same group, extremely sensitive detection of acetic anhydride has been achieved using monomode GaAs/GaAlAs strip waveguides and a QCL [46], achieving 1000-fold improvement in detection limit when compared with the multimoded silver halide waveguides [41].

48.5
Waveguide Spectroelectrochemistry

The planar geometry, surface sensitivity, and microfabrication technology employed in integrated optical waveguides render them ideal for integration with thin-film electrodes for spectroelectrochemical measurements, as first identified by Itoh and Fujishima [47] in 1988. Electrochemical absorption spectroscopy on waveguides is usually achieved by depositing a thin (10–100 nm) film of indium tin oxide (ITO) on the waveguide surface by sputtering or electron-beam deposition and using the waveguide as mentioned, but in a conventional three-electrode cell with the ITO film as the working electrode. The high sensitivity of waveguides to optical absorption requires that the ITO film be kept as thin as possible to minimize the excess attenuation, as ITO is strongly absorbing compared with most optical materials. However, the requirement of low sheet resistance for electrochemical cycling favors the use of thick films, resulting in a trade-off that depends on the exact configuration and measurement being carried out. Furthermore, the high index ($1.75 < n < 2.1$) of the ITO films will also pull the optical fields in the waveguide up to the surface, increasing the sensitivity of these waveguides to absorption [48], but, unfortunately, this also increases the loss due to the ITO absorption. These ITO loading losses are often reduced to an acceptable level by placing a low-index transparent layer (such as SiO_2) between the waveguide and the ITO, but this reduces sensitivity, emphasizing that careful design and well-controlled fabrication are required to optimize the device for the particular application.

Itoh and Fujishima [47] first demonstrated an optical waveguide combined with a thin-film ITO electrode for the oxidation and reduction of MB. A ~100 nm thick film of ITO was deposited directly on a potassium ion-exchanged slab waveguide by spray pyrolysis. Gratings were used to couple light from a He–Ne laser into and out of the waveguide, which was covered with a 1 cm long cell containing 10^{-3} M aqueous solution of MB. Both the transmitted optical power and a cyclic voltammogram were recorded as the electrode potential was swept between −1.0 and +0.5 V, showing a clear correlation between the oxidation and reduction current and the optical absorption. Subsequent measurements with the MB solution replaced by 0.1 M KCl showed similar behavior, indicating that the observed redox reaction is mainly due to adsorbed MB molecules. Piraud *et al.* [49] studied oxidation and reduction of a 10 nm thick film of lutetium biphthalocyanine ($Lu(PC)_2$) of length 4.5 mm on a potassium ion-exchanged channel waveguide, as an electrochemically resettable chlorine sensor. The waveguide was coated with a 200 nm thick film of silica and a 10 nm thick film of ITO by vacuum evaporation followed by annealing, achieving low losses and acceptable sheet resistance. White light was coupled from a tungsten halogen lamp into the waveguide via a monomode optical fiber, and a monochromator and avalanche photodiode (APD) were used to obtain transmission spectra at wavelengths between 550 nm and 1 μm as the electrode potential was swept between −0.1 and +0.8 V, with the cyclic voltammogram being recorded simultaneously. Strong absorption spectra were obtained for both the oxidized and reduced forms of these very thin $Lu(PC)_2$ films. Dunphy *et al.* [50] used a moderately high-index-sputtered glass slab waveguide ($n = 1.56$ on a substrate of index 1.51) to achieve highly sensitive single-wavelength measurement of the oxidation and reduction of a submonolayer film (<0.4% of a full monolayer) of MB, achieving enhancement in signal by a factor of 40 000 compared with conventional transmission. The waveguide film was 400 nm thick and it was coated with a 200 nm silica film followed by a 50 nm ITO film. Gratings were used to couple light from a He–Ne laser into and out of the waveguide. It was observed that the ITO film increases the sensitivity of the measurement because of its high refractive index. Cycling the electrode potential between 50 and −450 mV caused clear changes in waveguide absorption, which correlated well with the voltammetry. The device was then used to study the formation of Prussian Blue during the reduction of ferricyanide, showing that the complementary optical information helped in identifying otherwise concealed electrochemical processes. The authors then used a prism-based broadband coupling approach combined with an ITO layer on a similar waveguide with a flow-cell, to obtain broadband (500–700 nm) spectra of submonolayers of cytochrome *c* [51], in both the oxidized state when held at +0.4 V and reduced state when held at −0.4 V (with respect to an Ag/AgCl electrode). Similar measurements were then made on the weakly absorbing chromophore 1,1′-ferrocenedicarboxilic acid ($Fc(COOH)_2$). Ross *et al.* built upon earlier work combining ITO-coated IREs with a selective film into which the analyte is selectively partitioned [52] by combining a potassium ion-exchanged waveguide with a 150 nm thick ITO electrode coated with an anionically charge-selective sol–gel derived poly(dimethyldiallylammonium chloride): SiO_2 composite film [53]. This allowed both electrical and optical measurements, as in the earlier examples, but added the advantage of preconcentration of the electroactive species in the selective film. The same authors went on to realize a channel waveguide design with gold electrodes placed on either side of the waveguide, partially avoiding the problems of spurious absorption and unwanted interference from modulation of the optical properties of the electrode encountered when directly loading the waveguide with the electrode [54]. Matsuda *et al.* [55] used an ITO-coated slab waveguide to observe absorption spectra during electrochemical reduction and oxidation of adsorbed heptylviologen cation radicals, extending their work on waveguide absorption spectroscopy [27]. The addition of a Nafion film on the ITO allowed separation of the contribution to the absorption spectrum due to the Br^- ion, which is unable to enter the Nafion film. This was followed by a detailed quantitative study of the potential dependence of the optical properties of MB adsorbed on a 30 nm thick ITO electrode on a 50 μm thick glass plate acting as a slab waveguide [56]. To relax the requirement for a transparent electrode, Fujita *et al.* [57] demonstrated "noncontact optical waveguide spectroscopy," in which the molecules to be studied were adsorbed on a carbon electrode spaced by ∼120 nm from the waveguide surface, still within the evanescent field, in a configuration reminiscent of the "Otto" SPR configuration. Latex beads were used to space the carbon electrode from the highly multimoded quartz slab waveguide and oxidation and reduction of adsorbed cytochrome *c* was studied, with absorption spectra being obtained from 350 to 600 nm.

In summary, waveguide devices offer similar advantages in spectroelectrochemistry as they do in simple absorption spectroscopy, with particular convenience due to the simplicity with which planar electrodes and electrode arrays can be integrated with waveguides and waveguide arrays, using microfabrication techniques.

48.6
Fluorescence Spectroscopy

The advantages of internal reflection fluorescence spectroscopy were first laid out by Hirschfeld [58] in 1965 for a conventional IRE, and the approach was developed by Harrick and Loeb [59] for multiple internal reflection to observe both enhanced absorption and enhanced collection of fluorescence spectra. They noted a small shift of the emission spectrum compared with solution fluorescence possibly due to the changed environment of the molecules. TIRF brings the advantages of *enhanced absorption* as in the case of absorption spectroscopy, *enhanced emission* due to strong evanescent tunneling into the higher index medium, and the potential for *enhanced collection* of fluorescence spectra within the IRE. As in the case of absorption spectroscopy, improvements in sensitivity are achieved using thinner IREs, driving developments in TIRF toward ultrathin optical waveguides, as pioneered by Reichert [60] in 1987. Optimization of waveguides to maximize fluorescence from an analyte on an optical waveguide follows trends similar to maximization of the strength of absorption spectra, and is discussed in detail in several papers [14, 61, 62]. Key points to consider are (i) that the emission from a fluorophore in an evanescent field is increased compared with that in the homogeneous medium in which it is bathed, due to tunneling into the higher index medium and/or into the (higher effective index) modes of a waveguide [63] and (ii) that the angular emission pattern is strongly distorted by the presence of the high-index medium [64], so that optimization of collection efficiency must consider emission into waveguide modes and the angular distribution of emission into the substrate. Collection of light by most (asymmetrical) waveguides is usually quite inefficient, so that most waveguide fluorescence measurements exploit absorption from the waveguide mode but collect the emitted fluorescence conventionally with a high numerical aperture (NA) lens above or below the waveguide. A further advantage of evanescent fluorescence spectroscopy in real samples is the strong suppression of background fluorescence from the bulk of the sample due to the short evanescent penetration depth into the analyte.

Although many fluorescence assays have been demonstrated using waveguides, where total fluorescence intensity has been measured (e.g., [65–69]), rather few measurements of the fluorescence spectra themselves have been made, and these will be the focus of this description of the use of waveguides for spectroscopy. Plowman *et al*. [70] employed a silicon oxynitride channel waveguide to carry out fluorescence immunoassays with femtomolar sensitivity, using a He–Ne laser at 633 nm with prism coupling into the waveguides and monochromator and CCD detector normal to the waveguides to collect the fluorescence spectra. They made the important observation that while waveguide optimization may increase the fluorescence signal, the detection limit will improve only if the waveguide itself shows low fluorescence and low loss, leading to their choice of silicon oxynitride waveguides and a pump wavelength of 633 nm rather than the shorter wavelengths usually used. Fluorescence spectra for Cy5-tagged bovine serum albumin (BSA) at a wide range of concentration were obtained over a wavelength window from 650 to 750 nm. Simpson *et al.* [71] studied the fluorescence spectra of self-assembled monolayers (SAMs) of phthalocyanines having mercaptoalkyl chains of different lengths, on gold-coated glass slides acting as highly multimoded waveguides. A laser diode at 670 nm was used for excitation and the fluorescence was collected using a monochromator and photomultiplier. A significant redshift in the fluorescence spectrum was observed compared with solution spectra, potentially due to the ordered nature of the film on the surface. The molecule with the longer mercaptoalkyl chain yielded much stronger spectra, and this is believed to be due to reduction in quenching by the gold film. Exposure to NO_2 gas was found to cause partially reversible quenching of the fluorescence. Kelly *et al.* [72] formed a phospholipid bilayer containing donor and acceptor dye-tagged glycolipid receptors on a sputtered Corning 7059 glass waveguide 400 nm thick to study the dependence of fluorescence emission spectra from 550 to 700 nm on binding of cholera toxin. Excitation was by light from a frequency-doubled yttrium aluminum garnet (YAG) laser emitting at 532 nm, coupled into the waveguide using a grating. The fluorescence spectrum, collected from underneath the waveguide through the substrate using a fiber-coupled spectrometer, showed combined emission from the Bodipy TMR (donor) and the Bodipy TR (acceptor) fluorophores. The multivalent cholera toxin binds multiple receptors, increasing the proximity of donors and acceptors, leading to energy transfer and increased long-wavelength emission. Binding of cholera toxin was shown to cause an increase in the acceptor emission at 625 nm and a reduction in emission from the donor at 575 nm, and the ratio of these was correlated with cholera toxin concentration, allowing picomolar detection. Recently, this team extended their approach, with silicon oxynitride waveguides, to quantification of tumor markers [73] using a sandwich immunoassay for carcinoembryonic antigen (CEA) with Alexafluor 647 dye. Fluorescence spectra were recorded between 650 and 800 nm, and a detection limit of <0.5 pM CEA, an order of magnitude below the normal physiological concentration, was achieved.

A strong fluorescence signal from low densities of fluorophores usually requires collection over a waveguide length of some millimeters, requiring nonideally long devices and large sample volumes. The use of a microresonator can reduce the sample size and waveguide length by storing energy, for example, in whispering gallery modes [74]. The pump power circulating in the resonator is then greater than the power in the supply waveguide, owing to energy storage, so that stronger fluorescent emission is obtained as long as photobleaching is not a limiting factor. Enhanced waveguide fluorescence spectroscopy was demonstrated using an integrated optical disk resonator by Krioukov *et al.* [75]. The fluorescence spectrum of indocyanine green dye on a 30 μm diameter silicon nitride disk coupled was obtained by tunnelling from an underlying silicon nitride channel waveguide, through a silica layer, and collecting the fluorescence from above with a high NA lens. The volume probed by the evanescent field may be as low as ~10 fl and acquisition of spectra from 20 molecules with 1 μW input power was projected, with the use of an even lower fluorescence ZnO waveguide system to potentially allow single-molecule detection being proposed.

48.7
Waveguide Raman Spectroscopy

Enhanced Raman spectroscopy of thin-film materials acting as waveguides was proposed and demonstrated by Levy *et al.* [76] in 1974 using thin (1 and 6 μm) methyl methacrylate films on glass substrates. Strong Raman spectra were obtained, due to the high pump intensity maintained over a long path-length but, for the thinner film, the greater fraction of modal power traveling in the substrate caused interference in the polymer spectrum by the Raman spectrum of the glass substrate. Rabolt *et al.* [77] at Intercontinental Ballistic Missiles (IBM) subsequently improved the discrimination between film and substrate for thin polymer films by using a low-index substrate, which caused the waveguide mode to be better confined in the film, and then went on to use a purpose-built waveguide, rather than the film under analysis, to guide the light, allowing Raman measurements to be made on nonguiding submicrometer films. Here, the strong surface intensity over a long path length in an appropriately designed waveguide was exploited. The effects of molecular orientation on polarized waveguide Raman measurements were then explored in polymethyl methacrylate (PMMA) and polystyrene waveguiding films by Schlotter and Rabolt [78]. Rabe *et al.* [79] conducted waveguide Raman studies of LB films of cadmium arachidate, using both the polarizations of the waveguide mode (TE and TM) to study anisotropy and order in these films. A 1 μm thick sputtered layer of Corning 7059 glass on silica or Pyrex was used as the waveguide. Raman emission from the multilayer LB films was collected normal to the waveguide from above, and analyzed using a double monochromator and cooled photomultiplier. Excitation was at 488 nm and waveguide fluorescence caused some interference in the 800–1600 cm^{-1} range but was insignificant for the C–H stretching region around 2900 cm^{-1}. Measurements at temperatures up to 150 °C showed Raman peak broadening, yielding information on chain tilting in the multilayer. Zimba *et al.* [80] studied films of cellulose acetate doped with 4% 2-nitro-5-(N-methyl-N octadecylamino) benzoic acid, for example, using longer wavelength excitation (1064nm) to reduce background fluorescence and avoid resonant excitation of the chromophore, and employed a Fourier transform infra-red (FTIR) spectrometer for detection. A substantial reduction in fluorescence was obtained when compared with excitation at 488 nm. Walker *et al.* [81] reported the first observation of Raman spectra from a protein film adsorbed to a *dielectric* surface, using a low-fluorescence silicon oxynitride waveguide, of core refractive index 1.523, to which was bound horse heart cytochrome *c*. This study combined waveguide ATR (absorption) measurements of linear dichroism with polarized resonance Raman spectroscopy of the protein film, using radiation at 514.5 nm to both measure the Cyt C absorption near 520 nm and to excite the resonance Raman spectra. The orientation of the heme group of the Cyt C was partially inferred from the measured dichroism and differences in the Raman spectra with polarization. Surface coverage of the Cyt C was estimated from the absorption measurements to be $\sim$50 ng cm^{-2}. Kanger *et al.* [82] used a very thin ($\sim$120 nm) much higher index low-fluorescence ZnO waveguide ($n_{co} \approx 2.0$) to achieve high-sensitivity *spontaneous* Raman spectroscopy of a monolayer of bovine albumin, using excitation at 514.5 nm.

SERS is a topic of growing importance that exploits metallic nanostructures to enhance Raman signals by factors of up to 10^8, on average, with electromagnetic hotspots exhibiting much higher local enhancements [83]. There have been several reports of Raman spectroscopy studies combining dielectric waveguides with metallic nanoparticles to achieve SERS in waveguide geometry. Ellahi *et al.* [84] obtained strong resonance Raman spectra from thick (73 μm) and thin (3.5 μm) PVA film waveguides doped with ruthenium(II) tris(bipyridine) ($Ru(bpy)_3{}^{2+}$) adsorbed to colloidal silver, excited at 457.9 and 514.5 nm; detection of about 40 pg of $Ru(bpy)_3{}^{2+}$ was achieved. Baldwin *et al.* [85] attached colloidal silver nanoparticles to the surface of a glass optical waveguide to achieve SERS at the surface of the waveguide. The SERS spectra of 2-mercaptopyridine (2-MPy) and 4-mercaptopyridine (4-MPy) were obtained and, to demonstrate metal ion detection, 4-MPy spectra were collected during exposure to aqueous $Cu(NO_3)_2$. Cu/pyridine complexation resulted in irreversible changes to the Raman spectrum, which was interpreted as binding of the pyridine nitrogen to the cations in solution. Acid/base titration of the surface-bound 4-MPy using HCl or NaOH showed strong and reversible changes in the Raman bands corresponding to protonated 4-MPy. Lal *et al.* [86] studied the interaction between the resonances of gold-coated silica spheres of approximate radius 30 nm and a waveguide structure on which they were randomly distributed. Strong dependence was observed on the nanoparticle-waveguide separation with a redshift in the spectra with decreasing separation, having important implications for the design of SERS structures on waveguides and the interpretation of the spectra obtained.

The waveguide geometry is particularly advantageous for coherent Raman spectroscopy as the Raman signals depend strongly on the pump and probe intensities, which can be very high in waveguides, and grow quadratically with the length of the waveguide. Coherent Raman scattering from monolayers on dielectric waveguides was proposed by Stegeman *et al.* [87] and the Raman spectrum of a polystyrene waveguide itself was then determined [88] using two dye lasers, one fixed at 564 nm and the other tuned between 596.6 and 598.8 nm, as the pump and probe beams, resulting in strong coherent Stokes Raman spectra. Cancellation of contributions to the Raman spectrum from the waveguiding medium itself may be minimized using modal interference in the waveguide [87], allowing signals from a surface adlayer to be detected. Coherent anti-Stokes Raman spectra were obtained from pyridine and phenol adsorbed on the surface of ZnO optical waveguides [89]. Wijekoon *et al.* [90] went on to apply this technique to obtain the Raman spectrum of benzene adsorbed on a ZnO planar waveguide, with the objective of determining the frequency of the symmetric ring-stretch mode of the benzene ring, and its dependence on the nature of the adsorption. Kanger *et al*. [91] applied stimulated Raman gain spectroscopy to 30 nm thick polystyrene films on silicon nitride waveguides, proposing the advantages of reduced complexity over waveguide coherent anti-Stokes Raman scattering (CARS) due to self-phase-matching and lack of nonresonant background from the waveguide material.

48.8
Instrumentation

In all configurations, the precise determination of spectroscopic information from thin films and bulk media is governed by the signal-to-noise ratio (S/N), where noise is considered in its broadest sense. This observation is not confined to waveguide spectroscopies, so a full treatment of these aspects of instrumentation is beyond the scope of this chapter, being treated very well in many texts, such as [92]. However, it is worth pointing out a few important factors to consider when using waveguides for spectroscopy, partly because optical waveguide researchers often devote huge effort to increasing the sensitivity of devices (and hence signal) while paying little attention to the equally important aspects of noise, drift, and signal processing, which often yield greater gains in detectability more simply and more cheaply, and partly because there are specific issues associated with using waveguides for spectroscopy that need to be borne in mind. The accuracy and precision with which spectra are obtained is also dependent on system calibration and the variability in sample preparation, dwell times, and interactions of chemicals with surfaces. Micropumps and microfluidic devices are making a significant contribution to reducing the variability of samples and their presentation to sensing devices [17], and will make a similar contribution in miniature spectroscopic systems. From the point of view of the developer of the waveguide device and the surrounding instrumentation and software, it is usually sufficient to provide a protocol for calibration and to reduce the optical and electronic noise sources and mechanical and thermal drifts to the point where it is the lack of repeatability in sample preparation that dominates uncertainties in the data acquired.

Spectroscopy using waveguides normally operates in the low-light-level regime where the dominant noise source is thermal noise in the receiver. The effect of this on S/N may be reduced by low-pass filtering or integrating for longer durations (reducing noise bandwidth) and using phase-sensitive detection. The power coupled into a monomode waveguide from a source such as a tungsten lamp for white-light absorption spectroscopy is fundamentally limited, but 30 dB of dynamic range is easy to achieve if a monomode optical fiber is used to spatially filter the light, and is butt coupled to a waveguide which has been well matched to the fiber (by matching mode field dimensions), and assuming that the spectrum is not fast varying. A well-mode-matched fiber ensures not only that the power entering the waveguide is maximized but that any light scattered into the substrate and superstrate, which may reach the detector, is minimized. For fast measurements of absorption spectra, higher brightness sources of white light such as supercontinuum sources [93] may provide benefits, as much more power may be launched into a mode, requiring less stringent noise reduction.

Unfortunately, most surface-sensitive waveguides are usually poorly mode matched to conventional optical fiber, in which case a mode transformer must be incorporated, or it may be better to use a grating or a prism to couple light into the waveguide, as described later. Itoh *et al.* [94] described a composite device comprising a fiber-compatible potassium ion-exchanged input/output waveguide with mode transformers to a thin high-index high-sensitivity waveguide overlayer, and subsequently replaced the high-index overlayer with a diffused high-index silver-ion-exchanged region [95, 96], both approaches effectively relaxing the trade-off between sensitivity and coupling efficiency. A compromise approach with the advantage of simplicity but the potential disadvantages of increased scattering loss or lower sensitivity is to simply deposit a short section of high-index film directly onto the fiber-compatible waveguide surface without mode transforming tapered velocity couplers [48, 97].

Coupling of light into waveguides with optical fiber is probably the best approach for spectroscopy if the waveguide is fiber compatible and if the fiber may be permanently fixed to the waveguide, as problems with alignment and mechanical drift are minimized and the light is spatially filtered by the fiber. However, issues of cost and disposability of waveguide devices often dictate that a permanent connection is not practical, in which case a grating- or prism-based approach is preferred. In this case, a ‘‘free-space’’ beam is directed at the grating (see, e.g., [67]) or prism (see, e.g., [27]) at an angle that allows phase matching of the incident beam to the waveguide mode. For monomode waveguides, the prism or grating approach may relax positional tolerances on input coupling and removes the need for tricky and expensive fiber ‘‘pigtailing’’ but places a severe constraint on the phase-matching angle. In the case of single-wavelength input, for example, for fluorescence or Raman spectroscopy, this constraint can be readily met. However, in the case of broadband input coupling for absorption spectroscopy, the coupling angle is usually different for each wavelength. Nonetheless, this can usually be overcome by appropriate focusing of the input light to provide a range of coupling angles or by using more sophisticated broadband input couplers [34]. In all cases, the power coupling efficiency and the effects of light not coupled into the waveguide must be considered carefully and weighed up against cost.

Once coupled power has been maximized and fundamental noise sources have been reduced to an acceptable level, other common limiting factors such as mechanical, thermal, and instrumental drift and sources of spurious radiation such as ambient light, background fluorescence, and any incident light not coupled into the waveguide but arriving at the photodetector must be reduced. These are mostly common to any spectroscopic system and may suggest the use of light-tight enclosures, phase-sensitive (lock-in) detection, background subtraction, and spectral correlation or principal component analysis, for example. Issues associated specifically with waveguides depend on the application, but for fluorescence and Raman spectroscopy may include choosing low-fluorescence substrates as described by Walker *et al.* [98], and filtering the output of the pump laser before coupling into the waveguide, to improve its spectral purity, especially in the case of semiconductor lasers. Mechanical stability is usually the next most important issue, and is effectively solved by permanently pigtailing input and output fiber to the waveguide where this is practical, or providing a very robust assembly for prism or grating coupling. Residual mechanical drift can be compensated for by including a reference branch in the waveguide device, as shown in the example in Figure 48.7, to allow a differential measurement to be made. A simple approach to reduce the effects of scattered light is to coat the unused surfaces of the waveguide substrate with an absorbing medium, bearing in mind that Fresnel reflection occurs even from poorly matched absorbing media, and to spatially filter the waveguide output to reduce the collection of light from the substrate on the receiver. Thermal effects at the waveguide are often minimized by monitoring and controlling the waveguide, sample, and mount temperatures. Whether any or all of these are required depends, of course, on the specification of the spectroscopic measurements to be made.

External commercial spectrometers are usually used to analyze the spectrum at the output of a waveguide device, and there are many suitable high-performance, compact, low-cost fiber-coupled spectrometers now available. Several groups have implemented waveguide spectrometers for chemical analysis, and these include arrayed waveguide grating (AWG) spectrometers where the optical detection and spectrometer were integrated on the same chip for absorption spectroscopy [99] and fluorescence spectroscopy [100], and AWG spectrometers for external Raman spectroscopy [101]. Fourier transform spectrometers have several well-known advantages over dispersive spectrometers and recent demonstrations have shown the potential for waveguide FTIR spectrometers [102–104], which may find application in integrated systems for waveguide spectroscopy of chemical species.

48.9
Conclusions

Optical waveguides have been employed for spectroscopic measurements since 1971–1972 when it was realized that this approach would drive the technique of TIR spectroscopy to its ultimate sensitivity and bring the benefits of mass production and integration, in terms of cost, robustness, and stability. Integrated optical waveguides may be fabricated from a vast range of materials and these must be selected carefully with the particular spectroscopic application and analytes and the required optical performance in mind. Optical waveguides have primarily been developed for optical telecommunications systems and therefore tend to employ materials that are transparent between 500 and 1800 nm. However, recently, waveguides for short wavelengths (400 nm and below) and for mid-IR (and even Terahertz) wavelengths are becoming increasingly available for new spectroscopic applications. The principles of optimization of waveguides for surface spectroscopy are quite straightforward, to the first order, and guidelines for optimization have been given in this chapter. Waveguide techniques lend themselves particularly well to the spectroscopy of ultrathin films, for example, of submonolayer protein films, where a strong optical interaction can be built up by integration over a long length, and where interferences from the bulk of an analyte medium are minimized because of the rapid decay of the evanescent field into the analyte. The microfabrication techniques employed for optical waveguides, and their surface sensitivity, render them ideal for integration with electrodes for spectroelectrochemical measurements, bringing an extra dimension to the spectroscopic technique. While fluorescence sensing using optical waveguides is well established, there have been rather few demonstrations of fluorescence spectroscopy on optical waveguides, despite the advantages of enhanced absorption and enhanced emission. This may be due to the historic expense of low-light-level spectrometers, combined with the high background fluorescence of many waveguide materials, but with the advent of high-performance miniature CCD spectrometers at low cost, and lower fluorescence waveguides, this may be expected to change. Raman spectroscopy lends itself to waveguide techniques for the same reasons, and with the same caveats, as fluorescence spectroscopy. SERS requires a structured metallic surface so that integrated optical waveguides, which are realized using photolithographic techniques, lend themselves well to integration with a structured metallic surface for repeatable SERS. In general, improvements in the sensitivity of spectroscopic techniques are achieved as much by focusing on noise and drift reduction as they do on the enhancement of signal strength. Careful consideration of noise reduction, signal referencing, data processing, and mechanical and thermal stability allows the potential for ultrahigh sensitivity of optical waveguide spectroscopies to be fully exploited.

Acknowledgments

I thank Mr Chris Nash, Dr Hamish Hunt, Dr Li Na Ng, and Dr Yuwapat Panitchob for their contributions to this chapter, and Prof. Olivier Parriaux of Université Jean

Monnet St-Etienne and Dr Hugo Hoekstra of the University of Twente for very helpful discussions.

Mass Spectral Detection

John C. Fetzer

49.1
Introduction

49.1.1
Mass Spectrometers

There are several books that specifically cover the use of GC–MS and LC–MS in certain application areas, including pharmaceutical and illicit drug analysis [1], toxicology [2], essential oils [3], food analysis [4], wines and spirits [5], and environmental analyses [6], among many topical areas.

49.1.1.1 **GC**

GC–MS is now a routine analytical procedure with turnkey instrumentation. This is due to the development of interfaces that readily remove the large excesses of helium carrier gas and leave only a small amount of material to go into the high vacuum of the MS. These interfaces rely on the vastly different diffusion and momentum of flowing helium gas molecules compared to the analytes. MS technology has improved, so that new approaches such as MS-MS detection are now common. In MS–MS, the initial ions of an analyte molecule are each passed onto a second MS that monitors specific fragments. This MS–MS approach allows much greater specificity in detection. A typical commercial MS–MS detector is shown in Figure 49.1.

49.1.1.2 **LC**

Mobile-phase removal or limitations on mobile-phase composition have been an inherent requirement to do LC–MS. The flow rates used in LC are large enough that even when the mobile phase can be completely volatilized, there is still too much material to be compatible with the high vacuum of an MS (it must be remembered that a liquid volume of 1 ml becomes more than 20 ml of gas). This problem is compounded by the widespread use of aqueous mobile phases as water is a more difficult solvent for MS and for vacuum systems to remove [7, 8].

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

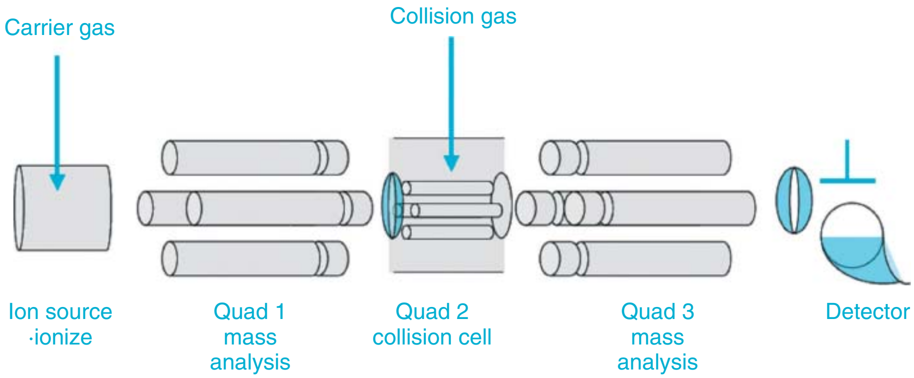

Figure 49.1 A typical quadrupole MS–MS as used for GC–MS–MS analyses.

49.1.2
Ionization Approaches for LC–ESI versus APCI

The mobile phase in LC determines, most often, which of the two main sample introduction approaches are used. A brief description will be given first.

Electrospray ionization (ESI) is based on nebulization of the LC effluent.

Atmospheric pressure chemical ionization (APCI) is an ambient-pressure method in which the mobile phase is heated and nebulized. Once evaporated, it is used as a chemical-ionization medium and reagent. This is accomplished by creating a plasma of the vaporized solvents.

ESI is a harder ionization source than APCI. Fragmentation of analytes and the creation of multiple charges on the ions can occur. Fragmentation reduces detection limits because not all of the analyte can be detected as the same ion. This fragmentation, however, can be used to determine structural details of an analyte. This is analogous to the fragmentation of molecules in normal electron-sector mass spectrometry. Multiple charges also reduce detection limits.

In chemical ionization, a chemical with certain affinities for compounds of interest is ionized. Through collisional deactivation, the charges are transferred to the analytes from the charged mobile-phase molecules. It is considered to be a ‘‘soft’’ ionization with little fragmentation of the analytes because the energy level is much lower than in traditional electron-impact ionization. Small amounts of chemicals can be added to the mobile phase, which do not affect the LC retention behavior but produce select detection. These dopant reagents undergo specific reactions with certain classes of compounds, yielding ions of a specific mass increase.

ESI is good for nonaqueous mobile phases but not for aqueous ones. Droplet formation and ionization kinetics can be problematic with aqueous mixtures.

Conversely, APCI is good with aqueous phases. APCI is also compatible with most organic and inorganic salts, so the buffered mobile phases used in pharmaceutical and clinical analyses are usable.

49.1.3
Application Examples for GC–MS and LC–MS

Applications of GC–MS and LC–MS are now commonplace and numerous. It would be impossible to cover most of the wide range of applications in a short chapter. That task would be the subject of a very long book. Instead, this section is an overview touching on several uses as examples of what LC–MS can do to give the reader a flavor of its scope and what kinds of information can be gained through using it.

This section gives a few recent examples of the variety of analyses published in tens of thousands of papers that utilized either GC–MS or LC–MS in the past few years. In most of these chapters, the authors function only as users of the instrumentation and techniques. They rely on the computer software and libraries to identify peaks and do little traditional mass spectrometry as it would be conceived of as a hyphenated technique. The chromatograph separates, the MS detector gathers data, and the data system gives results. These two techniques have become so commonplace and the instruments are so turnkey that any user can now produce high-level results.

Numerous example conditions for specific analyses have been developed by the instrument and column manufacturers. These are offered as a support service. One such chromatogram is shown in Figures 49.1–49.6. Figure 49.2 shows the separation of polybromodiphenyl ethers, formerly used as flame retardants until their health effects became known. The isomer groups severely overlap, so the specificity of MS detection is required.

Figure 49.3 shows the separation of the trimethylsilane derivatives cocaine and three of its major metabolites. Figure 49.4 is a total ion chromatogram, the sum of all ion responses to increase sensitivity, for the four tocopherol (vitamin E) iosomers. Figure 49.5 is a chromatogram of the many flavorants and additives found in a citrus-flavored soft drink. The complexity of gasoline is reflected in the chromatogram of Figure 49.6.

Ultrahigh-pressure liquid chromatography (UPLC) uses columns packed with particles of 1–2 μm in diameter. The LC systems for UPLC have extremely small dead volumes and operate at much higher pressures than conventional HPLC. The result is much greater resolution and shorter retention times. One example is shown in Figure 49.7. The detection was with fast-scanning MS over targeted mass ranges of analytes during ranges around their expected elution times (retention-time window monitoring) [9–11].

As in other areas of chromatography, GC–MS has benefited by the use of solid-phase extraction (SPE) and solid-phase microextraction (SPME) for sample cleanup or fractionation. Using reversed-phase SPME, very low levels of polycyclic

aromatic hydrocarbons in water samples were found [12, 13]. These techniques can be automated and even done within sample vials within the GC sample carousel, leading to high throughputs for routine analyses.

Many compounds of interest are biological or within an aqueous matrix. The polar functionalities of these molecules that lend them to aqueous solubility also create similar molecular interactions that decrease their volatilities. Increasing volatility by using higher temperature separations is often not possible because of potential degradation. Derivatization still remains the method of choice for GC–MS analyses of nonvolatile analytes. Ledauphin and coworkers used GC–MS of the 3-methylbenzothiazolin-2-one hydrazone derivatives of C5 to C11 *n*-aldehydes found in beverages [14]. Ten estrogen metabolites were analyzed by a GC–MS method [15]. Samples were cleaned through SPE on C18 cartridges and the analytes were derivatized with *O*-trimethylsilyl ether derivatization.

In contrast to GC, where derivatization is predominantly used to make compounds volatile, in LC derivatization is mainly used to make analytes detectable through increases in sensitivity or selectivity. An example in which this was done was the derivatization of amines by 1,2-benzo-3,4-dihydrocarbazole-9-isopropyl chloroformate [16]. In APCI mode, the $M+1$ ion of these derivatives is very intense, improving the sensitivity to around 1 ppm of the injected amount.

Selective ion monitoring (SIM) is a very important methodology in environmental analysis. In SIM, target ions are monitored in the retention-time window for the analytes' expected elution. The environmental pollutant dinitropyrene isomers have been separated by GC and monitored by MS [17]. Yeast metabolites were identified and quantified using GC–MS [18].

LC–MS has seen an even greater increase in application over the past decade than that of GC–MS. LC–MS once required a knowledge of both techniques to ensure their compatibility. Now, interface or the use of APCI means that the instrumentation no longer has these limitations. Therefore, users can essentially be operators only. Although much published work shows more sophistication than this, the need for knowledge of both LC and MS principles is much, much less. Figure 49.8 shows a chromatogram of 224 pesticides by LC-MS-MS.

Trace analytes are now routinely examined by LC–MS techniques. One was for 12 pesticide contaminants in various fruit samples of oranges, strawberries, cherries, peaches, apricots, and pears [19]. The pesticide amitraz and its degradation products were determined in pears using LC–MS after sample extraction and supercritical fluid extraction (SFE) cleanup [20].

Such sensitivity and the ability to identify molecules have led to LC–MS being used widely in clinical application. The identification of impurities within [21] and the metabolites [22–24] of pharmaceuticals and dietary supplements are common applications.

The metabolites of the important dietary flavonol quercetin were examined by LC–ESI–MS–MS [25]. A specific metabolite, tribendimidine, of the pharmaceutical tribendimidine was determined through the use of LC–MS techniques [26]. The evidence of traces levels of illicit steroids were found through the use of SPE sample preparation and reversed-phase LC–MS [27].

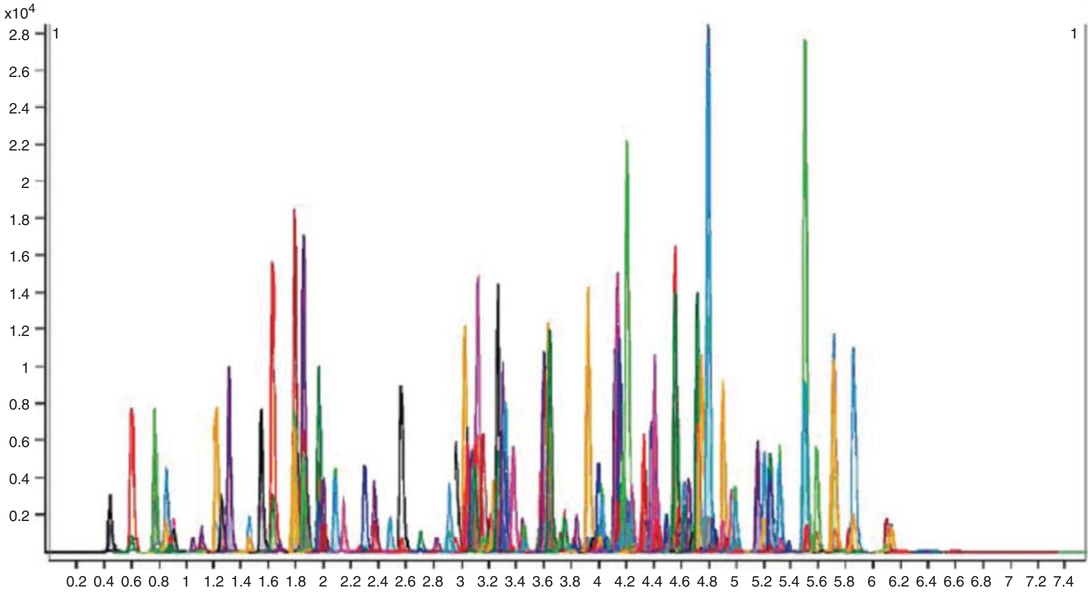

Figure 49.8 LC–MS separation utilizing ultrahigh-pressure LC and MS monitoring of retention windows for target masses in the analysis of 224 pesticides in a standard mixture.

The fungus *Fusarium verticillioides* infests many plants, including maize and other grains. *F. verticillioides* is a pathogen of many plants and produces fumonisins, which are both toxic to animals and humans and it affects the sprouting and growth of crops. An LC–MS method to determine the presence of the fumonisins was used to determine if this fungal contamination had occurred in maize samples [28]. An LC–MS method could determine 18 illegal drugs in samples of human saliva [29]. A method for the anticholesterol medication pravastatin and its metabolites in human plasma samples used LC–MS [30]. It provided both sensitivity and high throughput. An analogous type of method for the antipsychotic medication risperidone and its metabolites also utilized LC–MS–MS [31]. The method used positive ion detection and the separation was able to differentiate the various enantiomers of 9-hydroxyrisperidone.

The testing of animals for drugs and toxins is now routinely done by LC–MS to ensure food safety. One example is the analysis of antiinflammatory drugs in cattle used for milk and beef production [32]. Similarly, the antibiotic nitrofurazone was looked for in a variety of meat, poultry, dairy, and fish samples [33]. Yatsukawa and coworkers used LC–MS to analyze the antibiotics sedecamyin and terdecamycin (TDM) in meat and dairy products [34].

Optical Detection

John C. Fetzer

50.1

UV Detection

The photodiode array detector is the most used UV absorbance detector. Different instrument vendors abbreviate this as PDA or DAD (diode-array detector). PDA will be used in this review. PDAs are commonly utilized even when only single-wavelength monitoring is used and are produced by a wide variety of instrument companies.

The PDA relies on simultaneous detection of the intensity of light at all wavelengths within a selected range. This is accomplished through the use of an optical design and optical devices that are very different from what was formerly used for UV detection in liquid chromatography (LC). One such commercial design is shown in Figure 50.1.

In the past, only a single wavelength was monitored. The light from the source was separated by a prism or diffraction grating, and a monochromator passed only the one selected wavelength through the chromatographic sample cell. No spectral information could be collected, except through stop-flow scanning techniques.

The photodiode array detector (abbreviated as DAD or PDA by various instrument manufacturers – and DAD will be used here) passes the total beam from the light sources through the flow cell. In contrast to the monochromator-based detector, both the tungsten and deuterium light sources are used simultaneously if both high and low wavelengths are needed (in the monochromator-based system, the scanning aspect precluded the need for this). As all wavelengths obey the Beer–Lambert law independently, a separated sample component will absorb the wavelengths according to its UV spectral responses. The diffraction grating is placed after this, spreading the light into a band. This is focused onto a row of photodiodes, semiconductor devices that respond to light intensity. Each photodiode, thus, covers a small range of the diffracted light. The current from each photodiode correlates with the intensity each receives. The responses of all of the series of photodiodes correspond with the analyte's absorbance spectrum.

As a spectroscopic approach, UV is, in general, inherently less informative than other molecular spectroscopy techniques. The presence of a chromophore within

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

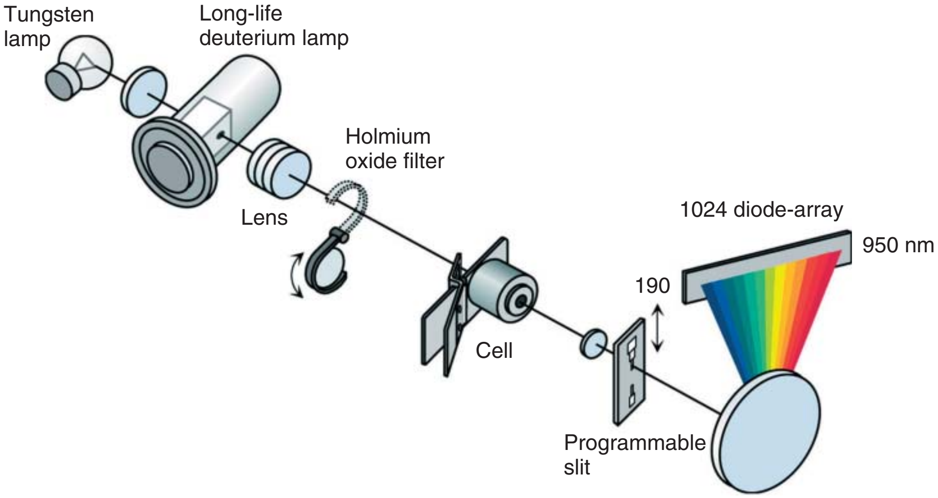

Figure 50.1 Schematic diagram of a typical diode-array UV detector. (By courtesy of Agilent Instruments.)

the viewing range of the mobile phase is one limitation. Some common LC solvents, such as tetrahydrofuran, acetone, and ethyl acetate, have high UV absorbances in the range where many molecules have their own absorbances.

UV activity usually involves electronic transitions of π or lone-pair electrons. These transitions are broad and featureless for most chemical structures, being 50–100 nm wide and having only a single, rounded peak. Minor differences in the location occur because of derivatization. A methyl group, for instance, shifts the spectrum upward by 1–2 nm, while deuteration shifts downward a similar amount. These are due to electron-withdrawing and electron-donating tendencies.

Solvent choices also have an effect on the use of UV spectral detection as the technique. The location of an absorbance band is usually solvent dependent. The range of shift may be as great as 15–20 nm from a nonpolar solvent, such as hexane, to a very polar mixture containing water and methanol. This limits the use of spectral atlases and library-matching programs to solvents of very similar interactions or necessitates corrections. Most software do not have such a feature, so this must be done manually.

Because UV bands are so broad and featureless, their use in identifying compounds is not often used unless a pure standard is available for comparison of the spectrum and chromatographic retention time. If that is the case, spectra of the standard and unknown peak can be directly compared without worries over solvent shifts and other artifacts.

The best-known exception to this generality for organic compounds is the class of polycyclic aromatic hydrocarbons. Their UV spectra are determined by the arrangement of the multiple fused aromatic rings in their structures. These various arrangements result in UV spectra with numerous bands, generally a dozen

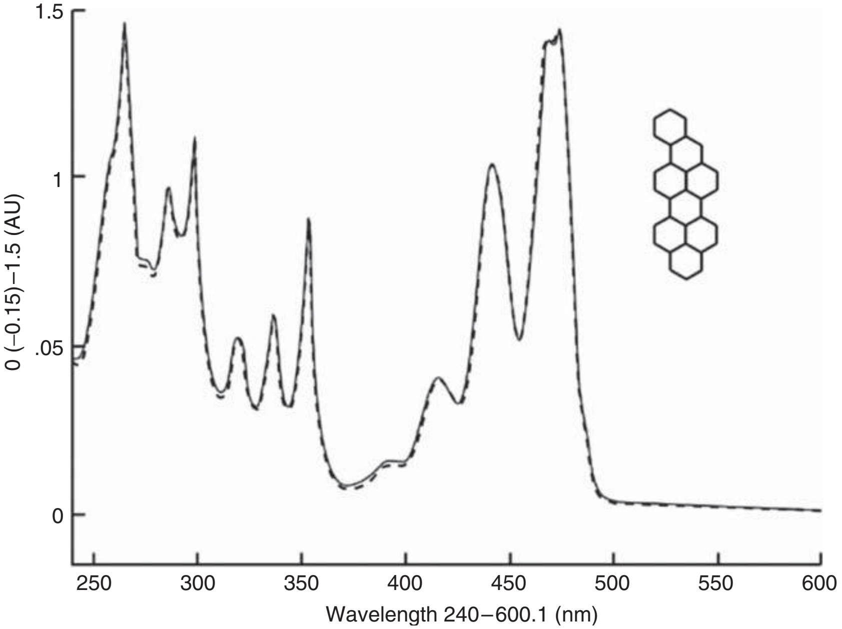

Figure 50.2 The UV spectrum of the nine-ring PAH.

or more, arranged in distinct patterns of different intensities and with narrow widths [1]. A typical UV spectrum obtained during a chromatographic run of a polycyclic aromatic hydrocarbon (PAH) is shown in Figure 50.2. These are often very intense, with molar absorptivities of five or six orders of magnitude. Figure 50.3 shows the separation of several eight-ring PAH isomers by reversed-phase high-performance liquid chromatography (HPLC).

Inorganic ions often have distinct UV spectra, so UV detection can be used both qualitatively and quantitatively. The ions of many transition metals have high-wavelength absorbance bands (thus, their characteristic colors that change with oxidation state). The best example of this is the lanthanide group of elements. In them, their buried f-shell electrons are what are seen in UV absorbance spectra. By not being involved in chelation or bonding, these electrons have many very narrow UV bands. These are distinct for each lanthanide.

A DAD detector is slightly less sensitive than a monochromator-based detector, typically 3–10 times less. The typical detection level is in the range of 0.1 milliabsorbance units (mAU) to 0.05 mAU. The lower limit for a typical intensity for a usable spectrum is 1–2 mAU, but analytes with very sharp and narrow bands may be identifiable below this level.

The resolution of a DAD is usually 1–2 nm. This is sufficient to even see the small upward shift in a spectrum when there is methyl or other alkyl substitution. The spectra of pyrene and three of its alkyl derivatives are shown in Figure 50.4, also showing that the basic pattern in the spectra does not change.

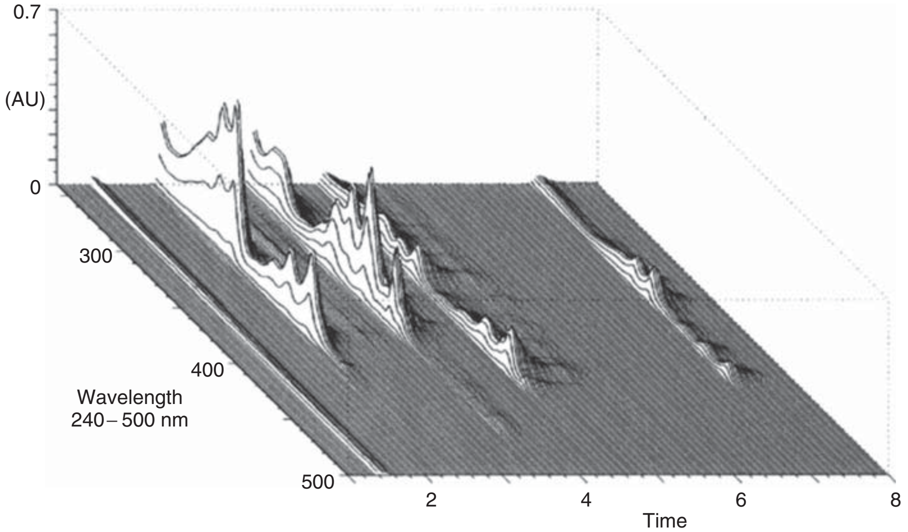

Figure 50.3 A three-dimensional chromatogram of PAHs separated by nonaqueous reversed-phase HPLC.

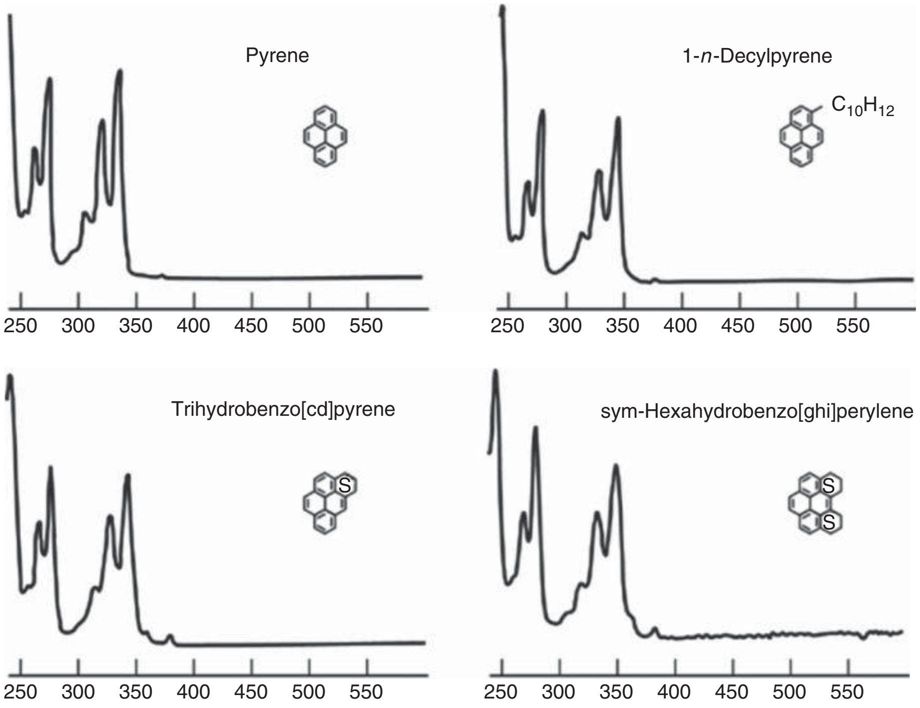

Figure 50.4 DAD spectra of pyrene and some of its alkyl derivatives showing the slight upward shifts.

50.2
Fluorescence Detection

Fluorescence excitation and UV absorbance involve the same electronic transition, that of an electron going from a ground state to an excited state. UV absorbance, however, involves all such transitions. Fluorescence excitation, as it is monitored by the resulting emission from the lowest excited state to the highest ground state, only involves the excitation of an electron upward through those two states. Therefore, a fluorescence excitation spectrum is usually only about 50–150 nm wide, in contrast to an absorbance spectrum that might be several hundred nanometer wide.

A typical spectral pair for a PAH is shown in Figure 50.5. The mirror-image quality between excitation and emission is common in PAHs.

How does this affect the use of a spectrofluorometer as a detector? With such a short range (the range for the emission spectra are similarly short), a fast-scanning spectrofluorometer might scan a peak in a short enough time where there is little change in concentration that might distort the spectrum. Stopping the flow to scan, however, is often the common practice when collecting fluorescence spectra.

There has been a commercially available diode-array-based detector. Unfortunately, its slit width settings were very wide, 15 nm, and not adjustable. This leads to much higher light throughput and better sensitivity for monitoring in the

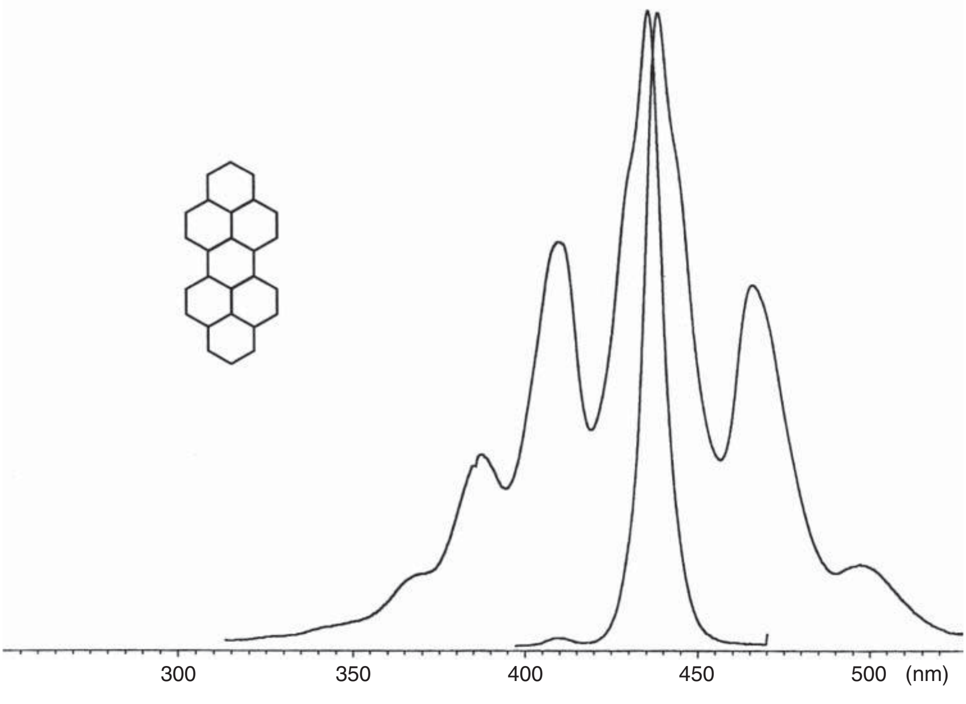

Figure 50.5 The fluorescence excitation and emission spectra of dibenzo[cd,lm]perylene.

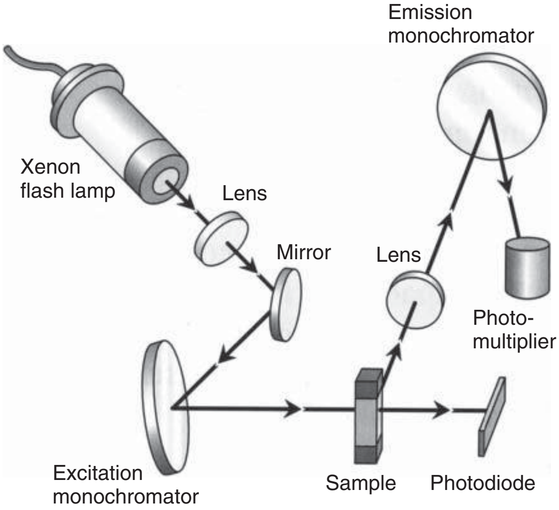

Figure 50.6 A schematic of a full-spectrum fluorescence detector. (By courtesy of Agilent Instruments.)

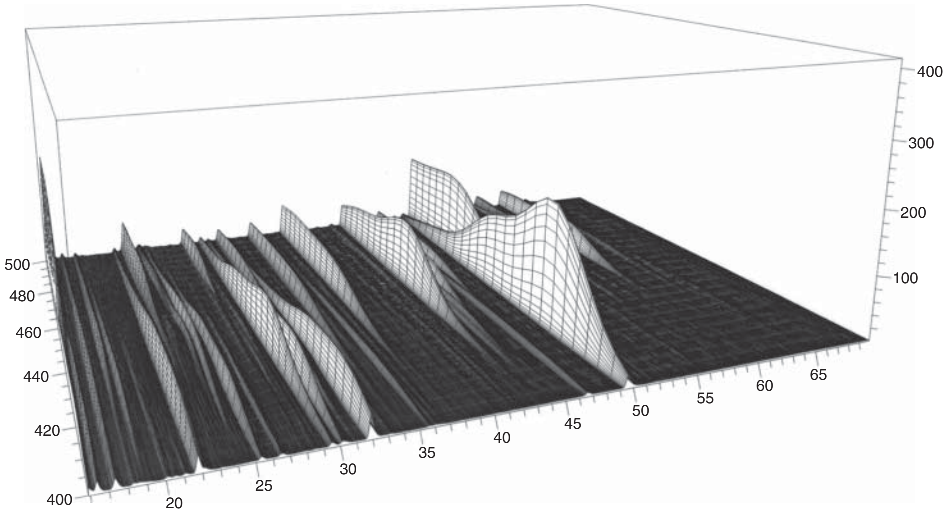

Figure 50.7 Chromatogram of a complex mixture of PAHs in a carbon-black extract. Each peak is in the nanogram-injected range.

chromatogram mode. The spectra, however, are broader. Any spectral features, such as the multiple bands seen in PAH spectra, are lost and peak identification is more difficult. The optical schematic of this detector is shown in Figure 50.6. A chromatogram of its output is shown in Figure 50.7, with the obvious broad and featureless spectra. If the resolution were better, these should be similar in pattern to the excitation spectrum in Figure 50.5.

50.3
Infrared Detection

The same separators developed for GC–MS are amenable for GC–FTIR. Griffiths describes the use of GC-FTIR to differentiate the four butylbenzene isomers. MS detection was unable to show the differences between two of the four.

Gas-phase infrared spectra can be quite different from solution ones. Two factors contribute to this, the much narrower transition lines for gas-phase molecular motions and the much higher experimental temperatures of the GC effluent than the room temperature. Reference spectra in the literature are almost always taken at room temperature and are solid-phase mixtures of neat liquids or solids mixed with potassium bromide.

This means that literature and library spectra cannot be matched to peaks found in the GC chromatogram. This necessitates building a library of gas-phase spectra by running standard compounds. Although this can be both tedious and limiting, it does add the chromatographic retention time as another confirming piece of data. The limitation is brought on by the requirement that a standard compound be available.

In LC, the mobile phase is present in hundred or even thousand times higher concentrations than the analytes. This results in large and significant spectral ranges being unavailable or limits the chromatography to several or more transparent solvents that may not perform the best separations.

50.4
Applications

UV detection is common in HPLC. Its application, therefore, is widespread. Multiwavelength and spectral detection are used to assess peak purity because a single component ought to obey the Beer–Lambert law throughout the peak, excepting in the very front and back portions where noise may be an issue. In addition, the absorbance spectra are used to identify the individual peaks.

One series of chapters uses HPLC-DAD to a high degree to identify PAHs produced in pyrolysis and combustion. The UV spectra are used both to identify unknown peaks through comparison to standard compounds and through interpretation of the locations of absorbance bands and the patterns within the spectra. In the latter methodology, several previously unknown large PAHs are identified [2–6].

An HPLC-DAD method was developed for quantification of aripiprazole and dehydro-aripiprazole, in human plasma. After a simple liquid–liquid extraction, chromatographic separation was carried out on a C18 reversed-phase column, using an ammonium buffer-acetonitrile mobile phase (40 : 60, v/v). The total run time was only 7 min at a flow rate of 1.0 ml min^{-1}. The precision values were less than 12% and the accuracy values were ranging from 98 to 113% and the lower limit of quantification was 2 ng ml^{-1} for both compounds. Calibration curves were linear over a range of 2–1000 ng ml^{-1}. The mean trough plasma concentrations in patients treated with aripiprazole were 157 and 29 ng ml^{-1} for aripiprazole and dehydro-aripiprazole, respectively [7].

The roles of isoflavones in the prevention of several hormone-dependent cancers and osteoporosis are of great interest. Despite many pharmacokinetics studies of the isoflavones, the actual types of conjugates circulating in the body and the position(s) of conjugation sites on the flavone skeleton are still uncertain because, in general, conjugated compounds in biological fluids have been evaluated by measuring the free aglycones obtained after selective enzymatic hydrolysis. Using a high-performance (HPLC)-UV-DAD method combined with solid-phase extraction, we have obtained HPLC profiles of isoflavone glycosides [daidzin (Din) and genistin (Gin)] and of intact isoflavone metabolites in human plasma: daidzein, genistein, daizein-7-glucuronide, daidzein-4′-glucuronide, genistein-7-glucuronide, genistein-4′-glucuronide, daidzein-7-sulfate, daidzein-4′-sulfate, genistein-7-sulfate, and genistein-4′-sulfate. We investigated the plasma profile of intact isoflavone metabolites in plasma obtained 1–7 h after oral administration of 50 g of kinako (baked soybean powder) to two healthy volunteers. The results of DAD analysis indicated that the main isoflavone metabolite peaks were identified on the HPLC chromatogram. Furthermore, the intact glycosides Din and Gin were detected in 1-h plasma samples by their positive electrospray ionization mass spectra, demonstrating that the glycosides Din and Gin can be absorbed from the gut [8, 9].

We report an offline multidimensional HPLC technique for the group separation and analysis of PAHs in a heavy gas oil fraction (boiling range 287–481 °C). Waxes present in the heavy gas oil fraction were precipitated using cold acetone at $-20\,^{\circ}$C. Recovery studies showed that the extract contained 93% (±1%; $n = 3$) of the PAHs that were originally present, while the wax residue contained only 6% (±0.5%; $n = 3$). PAHs present in the extract were fractionated, on the basis of the number of rings, into five fractions using a semipreparative silica column (normal-phase HPLC). These fractions were analyzed using reverse-phase high-performance liquid chromatography (RP-HPLC) coupled to a DAD. The method separated alkyl and unsubstituted PAHs on two reverse-phase columns in series using an acetonitrile/water mobile phase. UV spectra of the chromatographic peaks were used to differentiate among PAH groups. Further characterization of PAHs within a given group to determine the substituent alkyl carbon number used retention time matching with a suite of alkyl-PAH standards. Naphthalene, dibenzothiophene, phenanthrene and fluorene, and their C1–C4 alkyl isomers were quantified. The concentrations of these compounds obtained using the current method were compared with that of a GC–MS analysis obtained from an independent oil chemistry laboratory.

51

Atomic Spectral Detection

John C. Fetzer

51.1

Introduction

Atomic spectroscopy has been used for chromatographic detection for many years. Its use has become more widespread as a result of two factors: the importance of the elemental-speciation information that it generates is now of greater interest and the major advances in instrumentation. Plasma-based instruments are used because they offer continuous input of sample (the chromatographic effluent), multielement observation and robust, reliable operation.

Bioinorganic studies have grown rapidly in the past two decades. Before that, it was possible only to know the presence of an inorganic element through bulk analysis using techniques such as atomic absorption or X-ray fluorescence. Over 30 years ago, plasmas were first used in atomic spectroscopy. In the 1970s and 1980s, a variety of plasma sources were developed to atomize samples and then do optical emission spectroscopy (OES). The three main types of plasmas were the microwave-induced plasma (MIP), the direct-current plasma (DCP), and the inductively coupled plasma (ICP). Their history and features are not the scope of this chapter, but can be found in review articles [1, 2] and in other chapters of this book. In this chapter, the focus will be on the strengths and weaknesses of each for chromatographic detection.

51.2

Atomization and Plasmas

As the aim is to monitor individual elements, molecules must be broken down into their constituent atoms. This is generally readily done through generation of a plasma. A plasma is a low-pressure mixture of individual atoms and their ions.

Certain elements do form stable multiatomic fragments. Calcium and barium, for example, can occur as their oxides in some plasmas.

Interferences are not as prevalent as in molecular spectroscopy detection, but do occur. For mass spectral detection, isotopes can be numerous and overlapping with

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

other elements. This leads to the need for deconvolution algorithms based on the normal relative abundances for the isotopes of each element (a few elements have only one isotope). This process is generally straightforward because most elements contain a limited number of isotopes, the spread in masses between elements can limit the overlap, and chemically many of the overlapping elements are unlikely to occur together. The lanthanides, however, are chemically similar and possess numerous isomers, so quantitation can be more difficult because the deconvolution algorithms are not designed to deal with numerous interfering elements.

The type of atomization source determines operating conditions. These, in turn, define and limit the application. There must be compatibility between the type of chromatography and the type of atomization. The carrier gas in GC and the mobile phase in LC most often determine this, but flow rates are also an important factor.

An MIP is inherently incompatible with samples containing water. Microwave generators radiate at 2.45 GHz. This is a rotational resonance for water, so the energy is lost to that mode rather than to plasma formation. Thus, they cannot be used as part of a detector for LC because most separations are aqueous. In addition, the focal volume of an MIP is relatively small compared to that of the other sources. This limits its use in nonaqueous LC, as well, just as quenching and thermal effects can lower the atomization efficiency if normal LC flow rates are used.

The ICP does not work as well with helium as it does with argon, while the DCP and MIP do. This is an advantage in coupling to GC because the carrier gas is helium. For an ICP to be used, argon makeup gas must be introduced. This dilutes the analyte atoms and raises detection limits. In addition, the higher energy of the ICP requires that the gases dissipate some of the energy so that the surrounding instrumentation is not heated too highly. Argon has a higher heat capacity than helium. This would require a higher helium makeup gas flow, more than 50% greater than the $20\,\mathrm{l\,min^{-1}}$ usually used with argon. This adds to the potential cost of a GC-ICP instrument. Transfer lines may also melt or deform in extended use.

For LC, in contrast, ICP with either optical emission (OE) or MS detection has become the dominant plasma source for atomic detection. This has led to the development of numerous commercial instruments. Their pricing has greatly been reduced as these instruments are produced in greater numbers and market competition has grown. These instruments are now robust, turnkey, and reliable.

A secondary factor is the stability of the background, which translates into baseline stability in a chromatogram. This was one limit of the DCP, as the electrodes used to generate the plasma are consumed over time, creating an inherent background of the major elements (often, carbon from a graphite electrode, but also varying amounts of any trace-level contaminants). In some designs, a tungsten cathode is used with carbon anodes.

None of the plasmas are very robust with respect to changes in ionization energy and efficiency when a liquid stream is injected into it. The ICP is the most stable, but can tolerate only a few microliters per minute of flow. The development of narrow-bore HPLC columns and micro-LC, however, has given matching flow rates that have made LC-ICP possible.

The detection limits found when using the atomic emission spectroscopy (AES) version of an ICP instrument are approximately 1000 times greater than those of the MS version of the technique. This leads to a detection delay or hysteresis effect in which the incoming flows must expand and fill the detection volume of the spectrometer to levels above the detection limit. This leads to peak broadening and less apparent chromatographic resolution (it creates a large detection volume that merges resolved peaks back together). MS does not suffer from this because of the lower detection limits.

This difference in the optimum benefits of helium and argon in GC versus ICP use can be overcome by using helium as the GC carrier gas and argon as the makeup gas for a sensitive method such as ICP-MS.

The plasma in a DCP is very sensitive to longer term drift, which in chromatographic detection is seen as a gradual change in the baseline. The few applications of LC-DCP include the monitoring of the various oligomers in polyphosphate species from size-exclusion chromatography and the vanadium and nickel porphyrin species in heavy crude oils.

51.3
Spectrometric Detection

Once a sample has been atomized, there are two main ways of detecting the atoms, OES and MS. Both methods have multielement capabilities. The MS is less sensitive, but suffers from fewer interferences than atomic emission detector (AED).

51.4
MIP for GC Detection

Most gas chromatographs use either helium or hydrogen as the carrier gas because of the higher diffusion coefficients for molecules in them. The microwave plasma is more stable with helium as a medium than the other plasma sources. Helium has a very low thermal conductivity compared to many other permanent gases. This can lead to overheating in the plasma cavity. This in turn can cause melting and deformation of instrument parts. This can be a critical failure if it causes misalignment of the carrier-gas-containing analytes and the MIP focal volume.

Commercial MIPs for use in GC-AED are now robust and reliable. One commercial design of the plasma area is shown in Figure 51.1. The optical unit consists of a diffraction grating and a diode-array detector for multielement monitoring.

There have been many applications of GC-AED within the petroleum industry. The use of carbon, sulfur, and nitrogen monitoring in diesel fuel has been used to see the effects of various types of processing [3]. Not only can an AED monitor specific elements of interest, such as sulfur, oxygen, or metals, but it can be used as a universal detector because it can monitor carbon (Figure 51.2). This mode can be used with specific element monitoring to identify heteroatom-containing

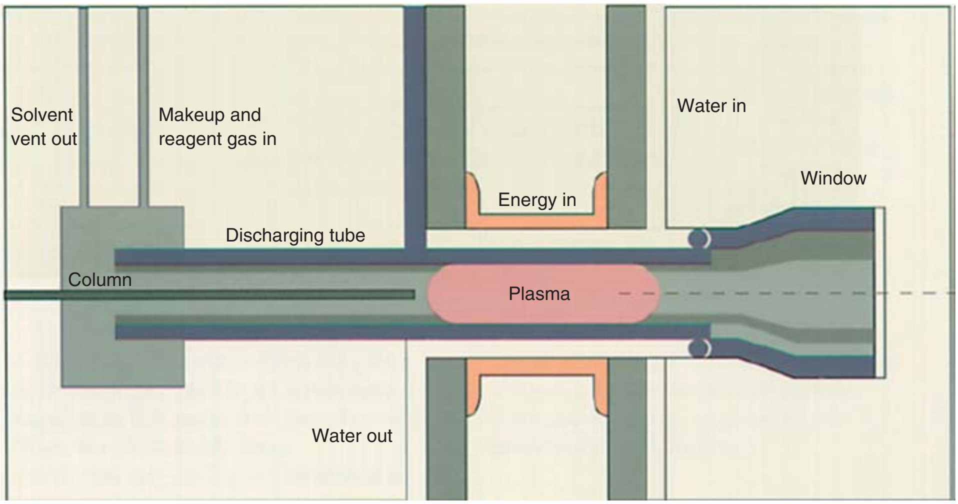

Figure 51.1 The arrangement of the plasma source within a commercial GC-AED.

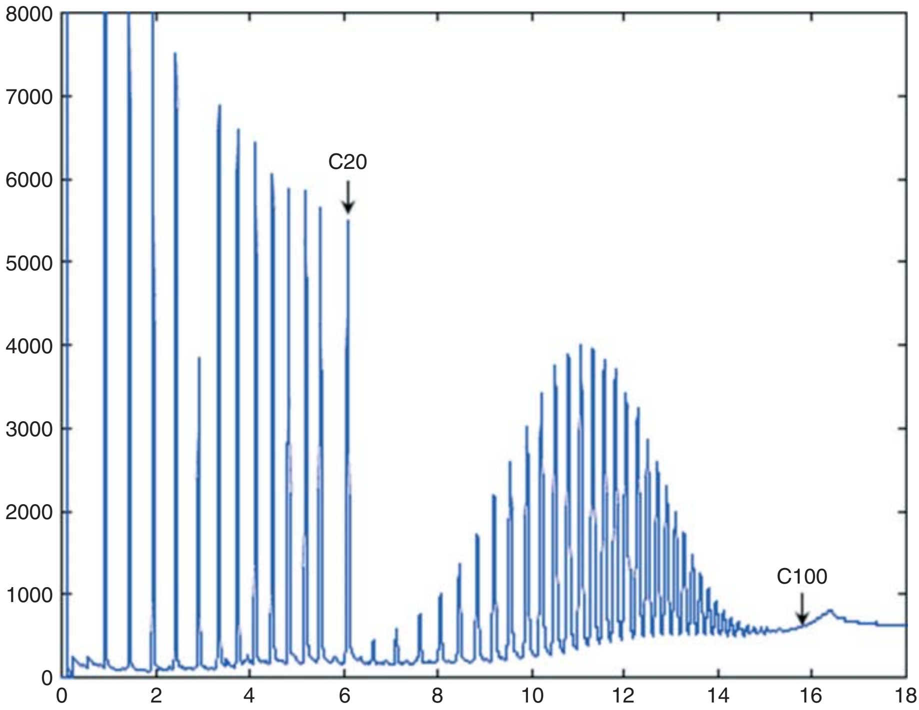

Figure 51.2 The use of carbon monitoring for universal detection in GC of a low-molecular-weight polystyrene.

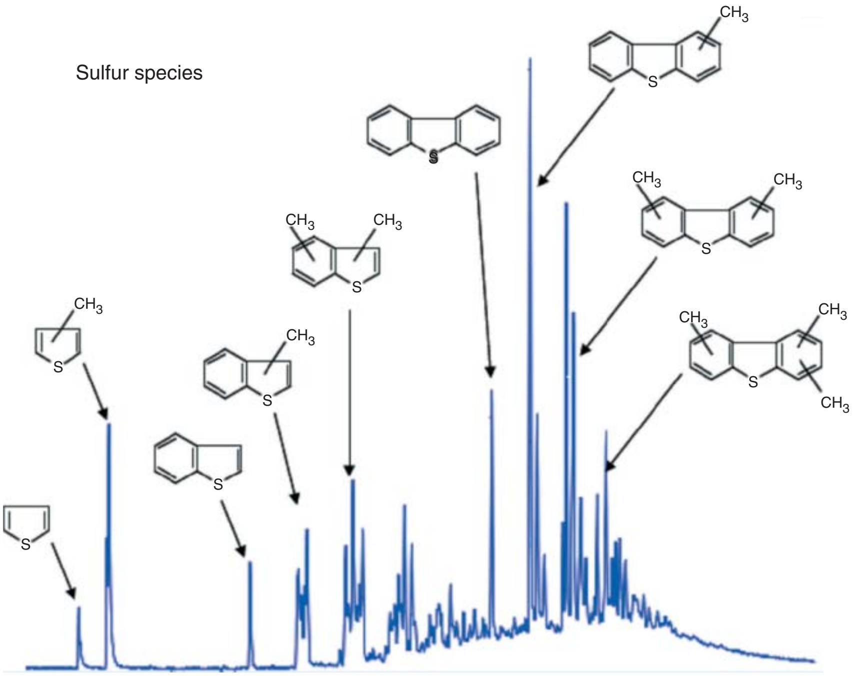

Figure 51.3 The determination of sulfur heterocyclics in a diesel fuel by GC-AED.

compounds. This is particularly important in the petroleum processing industry as certain molecule types have been shown to persist or to be formed during processing. In the case of sulfur- and oxygen-containing compounds, these are the source of sulfur and nitrogen oxides important in controlling air pollution. Other processing issues can be aided by GC-AED analyses. Vanadium and nickel naturally occur in petroleum as porphyrinic structures. These metals can poison certain processing catalysts and must be removed in steps before their use as feeds [4–7] (Figure 51.3, Figure 51.4, and Figure 51.5).

GC-AED was used to separate and identify several organotin compounds (Figure 51.6). These compounds are used as biocides, particularly for antifungal agents in paper products, wood pulp, and textiles; in the water systems of paper mills, breweries; and industrial cooling systems. Organotin compounds are also used in marine antifouling paint to lessen algal and barnacle growth on ship hulls (Figure 51.7).

51.5
ICP for LC Detection

The development of interfaces for LC–MS also spurred the use of other spectral detectors where mobile-phase removal was necessary. The mobile phase in LC puts several limits on the use of plasma detection and the type of plasma used.

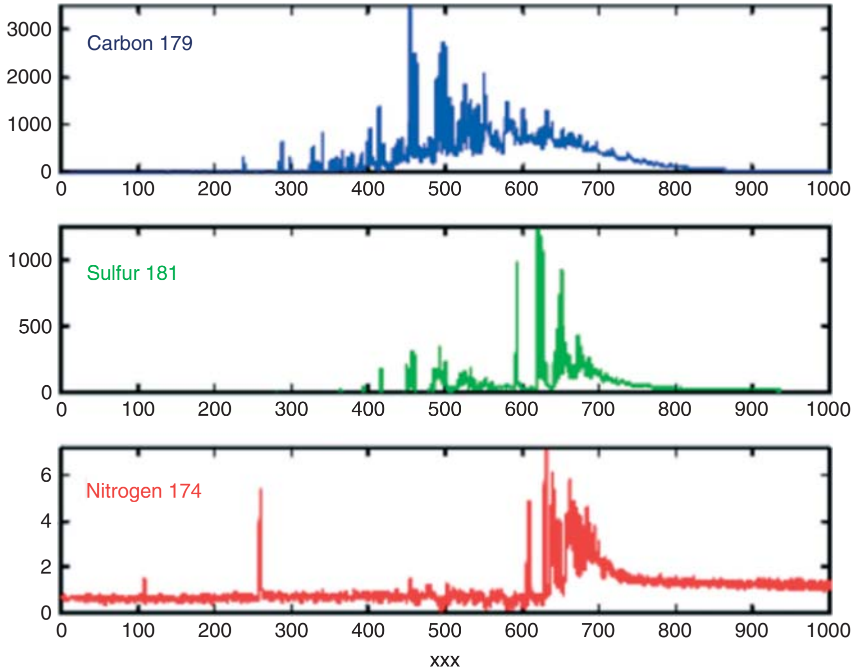

Figure 51.4 (a,b,c) A comparison set of chromatograms of the same type as in Figure 51.3, but with carbon monitoring to be used as a universal detection method and nitrogen detection to show the presence of carbazole-type nitrogen heterocyclics within the diesel fuel.

The amount of mobile phase nebulized into the plasma must be limited so as not to quench or alter the plasma ionization characteristics. Flow rates of 100 ml or less are often cited as the requirement as water has more effect than most organic solvents. The cooling due to thermal expansion of some solvents can alter the plasma. This effect also was the reason why MIP cannot be used for LC detection as it is even more sensitive to these effects. The microwave plasma that is very good in GC is not amenable at all to LC because of the widespread use of aqueous mobile phases. The microwave sources use 2.45 GHz. This is a rotation resonance line of water (and why microwave ovens work for cooking foods). This is incompatible with an aqueous mobile phase.

51.6
Application of LC-ICP MS

LC with atomic detection is now a commonly used technique when identification of peaks can be done by monitoring specific elements. This has become very useful in areas such as the study of metalloenzymes and of toxicity mechanisms for elements like arsenic and mercury.

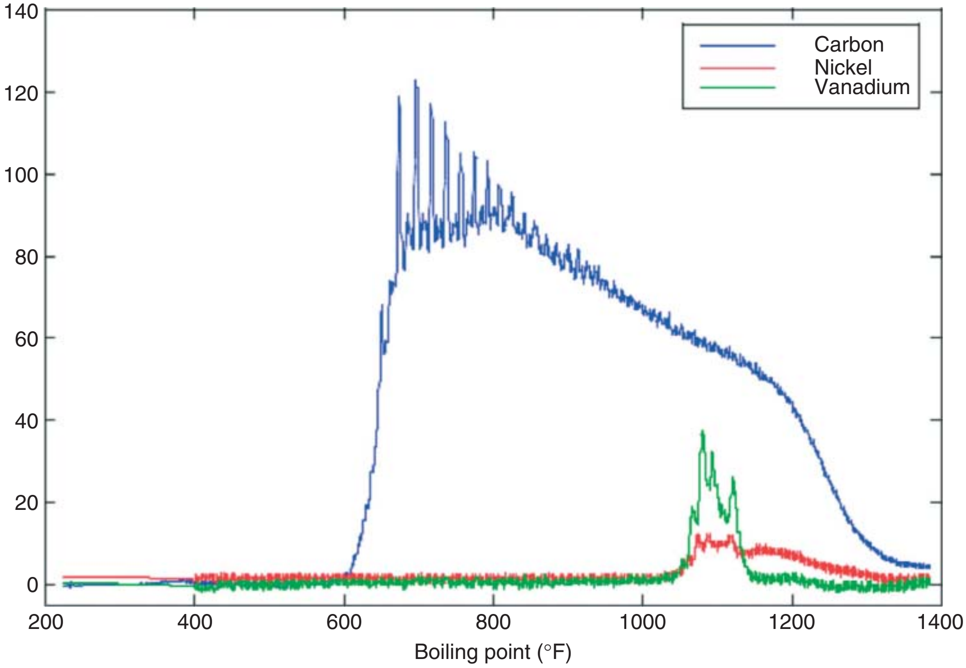

Figure 51.5 The monitoring of vanadium and nickel in a heavy oil residuum fraction. The vanadium is predominantly free porphyrin structures.

A GC has been coupled to an ICP-MS equipped with a novel detector array that permits simultaneous monitoring of up to 15 mass values. With this coupling, absolute limits of detection are in the sub-picogram range for organometallic species and in the picogram range for halogenated hydrocarbons [8, 9].

High-temperature aqueous LC with ICP-MS was used to detect Br in the disposition and metabolic fate of 2-, 3-, and 4-bromobenzoic acids [10]. A method was developed for the simultaneous determination of selenomethionine and selenocysteine in meat by HPLC-ICP-MS [11].

The mechanism of Cisplatin in chemotherapy by HPLC-ICP-MS of the Pt-bound proteins [12]. The nature of As species in algae from the Antarctic region. As speciation was obtained using anion- and cation-exchange chromatography with MS detection [13]. As species in groundwater samples was obtained by anion ion chromatography with ICP-AES [14].

A procedure for the simultaneous determination of 6 Se species and 6 Ar species in human urine by HPLC-ICP-MS was described [15]. The simultaneous detection by HPLC-ICP-MS of arsenic and sulfur as thioarsenicals in a fortified National Institute of Standards and Technology (NIST) freeze-dried urine sample. The molecular oxygen interference at m/z 32 was reduced through both sample introduction and collision-cell parameters optimizing. A 34-fold improvement in the detection limit was achieved using Xe instead of He as the collision gas [16].

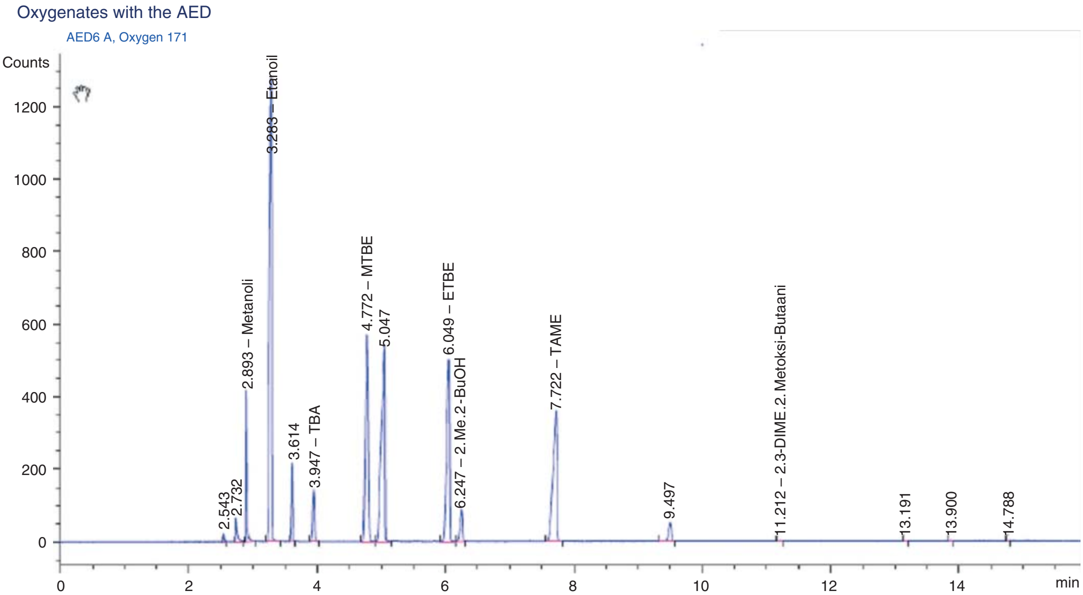

Figure 51.6 The monitoring of oxygen to identify fuel-additive molecules: *tert*-butyl alcohol (TBA); methyl *tert*-butyl ether (MTBE), ethyl *tert*-butyl ether (ETBE), *tert*-amyl-methyl-ether (TAME).

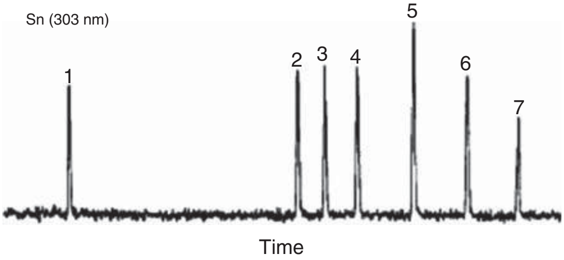

Figure 51.7 Separation of organotin biocides.

Organophosphorus fire retardants and plasticizers were determined at trace levels in wastewater by GC-ICP-MS for P [17].

Seven nerve agent degradation products were analyzed by GC-ICP-MS is described. The nonvolatile alkyl phosphonic acid degradation products included ethyl methylphosphonic acid, isopropyl methylphosphonic acid, ethyl hydrogen dimethylamidophosphate sodium salt, isobutyl hydrogen methylphosphonate (IBMPA, as well as pinacolyl methylphosphonic acid, methylphosphonic acid, and cyclohexyl methylphosphonic acid. The method separated and detected all seven, as well as phosphate, in <10 min. Detection limits for the developed method were <5 pg. This method was successfully applied to river water and soil matrices [18].

Speciation of selenium in dill, supplemented with sodium selenite during its growth, used ion-pairing reversed-phase and cation exchange chromatography. The chromatograms from different parts of the plant revealed differences in selenospecies as well as their concentrations. The major selenospecies found in different parts of the plant was Se-methyl-selenocysteine. Another major Se species identified was Se-methyl-selenomethionine, which had the highest relative concentration in the root, indicating possible Se volatilization from that plant part. Selenomethionine was present in minor quantities in all parts of the plant [19].

Acknowledgments

I thank Dr. Geoffrey N. Coleman for several helpful discussions on plasma behavior and uses, Dr. Matthew S, Klee for help in being able to use figures from Agilent Technologies, Dr. David A. Grudoski of We-measure-it, Inc., for information on GC-AED, and Dr. Axel Strebel and Dr. Joachim Gerstel for figures from Joint Analytical Systems (JAS), Moers, Germany.

NMR as a Chromatography Detector

Klaus Albert

52.1

Structural Assignment Techniques

The structural assignment of all peaks of a chromatographic separation is a demanding task. Hints on the structure of a separated compound can be derived from the retention behavior with respect to the employed stationary phase and the mobile phase composition. A wide range of mass selective detection techniques such as ultraviolet (UV), refractive index (RI), and electrochemical flame ionization detection can be used for selective detection but do not yield sufficient structural information. Diode-array detection at different wavelengths reveals more information if a UV-active chromophore is part of the molecule under investigation. A very sensitive and unique detection technique is mass spectrometry (MS). Therefore, hyphenated techniques such as GC–MS (gas chromatography–mass spectrometry) and HPLC–ESI–MS^n and HPLC–APCI–MS^n are versatile tools for deriving structural information. Especially in target analysis, where the mass of the investigated molecule is known, these techniques are a matter of choice. For instance, in water quality control, peak identification can be performed at the picogram sensitivity level with the help of hyphenated MS techniques.

In the case of nontarget analysis, with only the information of the retention time of the peak under investigation, the combination of hyphenated GC–MS, HPLC–MS with GC-NMR, and HPLC-NMR or HPLC-SPE-NMR (solid phase extraction) techniques has to be employed. MS^n techniques yield very important structural data, but only from NMR spectroscopic investigation can stereochemical information be derived. For instance, structural and stereoisomers can be assigned unambiguously only with the help of NMR techniques. Despite NMR spectroscopy not being as sensitive as MS, the methodical developments performed in the past years have rendered this technique a versatile tool in the online structure analysis of chromatographic separations [1–47].

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

52.2
NMR in a Flowing Liquid

NMR spectra are usually recorded by exciting nuclei (^{1}H, ^{13}C, ^{31}P) with a radio frequency (RF) pulse from the ground state level to the excited state level. The energy difference between the ground state level and the excited state level as well the population difference of nuclei (Boltzmann distribution) is dependent on the strength of the applied magnetic field Bo. Thus, a stronger magnetic field results in a higher sensitivity. Owing to two relaxation processes, the spin–lattice relaxation and the spin–spin relaxation, the excited nuclei move back from the excited state to the ground state. The spin–lattice relaxation time is named T_1 and the spin–spin relaxation time is named T_2. The decay of magnetization is observed in the transmitter detection coil as ''free induction decay (FID)'' with the time constant T_2. Employing the Fourier transformation technique, the time-dependent FID is converted to a frequency domain with distinct NMR signals [40]. NMR signal intensity is dependent on T_1, whereas NMR signal half width is dependent on T_2.

In the flowing mode, nuclei only stay for a distinct residence time τ within the NMR transmitter/detection coil. This results in an increase in relaxation rates (inverse relaxation times T_1 and T_2):

$$1/T_{n\ \text{flow}} = 1T_{n\ \text{static}} + 1/\tau$$

The overall effect of continuous-flow NMR is an increase in sensitivity versus given acquisition time and an increase in signal half width increasing flow rates. For instance, a residence time of 5 s leads to a signal broadening of 0.2 Hz, a residence time of 0.5 s to a signal broadening of 2 Hz.

52.3
Design of Continuous-Flow NMR Probes

52.3.1
Continuous-Flow ^{1}H NMR Probe for LC-NMR

Continuous-flow NMR probes should exhibit good flow characteristics for the chromatographic separation, for example, no peak broadening. On the other hand, the highest possible sensitivity for the NMR detection should be obtained. Thus, it is clear that a compromise between chromatographic and NMR spectroscopic requirements has to be obtained. Figure 52.1 shows the picture of one of the first continuous-flow NMR probes used at a 400 MHz NMR superconducting spectrometer. The NMR RF folio is directly attached to the glass of the up-leading part of the U-type detection cell, defining a detection volume of about 44 μl. The whole assembly is inserted in a glass dewar, enabling temperature-dependent measurements (Figure 52.1) [2]. The whole arrangement is centered in the glass dewar of a conventional probe body. The internal diameter of the glass tube varies between 2 and 4 mm, resulting in detection volumes between 30 and 120 μl. The

Figure 52.1 Continuous-flow ^{1}H NMR probe for HPLC-NMR.

glass walls of the flow cell are parallel within the length of the proton detection coil (18 mm) and taper at both ends to fit to polytetrafluorethylene (PTFE) tubings (ID 0.25 mm). PTFE tubings and glass tubes are connected by shrink-fit tubings. ‘‘Inverse’’ continuous-flow probes contain an additional coaxial coil (matched to the ^{13}C resonance frequency) surrounding the ^{1}H NMR detection coil for heteronuclear ^{1}H/^{13}C shift correlated experiments.

Newer probes are fabricated with Helmholtz saddle-type coils or cryogenic coils cooled with liquid helium. These cryoprobes show three to four times high sensitivity levels, leading to limits of detection in the lower nanogram range.

52.3.2
Solenoidal NMR Microprobe for Capillary HPLC-NMR and GC-NMR

An alternative probe design is shown in Figure 52.2. Besides the Helmholtz saddle-type coil (in analogy to conventional NMR probes) the solenoidal-type probe design

Figure 52.2 Solenoidal NMR microprobe for capillary HPLC-NMR and GC-NMR.

[40, 48–54], which is constructed by directly wrapping the RF coil around a capillary column, has successfully been utilized for capillary HPLC-NMR and GC-NMR coupling. Here, a copper coil is directly wound around an 180 μm internal diameter fused-silica (360 μm OD) capillary, resulting in a detection volume between 1.5 and 5 μl within the NMR radiofrequency coil. The polyimide coating of the capillary is removed over the length of the NMR detection window. The microcoil is immersed in a container containing perfluorotributylamine to compensate for susceptibility distortions between copper and air [48, 49]. The solenoidal probe design shows a threefold better sensitivity than saddle-shaped coils and therefore is especially beneficial in the case of the hyphenation of capillary HPLC to NMR. Owing to the use of a susceptibility-matching fluid high-resolution ^{1}H NMR spectra are obtained, but there might be problems with interfering signals in ^{13}C NMR measurements.

The solenoidal NMR microprobe shown in Figure 52.2 can be used for capillary HPLC-NMR and GC-NMR detection [48–64].

52.3.3
On-Line HPLC-NMR

For on-line HPLC-NMR, GPC-NMR (gel permeation chromatography), and SFC (supercritical fluid chromatography)-NMR experiments, the chromatographic separation system, consisting of either an HPLC or SFC pump together with an injection valve, separation column (250 × 4.6 mm ID) and an UV or RI detector, is located at a distance of 1.5–2.5 m besides the unshielded cryomagnet (Figure 52.3). If a shielded cryomagnet without any magnetic stray field is used, the chromatographic equipment can be directly placed besides the cryomagnet.

The outlet of the UV (RI) detector is connected by stainless steel capillaries (0.25 mm ID) to a switching valve. It is used for trapping a desired peak in the NMR flow cell in stopped-flow experiments. For online experiments with continuous registration of NMR spectra in distinct time intervals (1–8 s), the switching valve is open for a continuous flow through the probe into the waste. Instead of the switching valve, a Bruker peak sample unit (BPSU) can be used or the eluted peaks can be trapped on SPE cartridges. These techniques are advisable when long NMR experiment times are expected. With the help of the peak-sample unit or SPE cartridges, desired peaks of a separation can be stored in small capillary loops. When a separation is finished, every single peak can be transferred into the probe and the desired stopped-flow experiment can be conducted.

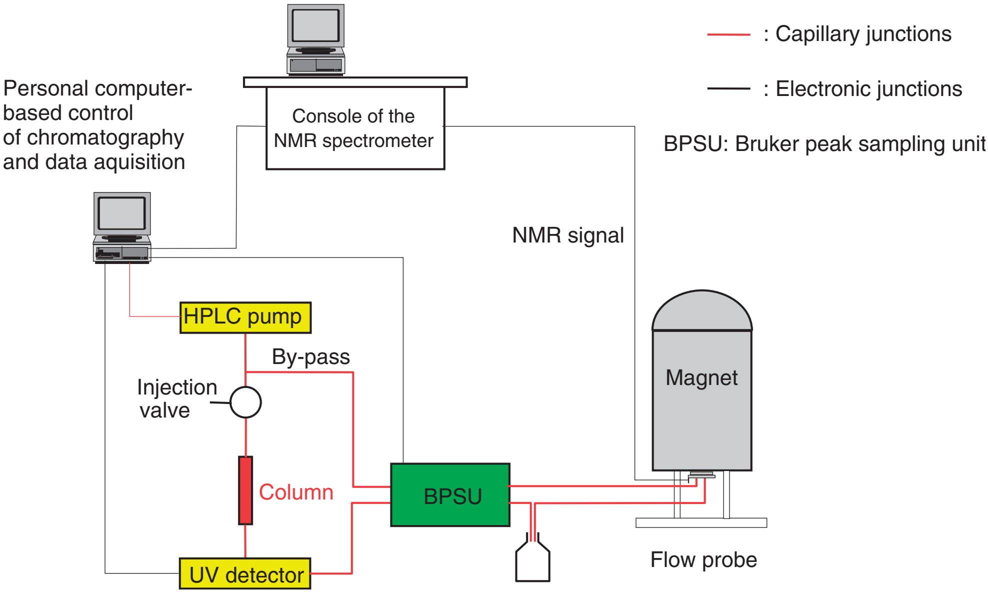

Figure 52.3 Experimental setup for HPLC-NMR.

52.4
Solvent Signal Suppression

Most HPLC separations are performed in the reversed-phase mode with surface-modified stationary phases and using binary solvent mixtures such as acetonitrile (ACN)/water or methanol/water as mobile phase. The intensity ratio of the protonated solvent versus sample signals is in the order 10 000 : 1 in a routine analytical HPLC-NMR run with about 10–25 μl of injected compound. For proper adjustment of the receiver gain of the NMR instrument, the intensity of the solvents should be reduced to the height of the sample signals either by the use of deuterated solvents (which can be easily and economically implemented in capillary separation techniques because of the low flow rates (1–10 μl min^{-1}) applied) or by the application of a solvent suppression technique. Efficient solvent suppression in the continuous-flow and in the stopped-flow mode can be performed by application of a nuclear Overhauser effect spectroscopy (NOESY)-type presaturation scheme. Figure 52.4 shows the effect of solvent signal suppression.

The gain in sensitivity by reducing the intensity of the methyl signal of ACN by a factor of 100 to the intensity of the ^{13}C satellites of ACN is clearly visible at the signal's retinoic acid between 5.6 and 8.0 ppm. With residence times in the order

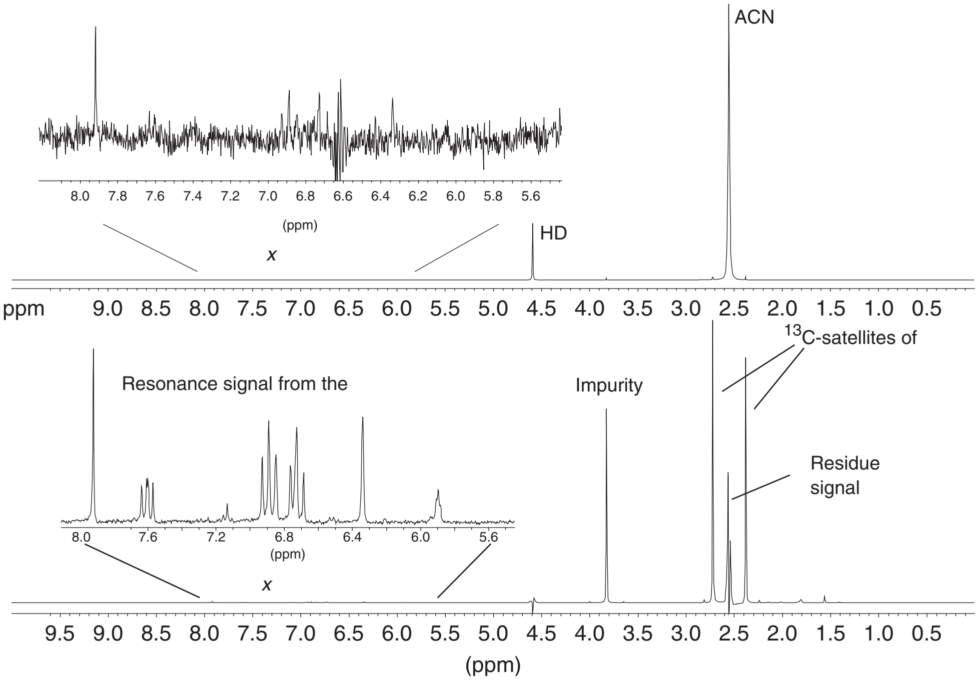

Figure 52.4 Effect of solvent signal suppression.

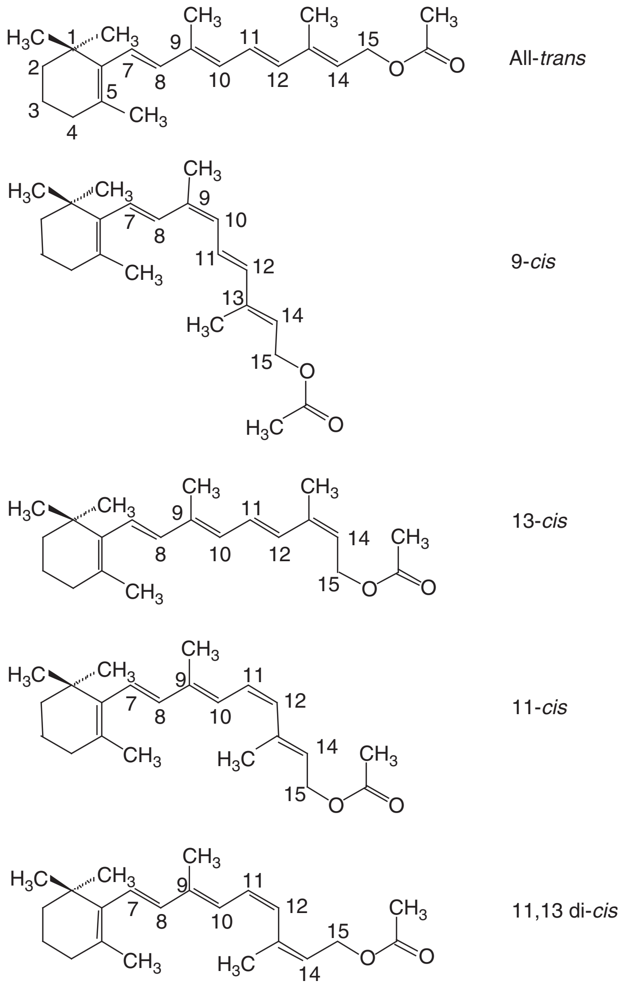

Figure 52.5 Structures of isomers of vitamin A acetate.

of 5 s and acquisition times for one transient of about 1 s, sufficient presaturation time is left even in the continuous-flow mode.

The acquisition of NMR spectra in the hyphenated HPLC-NMR techniques is possible in the continuous-flow and the stopped-flow mode. An example of the continuous-flow recording is the separation of different isomers of vitamin A acetate, whose structures are shown in Figure 52.5 [14].

The acquisition of online continuous-flow NMR spectra results in a two-dimensional contour plot of ^{1}H NMR signals of the separated compounds (x axis = ^{1}H chemical shift) against the retention times (y axis). Figure 52.6 shows the gained continuous-flow HPLC-NMR spectra of the continuous-flow ^{1}H NMR detection of the separation of vitamin A acetate isomers, the chemical shift is

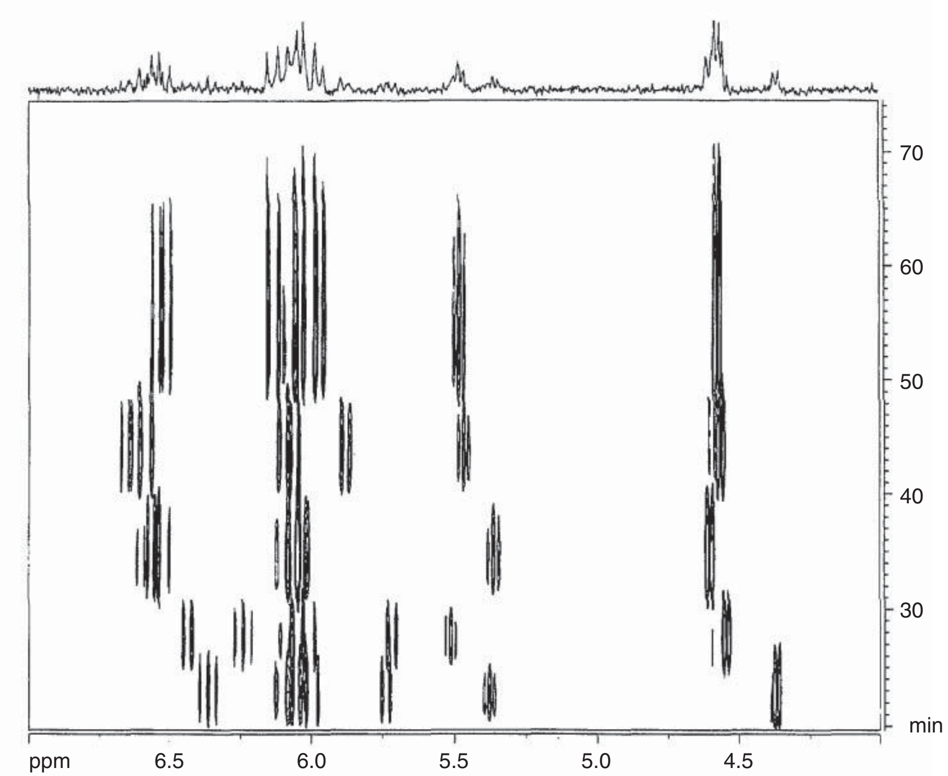

Figure 52.6 ^{1}H NMR chromatogram (contour plot, 400 MHz) of an HPLC separation of five vitamin A acetate isomers reordered in *n*-heptane.

plotted, while the *y* axis (F1 dimension) shows the retention time scale of the separation, resulting in a pseudo-2D NMR contour map.

All isomers of vitamin A acetate can unambiguously be identified. This can especially be noticed at the protons of peak 1 (11,13-di-*cis* vitamin A acetate) and peak 2 (11-*cis* vitamin A acetate).

For a more detailed interpretation of the ^{1}H NMR spectra, the contour plot of the continuous-flow NMR measurement is not useful. Therefore, the extracted proton NMR spectra of the vitamin A acetate isomers at the corresponding peak maxima of the continuous-flow measurement are shown in Figure 52.7. Structure elucidation of all vitamin A acetate isomers can be easily carried out.

In continuous-flow experiments, there is only a short time available for accumulation of transients and therefore for exposure of a ^{1}H NMR spectrum. So, this spectroscopic technique can only be used if there is a high concentration of the sample in the flow cell. Otherwise, the signal-to-noise ratio is too poor. It should be also mentioned that the chemical shifts depend on the solvent composition. Therefore, when utilizing gradient elution programs for chromatographic separation, stopped-flow NMR experiments have to be carried out, too.

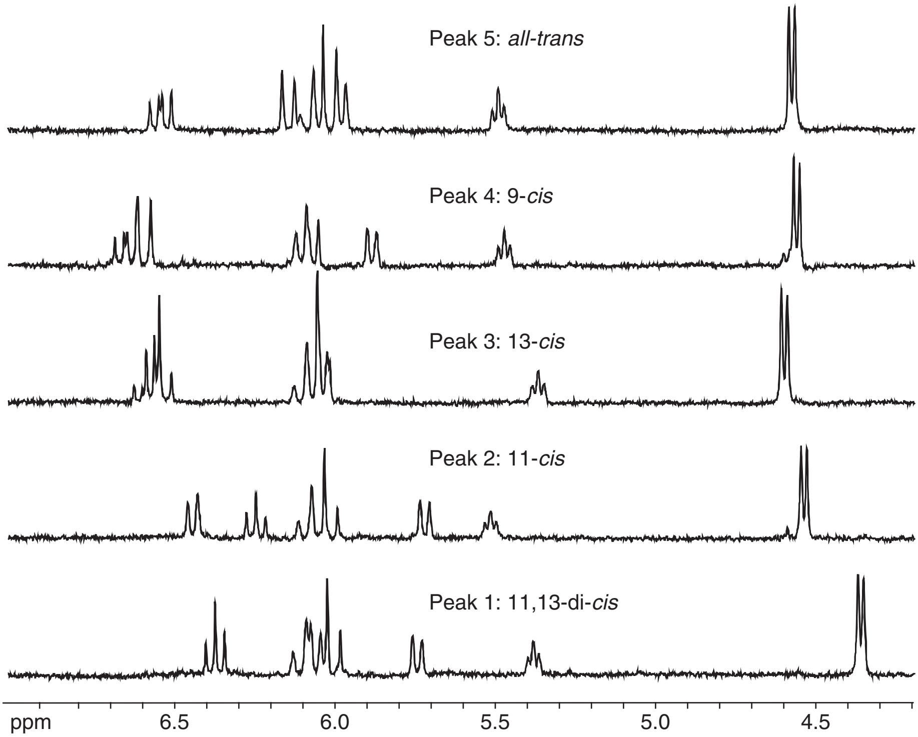

Figure 52.7 Continuous-flow ^{1}H NMR spectra (400 MHz) of the separated vitamin A acetate isomers.

In the stopped-flow mode, the chromatographic run is stopped as soon as the maximum of the peak is in the flow cell (indicated by the UV detector). By switching the valves of the sample or peak parking unit, the exposure of back pressure to the sample in the flow cell is precluded. Conventional NMR experiments can now be performed and, therefore, the NMR experimental time can be adjusted to the sample concentration. Preiss *et al.* [65–67] performed a lot of experiments for the investigation of explosives in environmental analysis employing the stopped-flow mode. Another advantage of the stopped-flow experiment is the acquisition of 2D NMR spectra. Here, SPE has to be performed. Microprobes can also be used for NMR experiments of pure compounds in the flow-injection mode without any loss of spectral information recorded within reasonable acquisition times. Despite the low amount of sample present in the detection coil, these spectra clearly show that all information for structural assignment can be derived. Figure 52.8 depicts one example of a heteronuclear single-quantum correlation (HSQC) 2D-NMR spectrum (^{1}H/^{13}C) of α-tocopherol acetate measured in the flow-injection mode in a solenoidal microcoil probe.

Figure 52.9 shows a homonuclear total correlation spectroscopy (TOCSY) spectrum of α-tocopherol acetate recorded within a saddle-type coil (200 nl detection

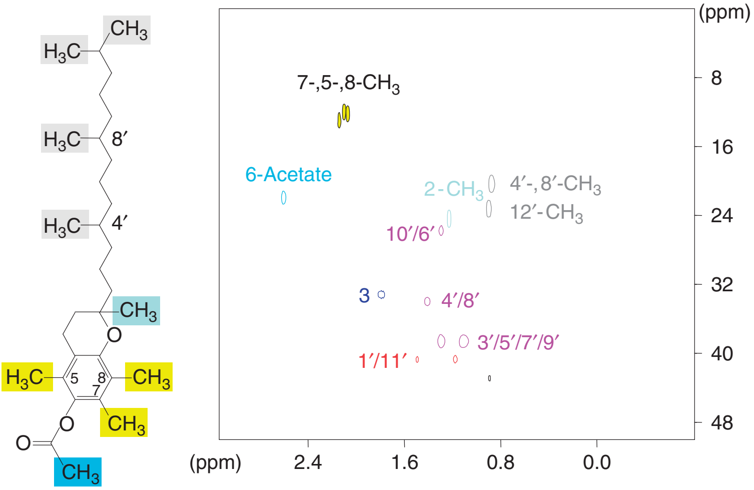

Figure 52.8 HSQC 2D NMR spectrum ($^1H/^{13}C$) of α-tocopherol acetate measured in a solenoidal NMR microcoil probe.

volume) with an acquisition time of 15 h. The projections in the F1 and F2 dimension show conventional ^1H NMR spectra of 0.1% of α-tocopherol acetate in methanol-d_4 directly injected within the capillary. The spectrum was recorded within 7 min with a pulse repetition time of 1.5 s.

52.5
LC-SPE-NMR

Owing to the still low sensitivity of the NMR detection, a modification of the stopped-flow acquisition mode is used. The trick is to trap the different peaks of an HPLC separation on different cartridges (mostly cross-linked polystyrene) and concentrate the peaks by multiple trapping (Figure 52.10).

The aim is to concentrate chromatographic peaks to elution volumes matching the detection volume of the continuous-flow NMR cell (between 30 and 120 μl). After drying the cartridge with nitrogen, the adsorbed analyte is redissolved in a deuterated solvent and pumped to the NMR detection cell. Thus, a narrow elution band is formed. Owing to the use of capillaries between the SPE unit and the NMR flow probe, peak diffusion is minimal. The whole procedure can be fully automated. Care has to be taken to perform a gentle and effective drying of the cartridge. Figure 52.11 shows the effect of multiple trapping ($n = 1$–7) for the ^1H NMR spectra of glyasperin H [68].

HPLC-SPE-NMR is the major technique for the analysis of crude extracts of plant materials. For the investigation of a compound with a molecular weight of about 700 Da, about 2 μg of analyte per 1 μl CD_3CN have to be transferred to the continuous-flow NMR probe. Here, a cryogenic cooled probe with very high

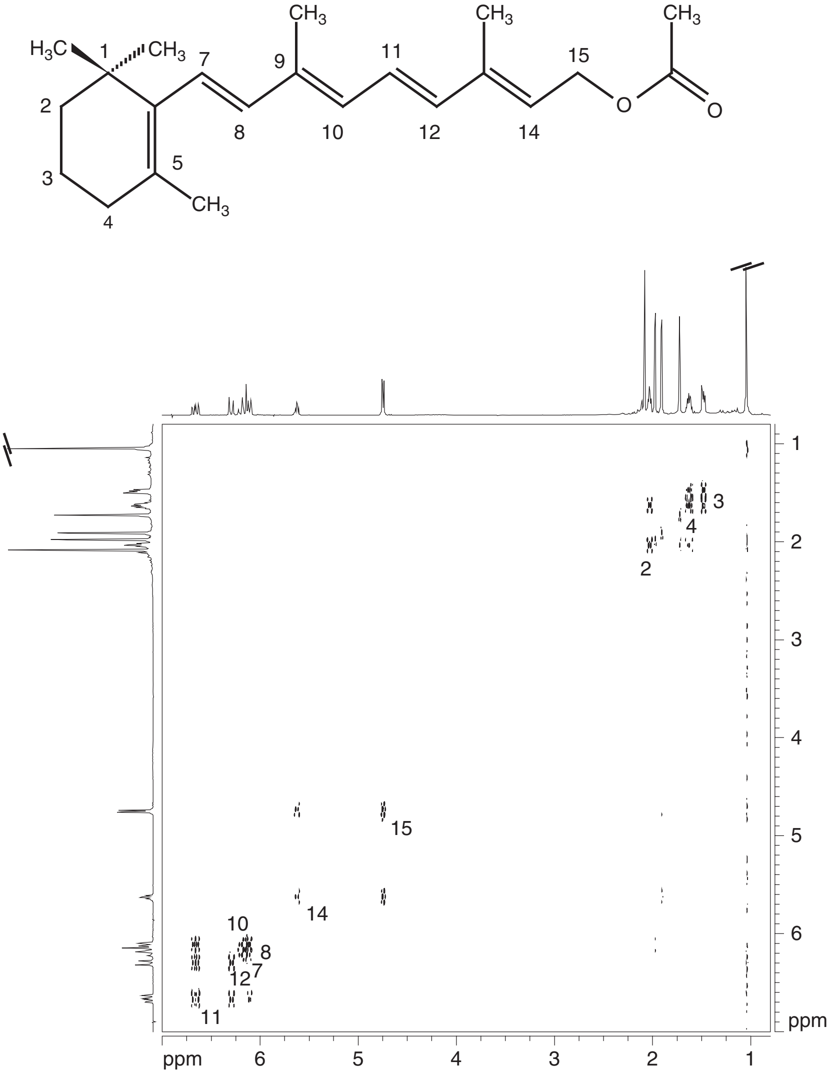

Figure 52.9 Homonuclear TOCSY spectrum of α-tocopherol acetate recorded within a saddle-type coil (200 nl detection volume).

sensitivity is used. A big advantage is the use of the newly introduced "cryo-fit" assembly. Here, a specially designed capillary can be introduced into a conventional cryogenic probe and connected to the SPE apparatus.

The application is pioneered by different groups. Phytopharmaceuticals have been investigated by the groups of Exarchou [45], Jaroszewski and Hansen [69–79], Seger and Sturm [68, 80, 81,], Schneider [82, 83], and Wolfender [84]. Owing to the gain in NMR sensitivity, all two-dimensional structural assignment techniques

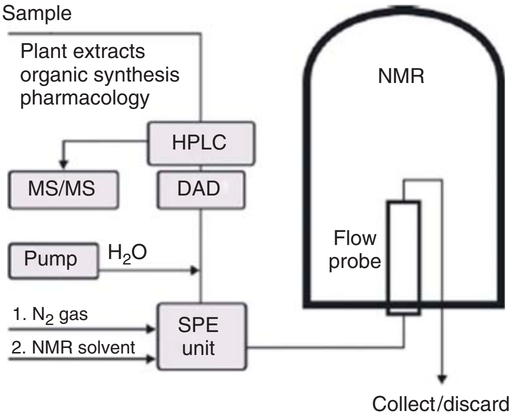

Figure 52.10 Experimental setup for online HPLC-SPE-NMR.

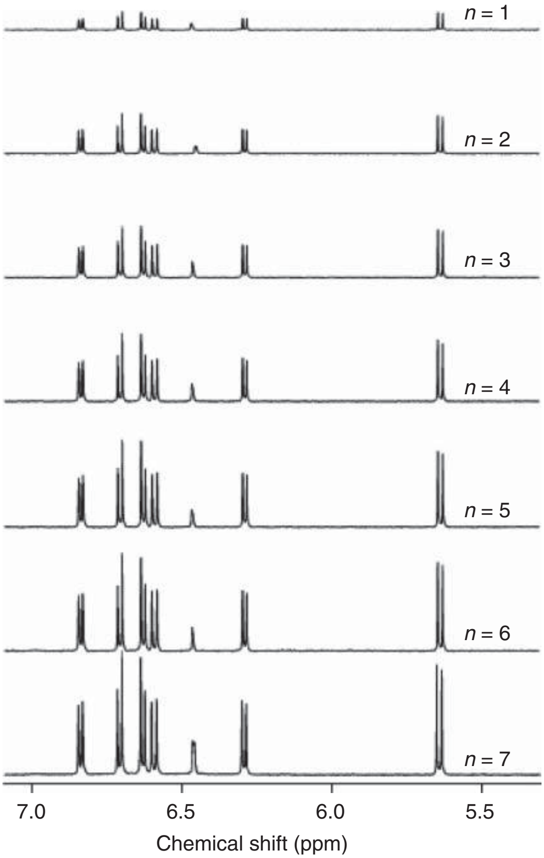

Figure 52.11 Effect of multiple SPE trapping.

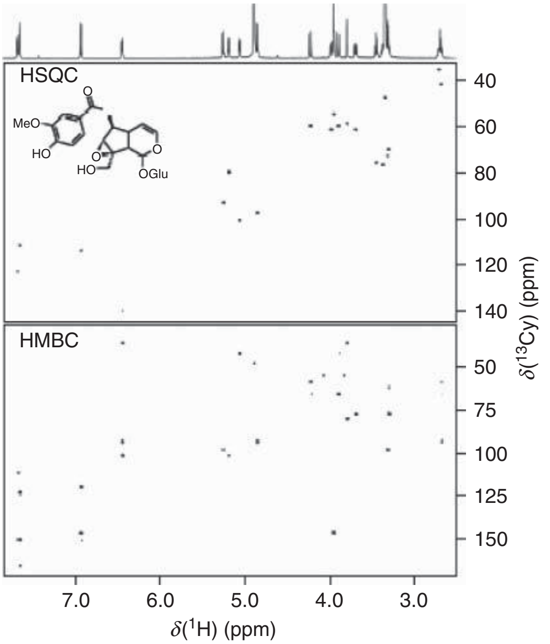

Figure 52.12 HPLC-SPE-NMR-derived HSQC and HMBC spectra of picroside.

can be performed. Figure 52.12 shows the HSQC and heteronuclear multiple bond correlation (HMBC) spectra of picroside [68].

The LC–SPE enrichment approach can be also combined with capillary NMR detection. This work was pioneered by the group of Wolfender and Jaroszewski [84].

52.6
Capillary HPLC-NMR Coupling

The NMR registration of capillary separations employs microcoils with detection volumes between 1.5 and 5.0 μl. The small flow rates used in liquid capillary separations enable the use of deuterated solvents. In capillary GC, NMR spectra are recorded in the gaseous state.

A possible instrumental setup for capillary HPLC-NMR coupling is shown in Figure 52.13.

A feasible experimental setup for online capillary HPLC-NMR (cHPLC-NMR) coupling is outlined in Figure 52.14.

A splitless Waters capillary HPLC pump together with an injection device (100–200 nl) and a separation capillary is connected by fused silica capillaries via a Bischoff UV detector to the NMR microprobe inserted into the room temperature bore of a Bruker 600 MHz cryomagnet. Separations are performed with capillaries (ID 100–250 μm, length 250 mm). Because a nonshielded magnet with a strong

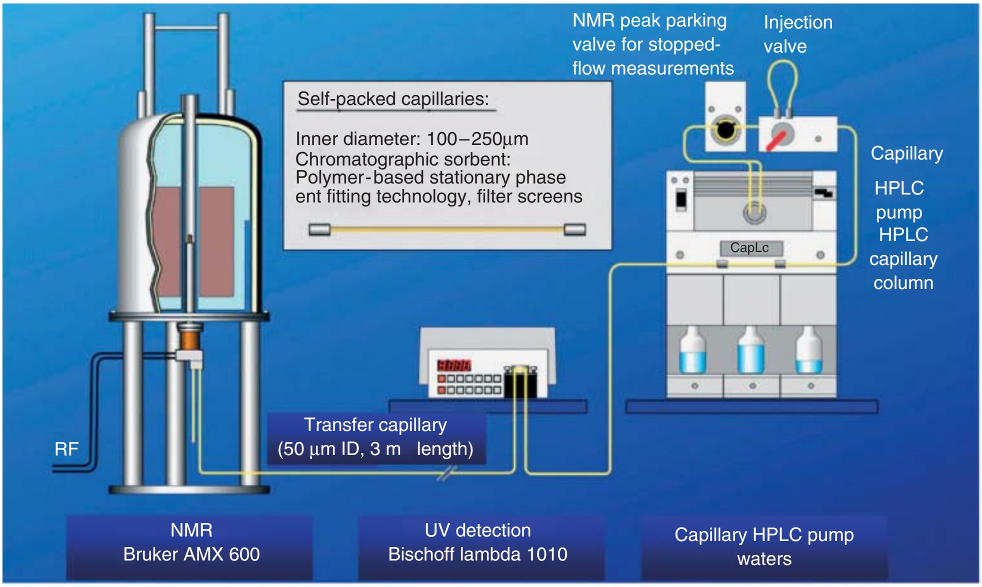

Figure 52.13 Experimental setup for online capillary HPLC-NMR.

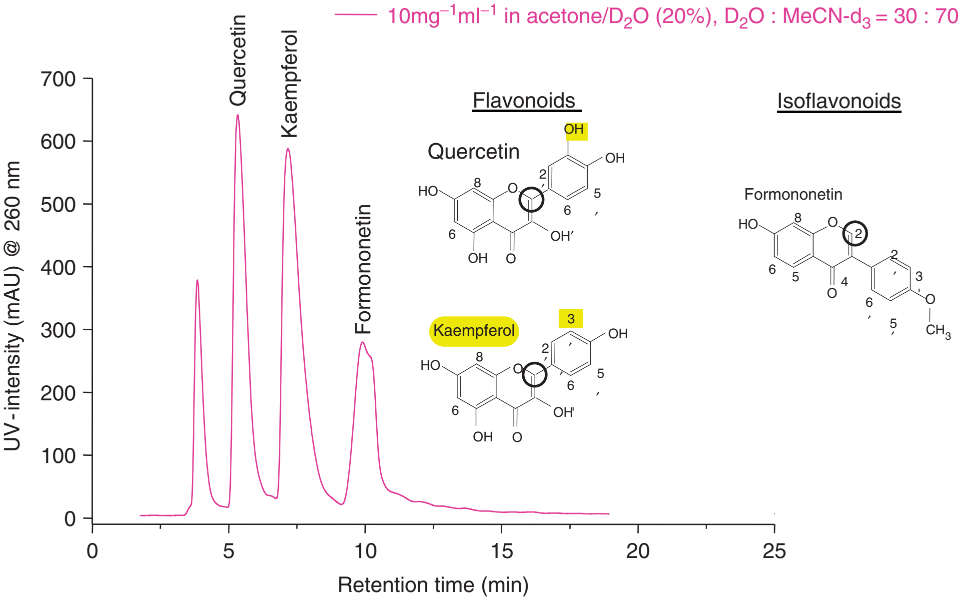

Figure 52.14 HPLC separation of different flavonoids and isoflavonoids.

stray field is used, a transfer capillary with an ID of 50 μm (OD 360 μm) and an overall length of 2.5–3.0 m is employed to connect the HPLC instrument together with the NMR detection cell. Owing to the small diameter of the transfer capillary, a peak broadening of only 1% is observed at flow rates of 5 μl min^{-1}.

Owing to the NMR peak parking valve (Figure 52.13) installed after the separation, capillary measurements either in the continuous-flow mode or the stopped-flow mode are possible.

The approach of coupling capillary compared to conventional separation techniques with NMR [48–62, 84] is promising. The reduced solvent consumption allows the use of deuterated solvents, thus rendering unnecessary the elaborate solvent suppression that minimizes the problems of overlapping analyte and solvent signals by the use of capillary separation techniques.

Real-world applications employing these techniques are possible with stopped-flow NMR detection limits in the 10 ng range [54–62].

Because of the still low sensitivity of the NMR detection, it is favorable to overload the chromatographic separation capillary. For this purpose, new types of C_{18} and C_{30} separation columns show a superior separation behavior. Figure 52.14 shows the HPLC separation of different flavonoids and isoflavonoids performed at a C_{18} capillary column (ProntoSil Eurobond 120 Å, 5 μm, 250 μm × 150 mm) at a flow rate of 5 μl min^{-1}.

At a concentration of 10 mg ml^{-1}, the continuous-flow detection NMR detection is possible. Figure 52.15 shows the contour plot of the ^{1}H chemical shift values versus the chromatographic retention times. Owing to the different chemical shift

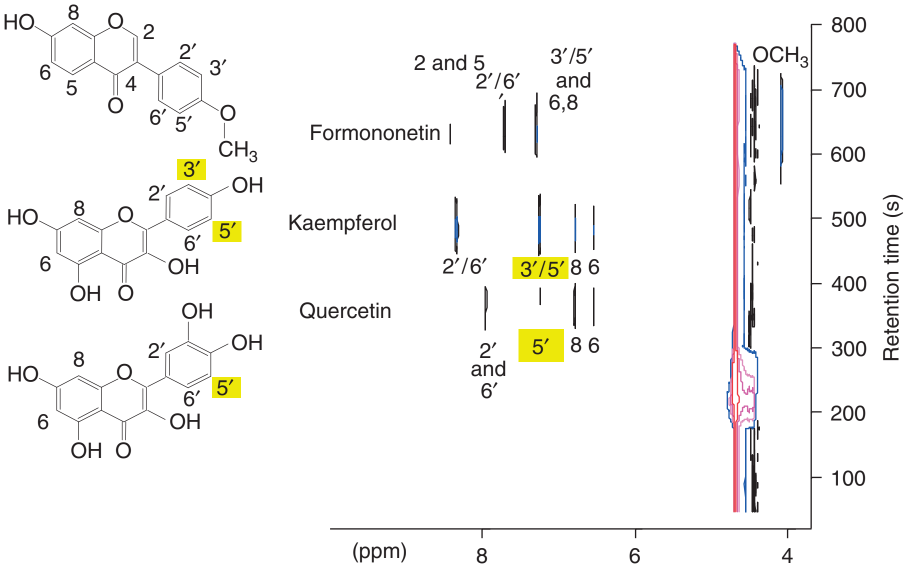

Figure 52.15 Contour plot of the capillary separation of different flavonoids and isoflavonoids.

values, the assignment of the three different compounds — quercetin, kaempferol, and formononetin — is clearly visible. Thus, the different substitution patterns with one or two hydroxyl groups at the phenyl ring of the two flavonoids, quercetin and kaempferol, can be easily recognized.

An example of the stopped-flow acquisition is the identification of the stereoisomers of the Brazilian plant bixin. The cis–trans isomers can be separated with a C_{30} column because of the high shape selectivity (Figure 52.16). The APCI mass spectra of both isomers (Figure 52.17) are identical because MS is unable to differentiate structural and stereoisomers. A clear structural assignment can be achieved by acquiring stopped-flow two-dimensional $^1H-^1H$ correlated spectra [$^1H-^1H$-COSY (correlation spectroscopy)]. Figure 52.18 and Figure 52.19 show the different chemical shift values and correlations for the proton pairs H-7/H-8 and H-7′/H-8′. Owing to the existence of the cis configuration, an isomerization shift of proton 8′ of 0.59–7.94 ppm occurs. The differences between the NMR spectra of the symmetrical *all*-trans and the nonsymmetrical 9′-cis isomer can be immediately recognized in Figure 52.18 and Figure 52.19. The chemical shifts of the protons H-8 and H-8′ of *all-trans*-bixin are the same, but differ for 9′-*cis*-bixin. Thus, unequivocal stereochemical assignment can be readily achieved.

52.7
GPC-NMR Coupling

One big advantage of the use of continuous-flow probes is the enormous gain in efficiency against the conventional recording in NMR tubes. When the amount of sample is not a problem, the application of continuous-flow NMR detection volumes between 40 and 120 µl is favorable [85–90]. Figure 52.20 shows the ^1H NMR spectrum of latex, a copolymer of styrene(S) and *n*-butyl acrylate (A) [86].

The assignment of the proton signals of both constituents is readily available from the ^1H NMR spectrum. With the help of GPC, molecular weight distribution of polymers can be obtained. Here, polymeric compounds with molecular weight elute first. The contour plot of the online GPLC (gel permeation liquid chromatography)-NMR detection is shown in Figure 52.21.

Besides the solvent signal of dichloromethylene, the signals of *n*-butyl acrylate together with styrene can be recognized. The change in the polymer composition can be derived from the changing integration ratio between the aromatic signal of styrene at 7 ppm versus the methyl signal of *n*-butyl acrylate at 0.8 ppm (Figure 52.22).

Thus, the molar concentration of *n*-butyl acrylate varies from row 34 at the beginning of the separation to 29% at row 80 at the end.

The registration of the online GPC-NMR run was accomplished within 1 h. To derive similar data, it would take over 24 h by conventional NMR recording.

The application of GPC-NMR for a detailed characterization of polymers was pioneered by Hiller [88–90]. Especially at the critical point of solvent composition, GPC-NMR experiments reveal valuable data [90].

52.8
SFC-NMR

SFC-NMR experiments are performed with a pressure-stable flow cell using a sapphire tube instead of the glass tube. This technique offers a big advantage in that it employs the nonprotonated solvent carbon dioxide. Thus, the whole chemical shift range of the resulting SFC-^{1}H NMR spectra is not obscured from any solvent signal and can be used for structure elucidation purposes [91].

A modified version of this Helmholtz design is also used for coupling of SFC with NMR [92–99]. The inner glass tube of the originating HPLC-NMR probe is substituted with a sapphire tube (detection volume 120 μl), whereas the polyetheretherketone (PEEK) capillaries used in the HPLC-NMR probe are replaced by Titan tubings. A double-tuned proton-deuterium coil is directly fixed to the sapphire flow cell. The whole arrangement is centered in the glass dewar of a conventional probe body, in which a thermocouple is inserted, allowing the execution of well-defined temperature-dependent measurements.

In SFC-NMR experiments, the outlet of the pressure-stable SFC probe is connected to a back pressure regulator to guarantee supercritical conditions in the detection cell (Figure 52.23).

This phenomenon is demonstrated in Figure 52.24, exhibiting the continuous-flow ^{1}H NMR spectra of a separation of five plasticizers [92]. The separation was

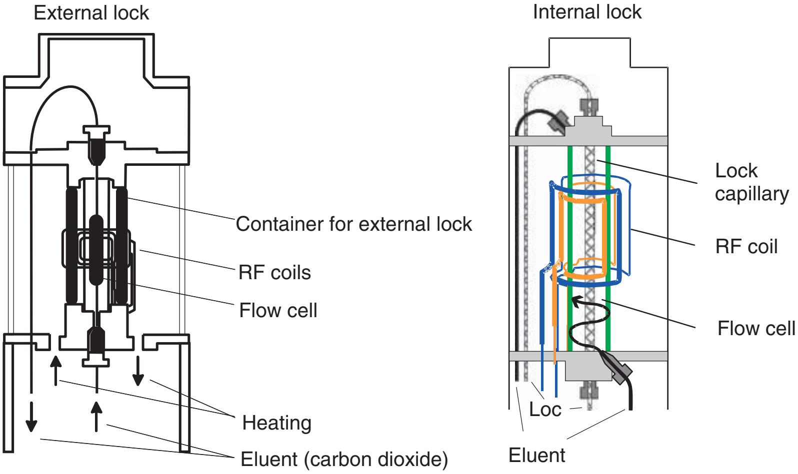

Figure 52.23 SFC-^{1}H NMR probes.

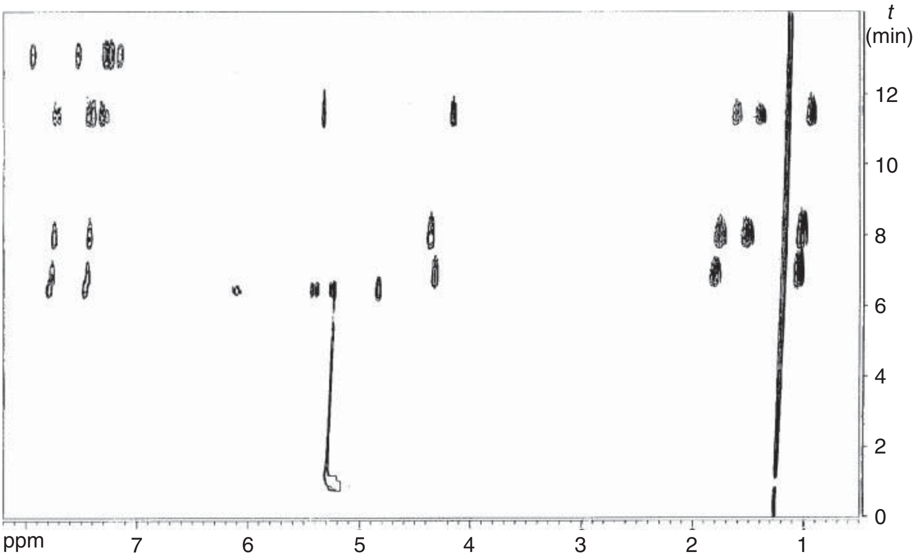

Figure 52.24 SFC-^{1}H NMR separation of five plastifiers.

carried out in supercritical CO_2 with a packed analytical SFC column (C_8 reversed phase, 4.6×250 mm) at a flow rate of 2.0 ml min^{-1}, a linear pressure gradient from 115 to 180 bar in 20 min at a temperature of 353 K. The NMR resolution of all SFC spectra is excellent; even the ^{1}H NMR spectrum of the last eluting compound, diphenylphthalate, does not show any distortion. Supercritical CO_2 is often used for supercritical fluid extraction (SFE) purposes in a lot of processes such as the decaffeination of coffee and the extraction of hops. The direct SFE-^{1}H NMR monitoring of the extraction process of roasted coffee and of black pepper was possible by employing an analytical SFC column as extraction cell. 2D NMR spectra of the extracted compounds could be measured in the stopped-flow mode within registration times of lower than 40 min.

52.9
GC–NMR

Because of the use of capillary detection in LC-NMR coupling in the liquid state, it is also straightforward to implement capillary detection in GC-NMR coupling [100]. Buddrus and Herzog [101, 102] have pioneered GC-NMR with conventional detection. The GC-NMR setup for capillary GC-NMR is shown in Figure 52.25 [63, 64]. The gas chromatograph is connected to a home-built solenoidal microprobe with a detection volume of 3 μl via a transfer capillary (ID 50 μm, length 3 m).

The contour plot of a separation of diethylether, hexane, and tetrahydrofurane (THF) is shown in Figure 52.26. Thirty microliters of the mixture of diethylether,

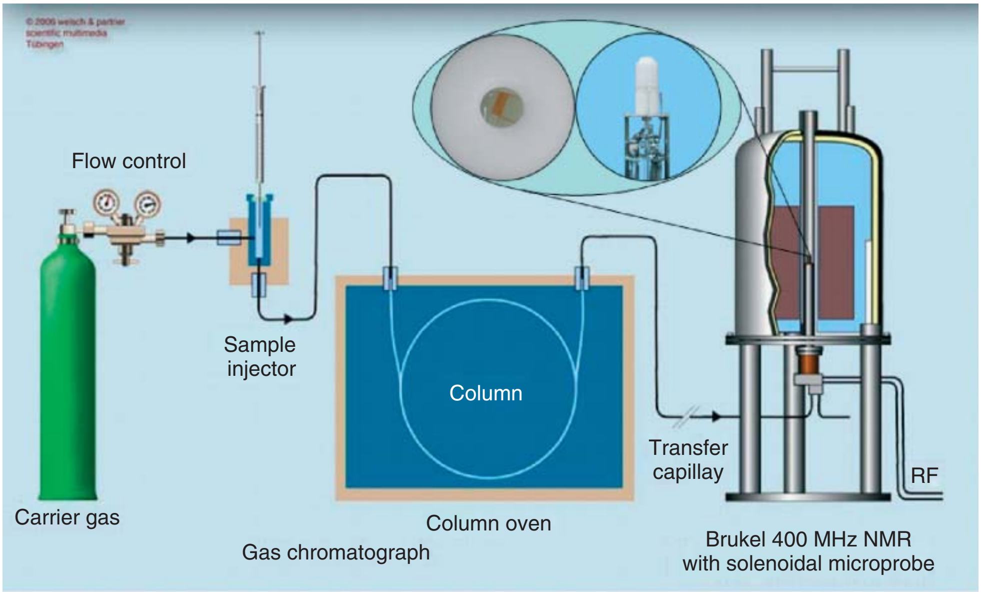

Figure 52.25 Experimental setup for GC-NMR.

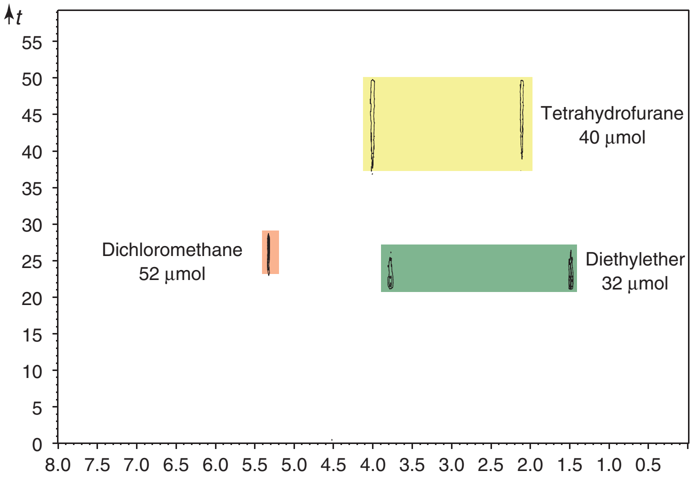

Figure 52.26 Contour plot of the GC-NMR separation of diethylether, hexane, and THF.

hexane, and THF have been injected at a semipreparative GC polysiloxane column. The carrier gas was nitrogen at a pressure of 1–7 bar. The injection temperature was 250 °C and the temperature of the GC oven was 60 °C.

The gas-phase continuous-flow ^{1}H NMR spectrum of diethylether is seen in Figure 52.27. Owing to inherent flow broadening at the employed flow rate of

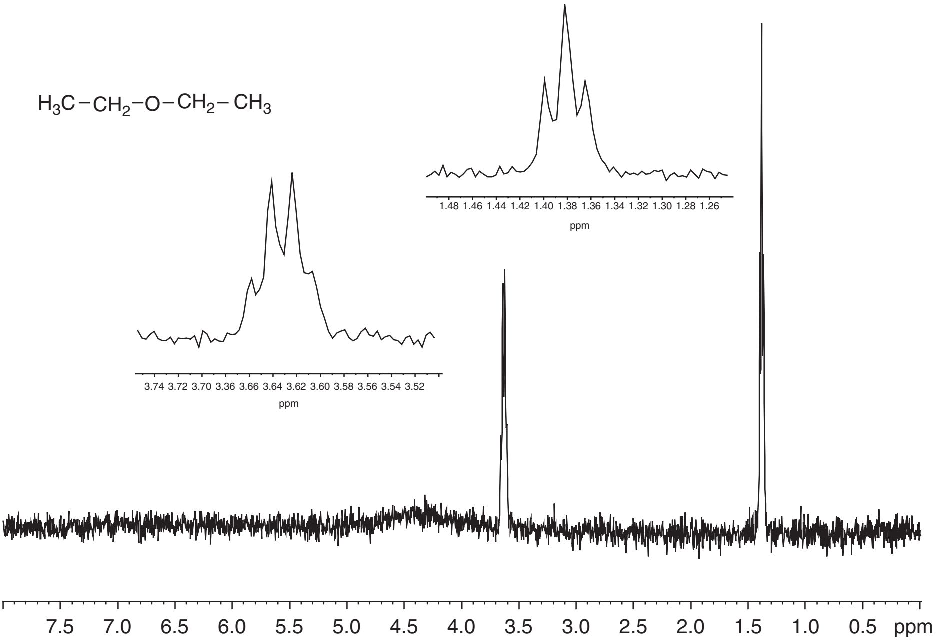

Figure 52.27 Continuous-flow gas-phase ^{1}H NMR spectrum of diethylether.

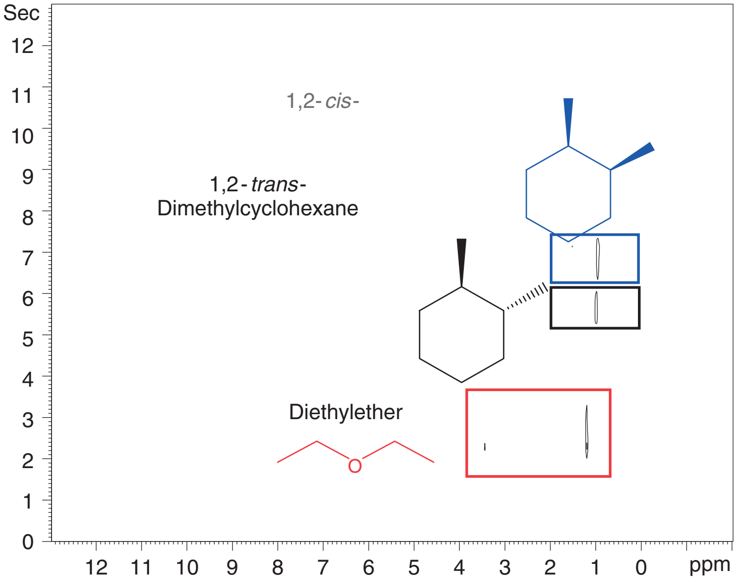

Figure 52.28 Contour plot of the GC-NMR separation of 1,2-*trans*- and 1,2-*cis*-dimethylcylohexane.

5 ml/min, the quartet and the triplet of the diethylether are not base-line resolved, but the stereochemical information of the coupling constant can be easily derived.

Another example is the GC-NMR separation of the stereoisomers of 1,2-*trans*- and 1,2-*cis*-dimethylcyclohexane. The separation shown in Figure 52.28 was performed on a chirasil-β-dex column (ID 250 μm, length 25 m, film thickness 0.25 μm), employing nitrogen as carrier gas at 1 bar pressure at an oven temperature of 60 °C. A further separation of 2-*trans*/*cis* pentene/hexene under similar conditions is shown in Figure 52.29.

The current further development of GC-NMR deals with the implementation of a heatable transfer capillary and the development of a solenoidal NMR probe for high-temperature NMR detection up to 200 °C.

52.10
CE-NMR and CEC-NMR

Electrodriven separations such as capillary electrophoresis (CE) and pressurized capillary electrophoresis (pCEC) have an application potential in separation science [103–114]. Because of the plug flow in electrodriven separations, very high number of plate rates can be obtained. Owing to the additional magnetic field introduced by the high current (up to 20 000 A) of the electroosmotic separation, the application of vertically oriented flow cell is favorable (Figure 52.30).

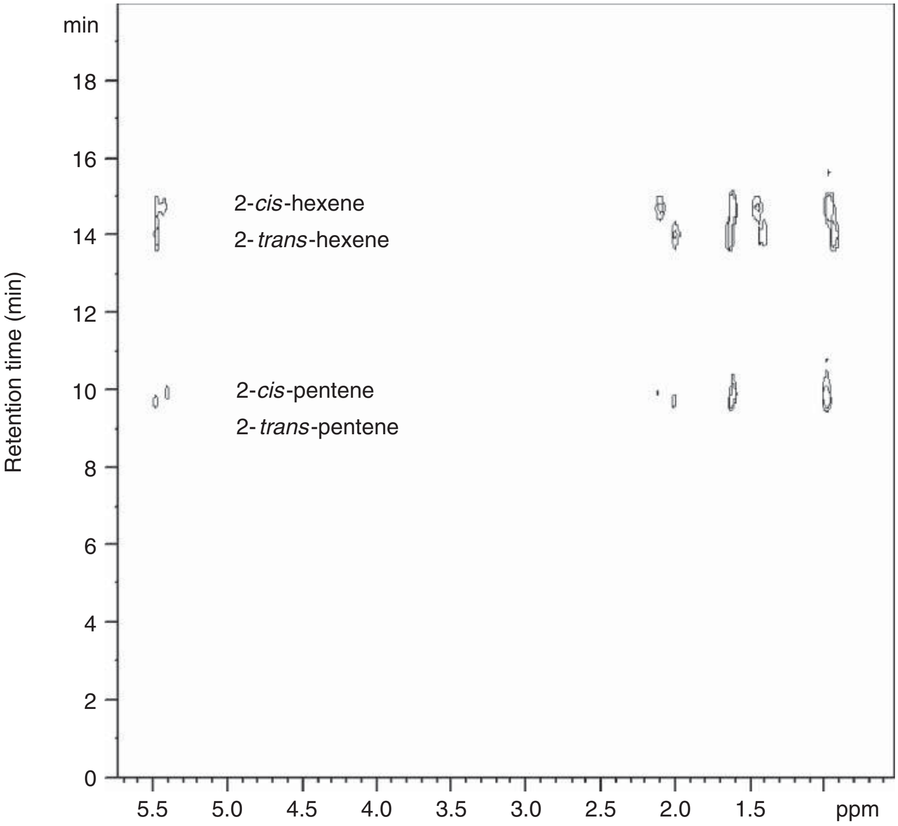

Figure 52.29 Contour plot of the GC-NMR separation of 2-*trans*/*cis* pentene/hexene.

Figure 52.31 and Figure 52.32 show the CE and pCEC separation of fatty esters. A further extension of the NMR registration of electrodriven separation is the use of isotachophoresis for peak focusing. This work was pioneered by Larive [111–114].

52.11
Current Developments

Modern NMR assignment techniques for the structure elucidation of unknown organic compounds employ the combined use of ^{1}H and ^{13}C NMR spectroscopy. This is outlined in Section 52.5 where the employed stopped-flow technique is ideal for the application of two-dimensional ^{1}H^{13}C assignment techniques such as HSQC and HMBC.

But similar to the direct online monitoring of a separation by ^{1}H NMR spectroscopy, it would be favorable to perform a continuous-flow registration by ^{13}C NMR spectroscopy. ^{13}C NMR spectroscopy offers the big advantage of direct

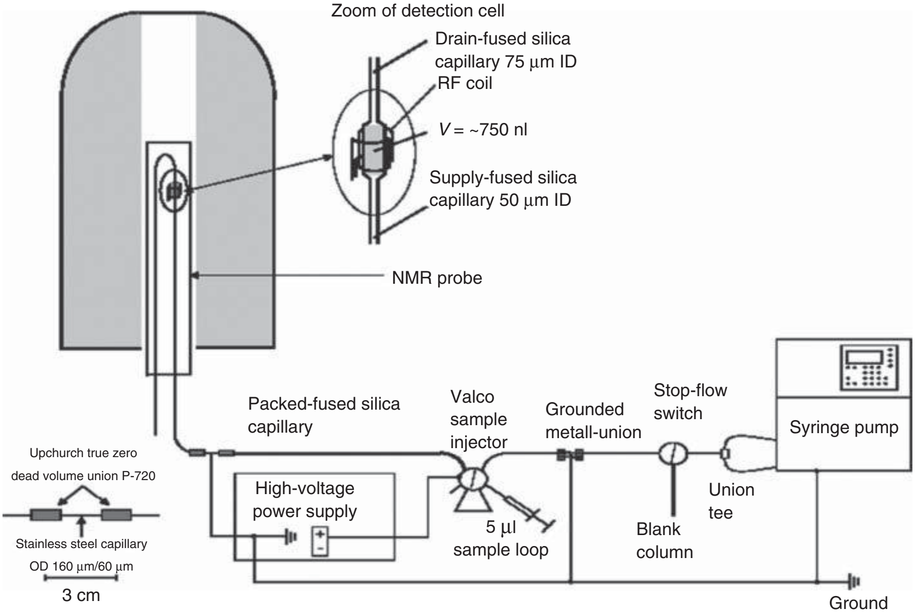

Figure 52.30 Experimental setup for CE-NMR and CEC-NMR.

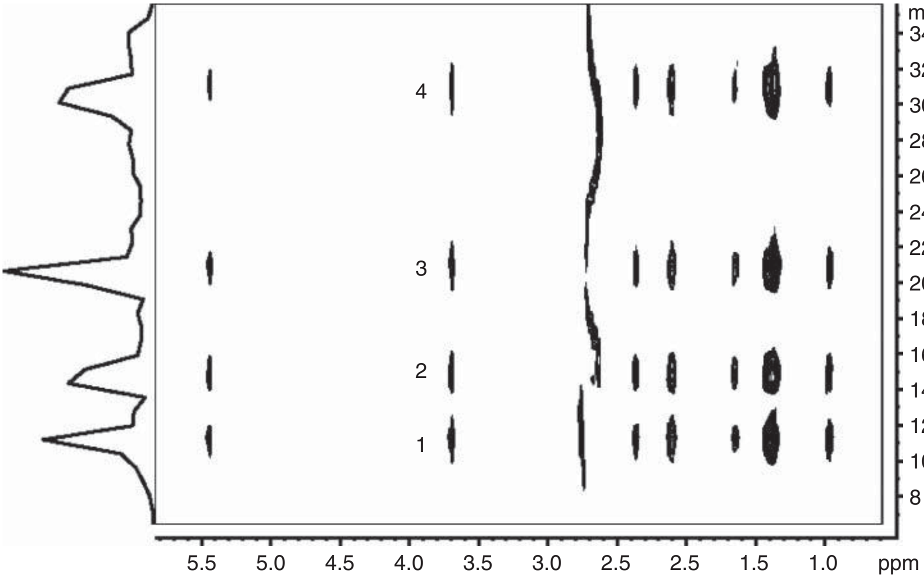

Figure 52.31 Separation of fatty acid methyl esters on a C_{18} phase 1 palmitoleic acid methyl ester (C16:1, *cis*-9), 2 oleic acid methyl ester (C18:1, *cis*-9,3 eicosenoic acid methyl ester (C20:1, *cis*-11), 4 erucic acid methyl ester (C22:1, *cis*-13) CE-^{1}H NMR coupling (flow rate 2 μl min^{-1}, voltage + 17 kV, current + 1.5 μA, back pressure 30 psi).

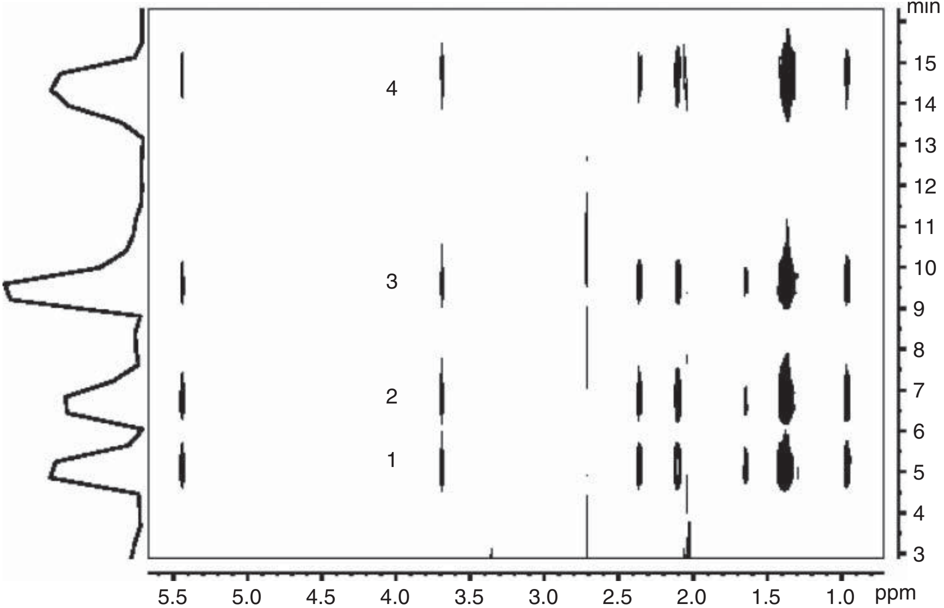

Figure 52.32 Separation of fatty acid methyl esters on a C_{18} phase pCEC-^{1}H NMR coupling (flow rate 4 µl min^{-1}, voltage + 17 kV, current + 1.5 µA, back pressure 550 psi).

access to the molecular framework of organic compounds. The high ^{13}C chemical shift range of 200 ppm versus the ^{1}H chemical shift range of only 10 ppm allows for a much easier peak assignment. The disadvantage of ^{13}C NMR spectroscopy is the low natural abundance of only 1.1% of ^{13}C nuclei and the long spin–lattice relaxation times T_1 up to several seconds. ^{1}H nuclei have a natural abundance of 99.9%, and spin–lattice relaxation times are between 0.1 and 1 s. Because spin–lattice relaxation times define the pulse repetition rate in the NMR acquisition (Figure 52.33), they directly define the sensitivity either in a static or continuous-flow NMR experiment.

There is one big advantage of continuous-flow NMR: that nuclei can pick up their magnetization before they enter the NMR detection cell. Thus, full Boltzmann

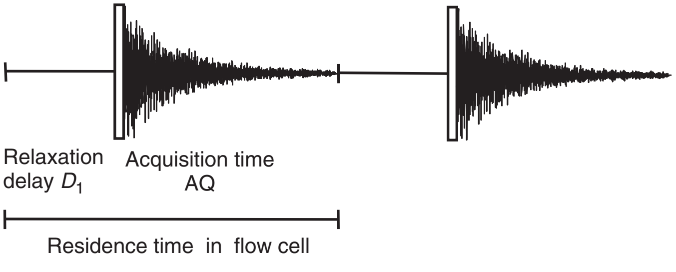

Figure 52.33 NMR acquisition in the continuous-flow mode.

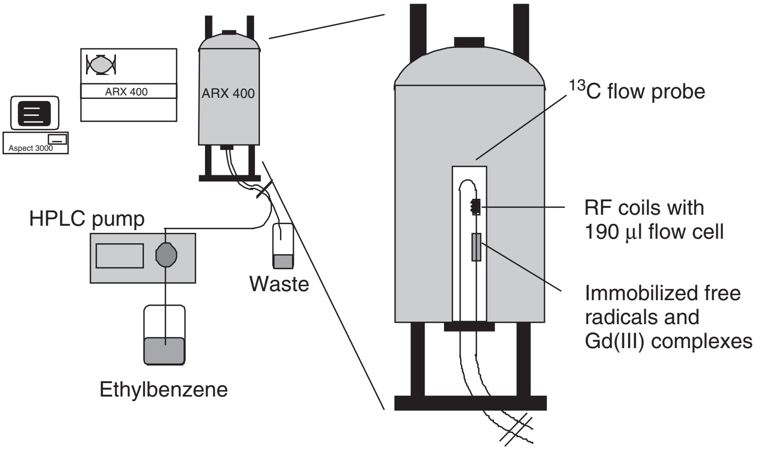

Figure 52.34 Experimental setup for continuous-flow ^{13}C NMR recording.

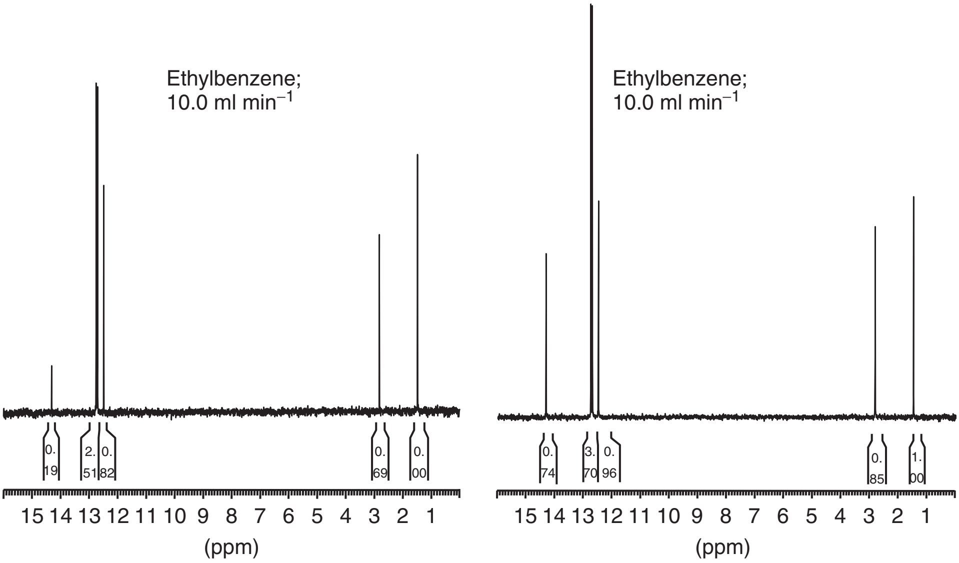

Figure 52.35 Continuous-flow (10 ml min^{-1}) ^{13}C NMR spectra of ethylbenzene without and with Gd-DOTA.

distribution can be obtained by passing the analyte through a premagnetization volume before the NMR detection coil. If this ''premagnetization volume'' is packed with an immobilized free radical, T_1 of the flowing nuclei is reduced and NMR sensitivity can be increased. In NMR imaging, paramagnetic contrast agents such as Gd-DTPA (gadolinium-diethylenetriamine penta-acetic acid) and Gd-DOTA (gadolinium-tetraazacyclododecanetetraacetic acid) are used to reduce the water T_1 in the human body and enable the detection of malignant tissues. The same principle can be used for continuous-flow ^{13}C NMR detection.

A container with immobilized Gd-DTPA can be inserted in the continuous-flow probe before the NMR detection coil (Figure 52.34) [115]. The relaxation effect can be readily seen in Figure 52.35. The signal intensity of the quaternary carbon of ethylbenzene is increased by a factor of 3.9. All ^{13}C signals of ethylbenzene show nearly same intensity ready for quantitation.

The next reach step will be the implementation of the immobilized relaxation agent together with a reversed phase in a special designed probe for ^{13}C NMR detection. This is an ongoing development with Prof. Andrew Webb from Leiden University in The Netherlands.

Because of the small detection volumes necessary for capillary microcoil NMR, it is possible to position several microcoils within one NMR probe. A recent review describes the current status and possible future developments of single and multiple microcoil NMR detection [116].

52.12
Conclusion

The high number of applications dealing with the hyphenation of all existing separation techniques with NMR spectroscopy really proves that NMR spectroscopy can be considered an important chromatography detector. The unambiguous information content derived by NMR spectroscopy justifies the high price of the most expensive chromatography detector.

Currently, two major online coupling strategies with NMR detection are used. One is the application of solid-phase extraction together with separation and NMR detection, for example, LC-SPE-NMR. Here, very sensitive cryprobes are used for NMR detection. The other strategy is the application of microcoils for NMR detection together with capillary separation techniques.

LC-SPE-NMR seems favorable for the investigation of plant extracts, whereas microcoils show some application value for capillary HPLC, GC, SFC; CE and CEC separations. One big advantage of LC-SPE-NMR is that it can be fully automated for screening purposes.

Overall, together with hyphenated MS techniques, online NMR techniques are the methods of choice of an efficient structural peak assignment in chromatography.

Section XV
General Data Treatment: Databases/Spectral Libraries

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

53
Optical Spectroscopy

Steffen Thiele and Reiner Salzer

53.1
Introduction

The spectra measured by any method of optical spectroscopy may be subject to qualitative (what is it?) or quantitative (how much is it?) evaluation. We assume here that the basic rules described in Chapters 1 and 2 for the overall analytical process are obeyed, in particular for sample selection and sample preparation. Errors during sample preparation or simply due to an incorrect positioning of the specimen in the optical beam can never be corrected for in the measured spectra. Restricted quality in the experimental spectra will lead to errors either in qualitative evaluation (e.g., ill-defined results in spectral search) and in quantitative evaluation (e.g., erroneous determination of concentration).

The contrast in spectral images arises from the spectroscopic information behind every pixel (cf. Section 4.7). The spectra behind a spectral image are treated the same way as individual spectra (cf. Section 5.6), that is, the procedures described in the subsequent sections can be applied either to individual spectra or to sets of spectral-like time series or spectral images.

Modern spectrometer software offers a variety of mathematical tools for processing of spectra. These tools provide powerful features to the experienced user but cause serious danger in case of noncritical application. Some types of processing tools do not alter the information content of the spectra (cf. Table 53.1, basic operations), other do (cf. Table 53.1, manipulations). Particular attention has to be paid if the latter have to be used.

The evaluation of spectra will be discussed separately for qualitative and quantitative analysis. Particular emphasis will be laid (i) on state-of-the-art methods for search of spectra in spectral libraries or search for spectroscopic information in data banks and on (ii) procedures for multivariate data analysis [1–3].

Two of the basic operations mentioned in Table 53.1 are of particular importance for the evaluation of spectra, centering, and standardization. They will be considered first.

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

Table 53.1 Types and objectives of spectra processing.

Basic operations	**Prettier display**	**Qualitative evaluation**	**Quantitative evaluation**
Conversion transmission T – absorbance A	X		X
Conversion wavelength λ – wave number k	X	X	X
Background reduction	X	X	X
Centering		X	X
Standardization		X	X
Spectra subtraction			X
Manipulations			
Baseline correction	X	X	
Smoothing	X	X	X !
Derivation	X	X	
Deconvolution		X	
Curve fitting		X	(X)
Band integration			X
Generation of band tables		X	
Spike correction (Raman spectra)	X	X	

53.2
Basic Operations

53.2.1
Centering

Centering is an important step in pretreatment of spectral data before multivariate evaluation both for qualitative as for quantitative analysis. At first, the mean spectrum $\underline{a}_{\mathrm{M}}^{\mathrm{T}}$ is calculated from the set of measured spectra:

$$\underline{a}_{\mathrm{M}}^{\mathrm{T}} = (\overline{a}_1, \overline{a}_2, \ldots, \overline{a}_p) \tag{53.1}$$

$$\text{where } \overline{a}_j = \frac{1}{n}\sum_{i=1}^{n} a_{ij} \quad j = 1, \ldots, p \tag{53.2}$$

The subscript j represents the number p of spectral data points, the subscript i the number n of measured spectra. Subsequently, the mean spectrum is subtracted from each measured spectrum:

$$\underline{a}_{\mathrm{C};i}^{\mathrm{T}} = \underline{a}_i^{\mathrm{T}} - \underline{a}_{\mathrm{M}}^{\mathrm{T}} \quad i = 1, \ldots, n \tag{53.3}$$

As a result of the given data treatment, the mean of the centered spectra $\underline{a}_{\mathrm{C};i}^{\mathrm{T}}$ amounts to zero, that is, the center of the data set of n spectra has been shifted to the origin of the coordinate system (cf. Figure 53.1). All subsequent matrix

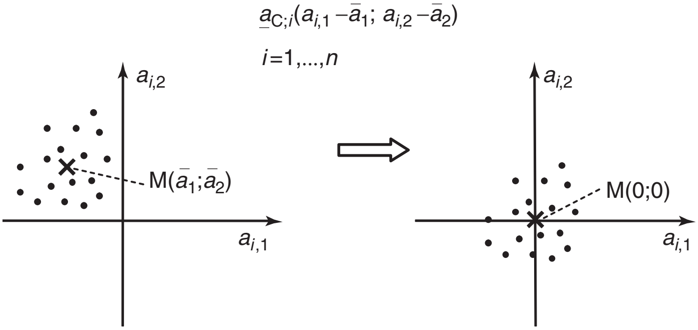

Figure 53.1 Effect of centering the measured absorbance values $a_{i,1}$ and $a_{i,2}$ illustrated for two spectral data points ($p = 2$).

operations in either qualitative or quantitative evaluation benef from the centering because the overlaid offset of the center has been removed and only the significant scattering of the measured spectra around the center is retained.

53.2.2
Standardization (Autoscaling)

Standardization is a method in pretreatment of spectral data before multivariate evaluation both for qualitative as for quantitative analysis, just like centering. In case of standardization, the standard deviation s is calculated at each of the p spectral data points for all n measured spectra:

$$s_j = \sqrt{\frac{\sum_{i=1}^{n}(a_{ij}-\bar{a}_j)^2}{n-1}} \quad j = 1, \dots, p \tag{53.4}$$

The standardized absorbance value of each measured spectrum ($i = 1, \dots, n$) at each spectral wavelength ($j = 1, \dots, p$) is calculated by using

$$a_{S_{ij}} = \frac{a_{ij}-\bar{a}_j}{s_j} \tag{53.5}$$

The standardized set of spectral data shows a mean of 0 and a variance of 1. Standardization may also be useful for gathering and comparing of multicollinearities in later evaluation steps (cf. Section 53.3).

One basic rule should be emphasized here: the set of mathematical operations chosen for the calibration samples has to be applied in an absolutely identical manner to all subsequent test samples. This rule holds as well for the above-mentioned basic operations and for the more advanced operations described later in this chapter.

53.3
Evaluation of Spectra

53.3.1
Introduction

Contemporary spectrometers are enabled to produce huge amounts of data within a very short time. This development continues because of the introduction of array detectors for spectral imaging (cf. Section 4.7). The utilization of as much as possible of the enclosed spectral information can only be attained by chemometric procedures for data analysis. The most commonly used procedures for evaluation of spectra are systematically arranged in Figure 53.2, with the main emphasis on application, that is, the variety of procedures was divided in methods for qualitative analysis and for quantitative analysis. Another distinctive feature refers to the mathematical algorithms on which the procedures are based. The dominance of multivariate over univariate methods is clearly discernible from Figure 53.2.

In case of qualitative analysis, unsupervised learning procedures are employed for explorative data analysis or for empirical investigation of samples with no additional information available. The analyst wants to sense the correlation within the data or the interrelation between the data and particular features or properties of the sample. Such information qualifies for structuring of data with respect to useful data range, property parameters, and arrangement into classes. Excessive data amounts require reduction to a reasonable size by automated procedures

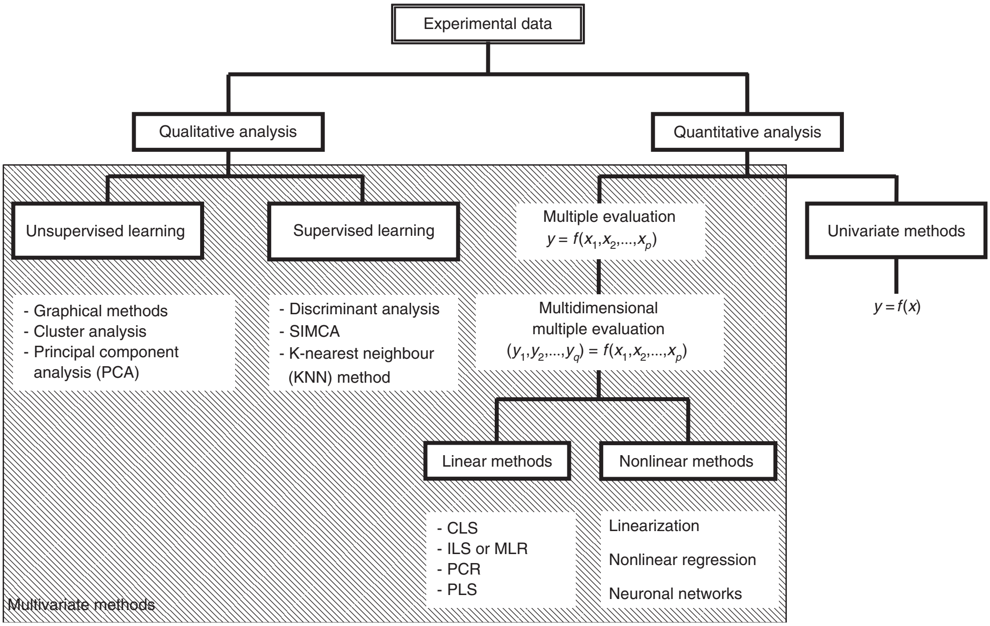

Figure 53.2 Survey of methods for data analysis.

before structuring. Principal component analysis (PCA) is an efficient method for such spectral data reduction. Supervised learning procedures are employed in order to assign new objects to already established classes (available additional knowledge). A simple case is the comparison of features between a new sample and previously characterized samples, for example, during the search for an analyte spectrum in a spectral data base. The aim of this search is the elucidation of the composition or structure, respectively, of an unknown.

In case of quantitative analysis, the amount of – or the exact relation between – the constituents of a compound or a mixture have to be established. The direct relation between the properties of a specimen and the concentration of its constituents could also be the aim of quantitative investigation. In the latter case, so-called calibration models have to be established, the corresponding model parameters have to be estimated, and they have to be confirmed by statistical methods. Calibration models established this way may then be used to determine on a statistically verified basis the concentration of constituents of an analyte within the calibrated range. All multivariate methods for quantitative analysis mentioned in Figure 53.2 are employed for evaluation of spectra.

53.3.2
Qualitative Evaluation of Spectra

53.3.2.1 Spectral Data Banks

Many digital spectral libraries have been transformed from printed spectra collections. Well-known printed collections are the Aldrich spectra collection [4], the Sadtler spectra collection [5–7], the Schrader–Meyer Atlas of IR and Raman spectra [8], the Hummel collection of IR spectra of polymers [9], Merck IR Atlas [10], and the Buback collection of NIR spectra [11]. IR spectra have the largest share of digital optical spectra, followed at a clear distance by Raman spectra. Larger collections of UV/vis spectra have not been established because of their missing fingerprint capability and moreover because of the strong sensitivity of the UV/vis spectra against solvent interactions. A variety of dedicated spectra collections have been created in industrial laboratories without access to the public.

The difference between in-house and online versions of spectral libraries consists mainly in the fee, which depends on conditions of usage. Usually, in-house versions have to be paid for only once on license acquisition and hardware purchase. Afterwards, the actual use is free, regardless of the frequency of usage. In certain cases, an annual license fee has to be paid. Follow-up costs may occur if updates are demanded or if hardware service is needed. In case of in-house systems running on workstations, initial costs as well as upkeep may approach considerable height. In contrast, the costs for online systems solely depend on frequency of usage. Both operativeness and speed of the Internet connection may remarkably influence the size of the expenses. If only occasionally used, the online version is financially certainly more viable than the in-house version. At best, one is able to find free-of-charge Internet offers, sometimes with restricted access to certain features (cf. Table 53.2).

Table 53.2 Optical spectral data bases (according to provider specifications, 1 December 2008).

Data base	Type and amount of spectra (if available)	Availability		Charge
		In-house version	Online version

Vapor phase of organic compounds	FT-IR: 5.220	X		yes

Spectral data banks contain all sorts of information about a particular substance in the form of tables. The requested field of a table can be accessed by the user either via abbreviations (e.g., MF for molecular formula) or via input masks, which place the necessary denominations of the field at the user's disposal. Some fields may contain searchable information only as alphanumerical text (e.g., compound names), others may be searched only numerically (e.g., molecular weight). In case of numerical fields, some numerical operators (e.g., <;=;> or – for area allocation) may be applied as well.

It is often possible to search for bands of particular intensity in selected wavelength ranges. During the search, all fields may be interconnected logically (search masks) or by logic operators (and; or; not; proximity operators). A summary of information contained in a spectral data bank for a given compound is given in Table 53.3.

The CAS number (Chemical Abstracts Service Registry Number) is of particular importance. This number went into a wide range of data banks (structural and factual data banks, bibliographic data banks, and substance data banks) and may advantageously be used for fast access to information related to a particular substance. Data banks comprising information about several spectroscopic methods are of high value for structural elucidation if a combination of methods has to be applied (e.g., NIST, SDBS, SpecInfo).

The spectral search itself is based on computation of similarity by comparison of full spectra or of band tables. Necessary means are structural editors and spectral editors, which are usually applied off-line before the spectral search is started. Spectral editors may be used to erase existing bands from or to generate new bands into spectra. Spectral editors may also be used for complete generation

Table 53.3 Searchable information in spectral data banks.

Compound identification	Compound name includes synonyms CAS number Molecular formula Molecular weight Graphical structure representation Additional data possible (e.g., melting point)
Acquisition of spectra	Sample source Sample purity Sample preparation Spectrometer type Spectral resolution Additional data possible (e.g., special sample conditions; file format)
Spectrum	Complete spectrum in numerical and graphical form Band table

of new spectra. Structural editors are used to generate chemical 2D structures or to modify structures, which were previously obtained from chemical drawing programs. These structures can be searched for in the data bank after they have been encoded by the structural editor. Substructure searches are uncommon in IR data banks because IR spectra are rather used for fingerprint identification of compounds than for assembling full structures from subunits.

In case of spectral search by comparison of band tables, the system first computes the necessary band table from the experimental spectrum of the analyte. For the subsequent search, both the position and the intensity of the bands in the spectrum of the unknown and in the spectra on the compounds contained in the data bank are compared. After the search has been completed, the top position in the hit list is assigned to the substance with least differences in band positions and band intensities.

In case of a full spectra search, the complete set of spectral features (absorbance values at p wavelength positions) is compared between the spectrum of the unknown and all spectra contained in the data bank. So-called similarity measures are computed for each individual comparison. In case of the mostly employed similarity measure, the Euclidean distance (cf. Figure 53.6), the spectrum is regarded as p-dimensional spectral vector (data points at p wavelength positions). The comparison between the spectral vector $\underline{u}$ of the unknown and the vector $\underline{b}$ of the data bank spectrum results in a value $d(\underline{u}, \underline{b})$:

$$d(\underline{u}, \underline{b}) = \sqrt{\sum_{j=1}^{p} (u_j - b_j)^2} \tag{53.6}$$

The library spectrum showing the minimal Euclidean distance $d_{\min}$ from the spectrum of the unknown will be assigned the top position in the resulting hit list. In order to ensure comparability of the distances d, each submitted spectrum has to be subjected to a particular normalization (cf. Figure 53.3). At first, the lowest absorbance value across the spectrum is subtracted from all p data points of the spectrum. Afterwards, the spectrum is normalized to the required absorbance

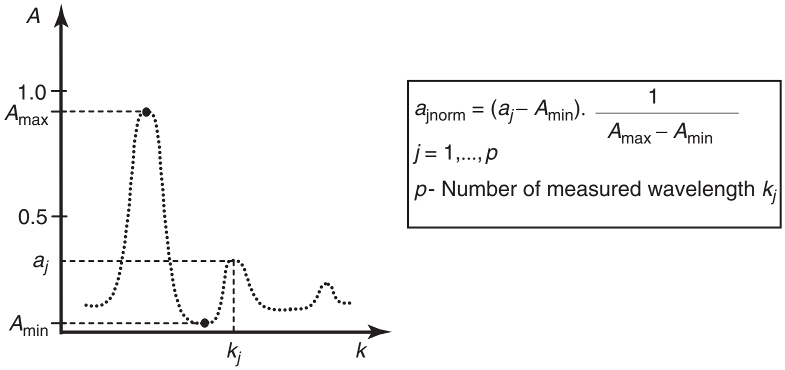

Figure 53.3 Normalization of a spectrum to the absorbance range between 0 and 1.

maximum. The necessity of such a normalization constitutes a serious limitation of the search procedure.

In contemporary search algorithms, each spectral vector is normalized to unit length (unit vector $\underline{x}_{\mathrm{E}}$). The length of a vector $\underline{x}$ (also called *absolute value* or *norm vector*) is given by

$$\|\underline{x}\| = \sqrt{\underline{x}^{\mathrm{T}}\underline{x}} \tag{53.7}$$

and the norm vector $\underline{x}_{\mathrm{E}}$ by

$$\underline{x}_E = \frac{\underline{x}}{\|\underline{x}\|} \tag{53.8}$$

By means of the definition of the scalar product of two vectors $\underline{x}$ and $\underline{y}$

$$\underline{x}^{\mathrm{T}}\underline{y} = \|\underline{x}\|\,\|\underline{y}\| \cdot \cos(\underline{x}, \underline{y}) \tag{53.9}$$

the library search in the p-dimensional Euclidean space (p – number of measured wavelengths) results in the following distance value d_{E}:

$$d_E = 1 - \cos(\underline{u}, \underline{b}) = 1 - \frac{\underline{u}^{\mathrm{T}}\underline{b}}{\sqrt{\underline{u}^{\mathrm{T}}\underline{u}}\sqrt{\underline{b}^{\mathrm{T}}\underline{b}}} \tag{53.10}$$

The calculated results correspond to the cosine of the angle between the spectral vector $\underline{u}$ of the unknown and the vector $\underline{b}$ of the library spectrum. In case of congruency of both vectors $\underline{u}$ and $\underline{b}$, we obtain $\cos(\underline{u}, \underline{b}) = 1$; thus, $d_{\mathrm{E}} = 0$.

A common problem for contemporary search algorithms, caused by varying baseline offsets, can be overcome by centering the spectra (cf. Section 53.2). Centered spectra $\underline{u}_{\mathrm{Z}}$ are obtained by calculating the average $\overline{u}$ of a spectral vector $\underline{u}$ measured at p wavelengths:

$$\overline{u} = \frac{1}{p}\sum_{j=1}^{p} u_j \tag{53.11}$$

The average $\overline{u}$ is subsequently subtracted from all components u_j of the vector $\underline{u}$:

$$\underline{u}_{\mathrm{Z}} = (u_j - \overline{u})^{\mathrm{T}} \quad j = 1, \ldots, p \tag{53.12}$$

These centered vectors $\underline{u}_{\mathrm{Z}}$ are now used for the calculation of a correlated distance d_{C}, as in Eq. (53.10)

$$d_{\mathrm{C}} = 1 - \cos(\underline{u}_{\mathrm{Z}}, \underline{b}_{\mathrm{Z}}) = 1 - \frac{\underline{u}_{\mathrm{Z}}^{\mathrm{T}}\underline{b}_{\mathrm{Z}}}{\sqrt{\underline{u}_{\mathrm{Z}}^{\mathrm{T}}\underline{u}_{\mathrm{Z}}}\sqrt{\underline{b}_{\mathrm{Z}}^{\mathrm{T}}\underline{b}_{\mathrm{Z}}}} \tag{53.13}$$

On the basis of the mathematical definitions, Eq. (53.13) can be reformulated (corr stands for correlation)

$$\operatorname{corr}(\underline{u}, \underline{b}) = \frac{\underline{u}_{\mathrm{Z}}^{\mathrm{T}}\underline{b}_{\mathrm{Z}}}{\|\underline{u}_{\mathrm{Z}}\|\|\underline{b}_{\mathrm{Z}}\|} = \frac{\underline{u}_{\mathrm{S}}^{\mathrm{T}}\underline{b}_{\mathrm{S}}}{p - 1} \tag{53.14}$$

After introduction of the standardized vectors $\underline{u}_{\mathrm{S}}$ and $\underline{b}_{\mathrm{S}}$

$$\underline{u}_{\mathrm{S}} = \frac{\underline{u}_{\mathrm{Z}}}{s(\underline{u})} \text{ and } \underline{b}_{\mathrm{S}} = \frac{\underline{b}_{\mathrm{Z}}}{s(\underline{b})} \tag{53.15}$$

where s denotes the standard deviation of the vectors $\underline{u}$ and $\underline{b}$ (cf. Section 53.2.2):

$$s(\underline{u}) = \frac{\|\underline{u}_Z\|}{\sqrt{p-1}} \text{ and } s(\underline{b}) = \frac{\|\underline{b}_Z\|}{\sqrt{p-1}} \tag{53.16}$$

we obtain

$$\underline{u}_S = \frac{\underline{u}_Z}{\|\underline{u}_Z\|}\cdot\sqrt{p-1} \text{ and } \underline{b}_S = \frac{\underline{b}_Z}{\|\underline{b}_Z\|}\cdot\sqrt{p-1} \tag{53.17}$$

Equation (53.17) corresponds to Eq. (53.8) with the vectors now standardized to the length $\sqrt{p-1}$. In summary, the improvement in the correlated distance value is due to the removal of the baseline offset and to the scale invariance of the pretreated vectors of the unknown and of the library spectrum. The following problems in searching for an unknown in a spectral library persist.

1) The spectrum cannot be satisfactorily normalized because of a nonhorizontal or nonlinear baseline.
2) The composition of the spectral library usually does not cover all necessary groups of chemical compounds.
3) The similarity scores that are used to construct the hit list are not necessarily significant measures for the similarity of structures.

A nonhorizontal baseline may be corrected for by subtracting an angled straight line. In case of a nonlinear baseline, much experience is needed to minimize possible effects of a mathematical correction on the search results. Here, the computation of the second derivative of the spectrum might be the favorable option.

Even if an unknown belongs to a particular class of compounds, which is not represented in the library, the search will always result in a hit list with a number of entries. In general, entries with small scores are not relevant to an identification. In order to gain a feeling for the significance of an entry of its scores, one should experiment with the library, and a sound chemical knowledge is necessary.

53.3.2.2 Data Banks Containing Spectroscopic Information

Fields containing spectroscopic information can specifically be accessed in the data banks Beilstein (organic chemistry) and Gmelin (inorganic chemistry, organometallic chemistry) by means of the on-line system Reaxys. Covered spectral ranges, measured spectral intensity maxima, and references, may be found. Data concerning the state of aggregation of the sample or the solvent may possibly be included as well. Of course, the full text option may be used in any data bank to search for spectroscopic data or experiments, for example, in Chemical Abstracts or in Analytical Abstracts (e.g., Raman spectrum).

If interdisciplinary matters are searched, bibliographic data banks such as Biosis (biosciences and biomedicine), Medline (medicine), Inspec (physics, electroengineering, and engineering) as well as all data banks containing patent information should be considered.

53.3.2.3 Interpretation of Spectra by Means of Group Frequencies and of Characteristic Bands

This topic has already been dealt with in Chapter 6. Currently, there are numerous software products available on the market or under development, which are intended to support the task of spectra interpretation (e.g., AnalyzeIt IR, AnalyzeIt Raman [12], IR-Tutor [13], and SpecTool [14]). Certain tools even permit a spectrum simulation of the structure guessed [15]. Some spectrometer operation systems include tools to aid simple spectra interpretation.

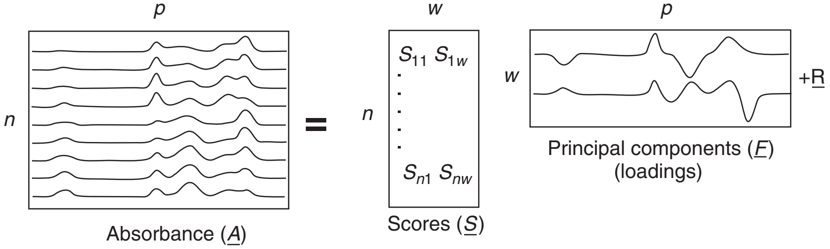
53.3.2.4 PCA (Principal Component Analysis)

PCA is an efficient method for data reduction, in particular, in spectroscopy (cf. Figure 53.4). It has to be performed also before quantitative evaluations by PCR (principal component regression) or PLS (partial least squares).

The mathematical background of PCA consists in the transformation of the initial coordinate system into a new one in order to display the variance of the experimental data optimally. To this aim, the mathematical algorithms provide that

- the principal components (PCs) consist of linear combinations (i.e., weighted sums) of the initial variables (i.e., absorbances at the measured wavelengths);
- the PCs are computed in a way to cover the largest amount of variance (e.g., assuming the variance in spectral data due to the different properties of the measured samples);
- the linear combinations represent new, so-called latent variables (e.g., variables which cannot be assigned to a particular spectral band) with appropriate properties.

Initially, the *n* experimental spectra, each comprising *p* data points, are collected into an *n*,*p*-dimensional data matrix $\underline{A}$. Any row of the matrix $\underline{A}$ comprises all *p* absorbance values of a particular spectrum. Any column consists of all *n* absorbance values at a particular wavelength. As a first step, the data matrix is either centered ($\underline{A}_Z$) or standardized ($\underline{A}_S$) (cf. Section 53.1.2). In order to achieve the above-stated



n - Number of spectra
p - Number of measured wavelengths = number of data points
v - Number of neglected principal components
w - Number of retained principal components $w = p - v$

Figure 53.4 Decomposition of the absorbance matrix $\underline{A}$.

aims, this pretreated matrix is afterwards split into two matrices by the chosen algorithm:

$$\begin{array}{lcccc} & \underline{A}_{Z} = & \underline{S}_{n} & \cdot & \underline{F}_{n}^{T} \\ \text{dimensions} & n,p & n,p & & p,p \end{array} \tag{53.18}$$

Matrix $\underline{S}_n$ is called the *score matrix*. The subscript n indicates that no data reduction has been introduced yet. The columns of matrix $\underline{S}_n$ comprise the scaling coefficients. Matrix $\underline{F}_n$ may be called the *loading matrix* or *principal components* or *factors* or *eigenvectors*. Its columns comprise the calculated PCs. The maximum number of components is min(n,p). By multiplication of the matrices $\underline{S}_n$ and $\underline{F}_n$, we are able to reconstruct the centered or the standardized spectra.

As the calculation of the PCs is based on the criterion of covering the largest amount of variance in the experimental data ($\underline{A}_Z$ or $\underline{A}_S$), the first PC features the maximum variance. Subsequent PCs cover less and less variance. Distant PCs may be omitted for data reduction. In that case, Eq. (53.18) may be rewritten as

$$\begin{array}{lcccccc} & \underline{A}_{Z} = & \underline{S} & \cdot & \underline{F}^{T} & + & \underline{R} \\ \text{dimensions} & n,p & n,w & & w,p & & n,p \end{array} \tag{53.19}$$

where w represents the number of retained PCs ($w = p - v$), v is the number of neglected PCs, and $\underline{R}$ is the residual matrix (error matrix) (cf. Figure 53.4). An analysis of the error matrix $\underline{R}$ is necessary in order to choose w. Chemical knowledge has strictly to be applied during interpretation of the PCs, which are computed on pure mathematical considerations. Ideally, $\underline{R}$ merely contains the spectral noise as well as unnecessary information from the experimental spectra.

One method in error analysis is the computation of residual variances. The shares of different PCs in the total variance are sketched in Figure 53.5.

If six PCs are retained for further evaluation, a residual variance in the experimental values remains beyond consideration. Other methods of estimating a reasonable size of w are the eigenvalue-one criterion [16, 17], the Scree-test [16, 17], and cross validation (cf. Section 53.3.3.2).

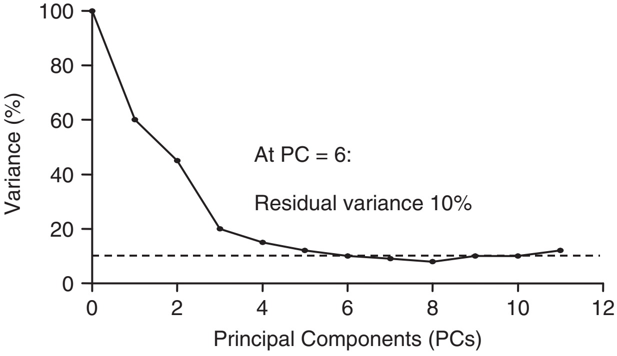


Figure 53.5 Analysis of residual variance in PCA.

53.3.2.5 Cluster Analysis

The aim of cluster analysis is the stepwise merger of objects (spectra) with respect to the similarity of their properties (absorbances at p measured wavelengths). A cluster comprises a group of objects whose similarity is closer than their similarity toward objects outside this group. The similarity of objects is assessed using the same distance measures as described earlier, for example,

- Euclidean distance (cf. Figure 53.6) or
- Mahalanobis distance [18, 19].

The calculation of the Mahalanobis distance is based on the interrelations between absorbance values at various wavelengths using their covariances. For this reason, the Mahalanobis distance is of particular importance for assessing spectroscopic data [16, 17].

Cluster analysis is often the preceding step for discriminant analysis.

53.3.2.6 Discriminant Analysis

In the simplest case, a discriminant analysis is performed in order to check the affiliation (yes/no decision) of an unknown to a particular class, for example, in case of a purity/quality check or a substance identification. A sample may as well be assigned between various classes (e.g., quality levels) if a corresponding series of mathematical models has been established. Models are based on a series of test spectra, which has to completely cover the variations of particular substances in particular chemical classes. From this series of test spectra, classes of similar objects are formed by means of so-called discriminant functions. The model is optimized with respect to the separation among the classes. The evaluation of the assignment of objects to the classes of an established model is performed by statistically backed distance and scattering measures [16, 17].

53.3.2.7 SIMCA (Soft Independent Modeling of Class Analogy)

In soft independent modeling of class analogy (SIMCA), an independent PC model (cf. PCA) is established for each individual class of the test data set. The evaluation

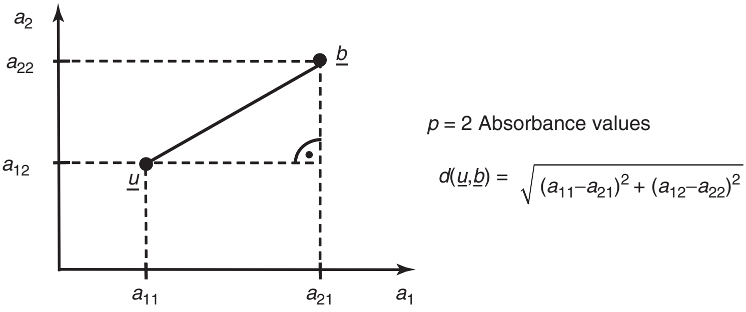

Figure 53.6 Euclidean distance between vector $\underline{u}$ (spectrum of unknown substance) and vector $\underline{b}$ (library spectrum) illustrated for absorbance values at two wavelengths.

of the assignment of objects to these classes of an established model is performed by statistically backed distance measures [16, 17].

53.3.3
Quantitative Evaluation of Spectra

With respect to the applied mathematical algorithms, quantitative evaluation of spectra can be subdivided into univariate and multivariate methods (cf. Figure 53.2). The independent variables x and x_i, respectively, are denoted regressors, whereas the dependent variables y and y_i, respectively, are denoted regressands. The basic sequence of a quantitative evaluation is always the same:

Step 1: Choosing a model.
Step 2: Choosing a training set.
Step 3: Estimation of model parameters.
Step 4: Validation of the model by statistical means.
Step 5: Application of the model for prediction.

In the following paragraphs, the above-mentioned sequence of steps will be discussed for all relevant methods used in evaluating optical spectra quantitatively.

53.3.3.1 Univariate Methods

The only method considered is least squares regression (LSR).

53.3.3.1.1 LSR (Least Squares Regression)

- Step 1: Choosing a model.
  The Beer–Lambert law is expressed

$$A_k = C \cdot K_k \tag{53.20}$$

$$\text{where } K_k = \epsilon_k \cdot l \tag{53.21}$$

  ϵ_k is the absorptivity coefficient at wavelength k and l the thickness of the absorbing medium.
  Within its application range, a linear calibration model can be established already by measuring at a single wavelength position

$$A = bC + a \tag{53.22}$$

  The sample concentration C is calculated from the measured absorbance value A at the sensitivity b and the blank value a.
- Step 2: Choosing a training set.
  Spectra are measured with the analyte at n different concentrations. The absorbance values A_i are determined right at the maximum of a spectral band, which is unambiguously assigned to the analyte.
  The calibration based on band area evaluation instead of a simple height determination might be advantageous. Likewise, ratioing the heights or areas of two bands might be useful to trace a concentration ratio. An initial baseline

correction might be necessary (cf. Sections 53.1 and 53.3.3). Preferably, a straight line should be employed for such corrections (cf. Figure 53.7).

- Step 3: Estimation of model parameters.
  A least squares regression (LSR) is performed in order to estimate $\hat{a}$ and $\hat{b}$:

$$\hat{a} = \frac{1}{n}\left(\sum_{i=1}^{n} A_i - \hat{b}\sum_{i=1}^{n} C_i\right); \quad \hat{b} = \frac{n\sum_{i=1}^{n} C_i A_i - \sum_{i=1}^{n} C_i \cdot \sum_{i=1}^{n} A_i}{n\sum_{i=1}^{n} C_i^2 - \left(\sum_{i=1}^{n} C_i\right)^2} \tag{53.23}$$

- Step 4: Validation of the model by statistical means can be done in two ways:
  a. Analysis of residuals.
  The analysis is performed by calculating

$$r_i = A_i - \hat{A}_i \quad i = 1, \ldots, n \tag{53.24}$$

using the absorbance values $\hat{A}_i$, which were calculated according to the model by

$$\hat{A}_i = \hat{b}C_i + \hat{a} \tag{53.25}$$

and subsequent graphic representation of r_i over C_i (cf. Figure 53.8)

b. Analysis of variance
The variances s_a and s_b of the estimated parameters $\hat{a}$ and $\hat{b}$ are calculated according to

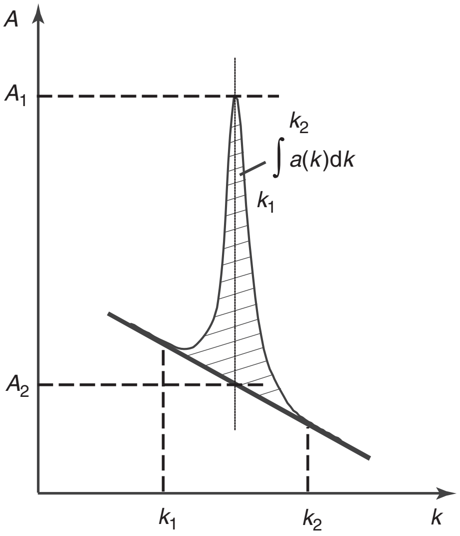

Figure 53.7 Quantitative evaluation of a baseline-corrected spectral band.

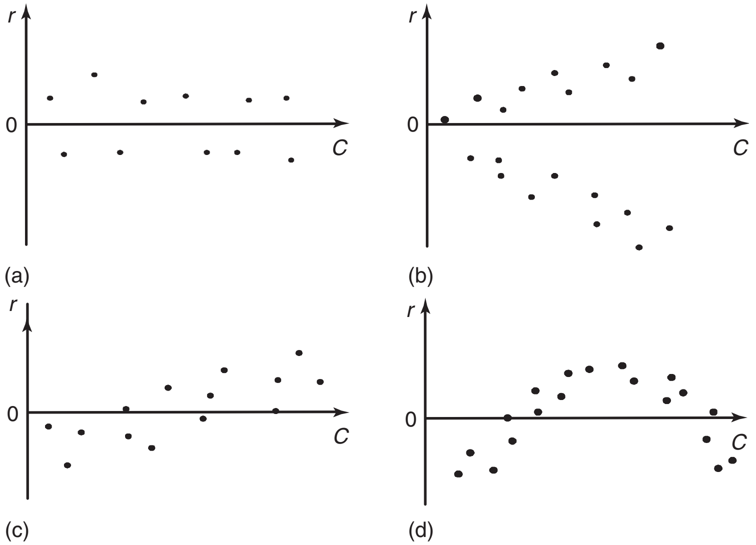

Figure 53.8 Examination of a linear model by analyzing the residuals. The model is validated only for application A. (a) r_i shows normal distribution and uniform variance. (b) r_i shows uneven variance. (c) Erroneous linear model parameter. (d) Nonlinear model.

$$s_a^2 = \frac{s_0^2 \sum_{i=1}^{n} C_i^2}{n \sum_{i=1}^{n} (C_i - \overline{C})^2}; \quad s_b^2 = \frac{s_0^2}{\sum_{i=1}^{n} (C_i - \overline{C})^2} \tag{53.26}$$

$$\text{where } s_0^2 = \frac{\sum_{i=1}^{n} (A_i - \hat{A}_i)^2}{n-2} \text{ and } \overline{C} = \frac{1}{n} \sum_{i=1}^{n} C_i \tag{53.27}$$

The confidence intervals Δa and Δb are calculated according to

$$\Delta a = \pm t(P,f) s_a \text{ and } \Delta b = \pm t(P,f) s_b \tag{53.28}$$

where t indicates a t-distribution, f the degree of freedom ($f = n - 2$), and P the requested probability for the confidence interval.

- Step 5: Application of the model for prediction.
  The predicted concentration C_{pred} may be calculated from measured absorbance values A_{meas} using the developed calibration model according to

$$C_{\text{pred}} = \frac{(A_{\text{meas}} - \hat{a})}{\hat{b}} \tag{53.29}$$

It should be mentioned here that samples used for the estimation of the model parameters in steps 1–4 must not be reused for prediction in step 5.

Advantages and disadvantages of LSR are summarized in Table 53.4.

Table 53.4 Advantages and disadvantages of least squares regression.

	Least squares regression
Advantages	**Disadvantages**
Simple model	Analyte has to have an isolated spectral band
Fast calculation	No application to complex mixtures with overlaid spectral bands

53.3.3.2 **Multivariate Methods**

From a mathematical point of view, applications of multivariate methods [1–3, 16, 17, 20] may be subdivided into the multiple case and the multidimensional multiple case (cf. Figure 53.2). In the former case, several independent variables or features are mapped to merely one dependent variable or target value. In the second case, several independent variables or features are mapped to several dependent variables or target values. As a rule, linear models are used for such problems in optical spectroscopy. In case of nonlinear relations, the calibration range gets restricted, a linearizing data pretreatment is performed in order to get away with linear models, or nonlinear methods (usually neural networks) have to be applied.

All models discussed here belong to the multidimensional multiple case.

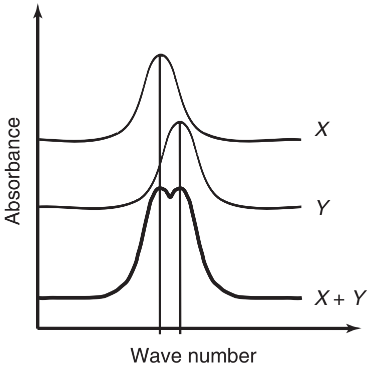
53.3.3.2.1 **CLS (Classical Least Squares), K-Matrix**

- Step 1: Choosing a model.

  The generalized form of the Beer–Lambert law for mixtures containing m components may be written in matrix form (cf. Figure 53.9) as

$$\begin{array}{lcccc} & \underline{A} = & \underline{C} & \cdot & \underline{K} \\ \text{dimensions} & n,p & n,m & & m,p \end{array} \tag{53.30}$$

  The measured absorbance values of a spectrum (p data points) are contained in one row of the absorbance matrix $\underline{A}$. The number of rows n in $\underline{A}$ corresponds



$$A_{k1} = C_X K_{X,K1} + C_Y K_{Y,K1}$$
$$A_{k2} = C_X K_{X,K2} + C_Y K_{Y,K2}$$
$$(A_{k1}\ A_{k2}) = (C_X\ C_Y)\begin{pmatrix} K_{X,K1} & K_{X,K2} \\ K_{Y,K1} & K_{Y,K2} \end{pmatrix}$$

Figure 53.9 Beer–Lambert law for a two-component mixture.

to the number of measured spectra in the training set (cf. Figure 53.4). In the concentration matrix $\underline{C}$, a row contains the concentrations of the individual components of the particular training spectrum. $\underline{K}$ represents the matrix of the absorptivity constants. A row contains these constants of a particular component for all p measured wavelength positions.

- Step 2: Choosing a training set.
  Preparation of n mixtures by variation of the concentration of all m components and subsequent measuring of their absorbance spectra.
- Step 3: Estimation of model parameters.
  Matrices $\underline{A}$ (measured) and $\underline{C}$ (prepared) in Eq. (53.30) are now known. Estimation of the calibration matrix $\underline{\hat{K}}$ is performed by the equation

$$\underline{\hat{K}} = (\underline{C}^{\mathrm{T}}\underline{C})^{-1}\underline{C}^{\mathrm{T}}\underline{A} \tag{53.31}$$

  The condition $n < p$ has to be observed in order to avoid problems with correlating variables and instable matrix inversion. PCR and PLS are more appropriate methods if the above-mentioned condition cannot be met.
- Step 4: Validation of the model by statistical means can be done in several ways, for example,

  a. Analysis of residuals.
  The residual matrix $\underline{R}$ is obtained by calculating the difference

$$\underline{R} = \underline{A} - \underline{\hat{A}} \tag{53.32}$$

$$\text{where } \underline{\hat{A}} = \underline{C}\ \underline{\hat{K}} \tag{53.33}$$

  The n rows of $\underline{R}$ contain difference spectra. Each difference spectrum can be assigned a particular error value

$$\underline{R}_i = \sum_{j=1}^{p} r_{ij}{}^2 \quad i = 1, \ldots, n \tag{53.34}$$

  These error values may be depicted graphically with the number n of the corresponding training spectrum on the abscissa (cf. Figure 53.10). This graph permits an easy detection of outlier spectra.

  b. Cross validation.
  The following sequence has to be completed (leave-one-out strategy):

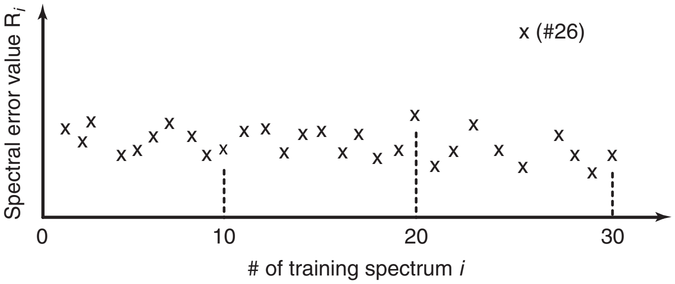


Figure 53.10 Detection of outlier spectra.

  - Selection of a subset of $n-1$ training spectra
  - Estimation of a model
  - Prediction of the concentration of the omitted sample
  - Repetition of the above-mentioned sequence until each of the n training spectra has been omitted and predicted once.

After completion of the above-mentioned cycle, all n experimentally prepared concentration values (C_{exp}) are depicted graphically against the predicted concentration values (C_{pred}) for each of the m components (cf. Figure 53.11). The quality of the calibrated model can be rated from this set of m diagrams.

The data couples (C_{exp}; C_{pred}) in Figure 53.11 may be evaluated by all statistical procedures. Cross-validation is a powerful method for outlier detection and optimization of calibration models. If the predicted concentrations obey the necessary quality standard for all but one training spectrum, the latter can be regarded as outlier. Cross-validation often provides too optimistic results because merely one training spectrum is taken into account. For this reason, the subsequently described set validation may be preferred.

c. Set validation.

The training spectra are randomly separated into two sets. The first set is used for calibration, the second set for validation. Set validation does not demand as much computing power as cross-validation and should be applied only for large data sets. Validation using sets of varying sizes (e.g., 50, 25, 20% of the training data) permits more robust predictions concerning the quality of the model.

- Step 5: Application of the model for predictions.

The calibrated model is finally used to predict the concentrations of the m components (vector $\underline{c}^{\mathrm{T}}$ comprising m concentration values) from the experimental spectrum (vector $\underline{a}^{\mathrm{T}}$ comprising p absorbance values):

$$\underline{c}^{\mathrm{T}} = \underline{a}^{\mathrm{T}} \times (\underline{\hat{K}}^{\mathrm{T}}\underline{\hat{K}})^{-1}\underline{\hat{K}}^{\mathrm{T}} \tag{53.35}$$

Advantages and disadvantages of classical LSR are summarized in Table 53.5.

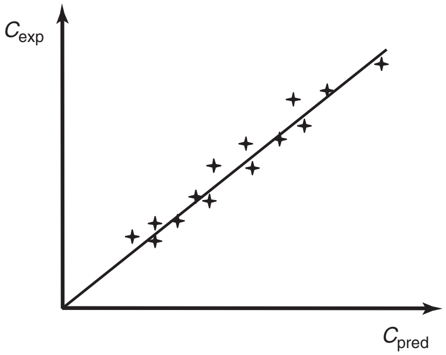

Figure 53.11 Rating of the quality of the calibrated model for one of the m components.

Table 53.5 Advantages and disadvantages of classical least squares regression.

	Classical least squares
Advantages	**Disadvantages**
Relatively fast calculation	The components of the sample have to be known completely, all concentrations have to be varied during calibration
No wavelength selection necessary, complete spectrum applicable	During prediction, all these and only these components have to be present in the sample
Large number of data points per spectrum and large number of calibration spectra ensures low noise	Fails in case of new impurities or components which were not present in the mixture during calibration
	Matrix inversions necessary both during calibration and during prediction

53.3.3.2.2 **ILS (Inverse Least Squares), P-Matrix, or MLR (Multiple Linear Regression (Multidimensional))**

Step 1: Choosing a model.

The generalized form of the Beer–Lambert law (cf. Eq. (53.30)) may be rearranged with respect to the concentration:

$$\begin{array}{lccccc} & \underline{C} & = & \underline{A} & \cdot & \underline{P} \\ \text{dimensions} & n,m & & n,p & & p,m \end{array} \tag{53.36}$$

The structure of matrices $\underline{C}$ and $\underline{A}$ was already described for classical least square (CLS). The elements of the $\underline{P}$ matrix are proportional to the reciprocal absorptivity constants. It is the crucial advantage of inverse least square (ILS) over CLS, that only the concentrations of the components of interest have to be known during calibration.

Step 2: Choosing a training set.

Owing to the mathematical requirement $n > p$ (dimension of the matrix), a very large number of training spectra should be measured. This might evoke the problem of collinearity among the spectra, that is, the spectra are not any more completely independent among each other – as mathematically necessary. Instead, they might be transformed in each other by linear combinations. Linear dependencies occur, for example, if calibration mixtures are simply diluted without changing the concentration ratios between the constituents. Spectra of such diluted samples contain redundant information, which in turn causes mathematical instabilities. In order to keep p small, one should restrict the calibration to spectral areas that comprise distinct contributions by the components of the mixture. Such decisions demand chemical knowledge as well as sure instinct.

Step 3: Estimation of model parameters.

Using the matrices $\underline{A}$ (measured) and $\underline{C}$ (prepared) (cf. Eq. (53.36)), one can now estimate the calibration matrix $\hat{\underline{P}}$:

$$\hat{\underline{P}} = (\underline{A}^{\mathrm{T}}\underline{A})^{-1}\underline{A}^{\mathrm{T}}\underline{C}. \tag{53.37}$$

Step 4: Validation of the model by statistical means.

The validation of the model is performed in the same way as described for CLS.

Step 5: Application of the model for prediction.

On the basis of a measured spectrum of an unknown (vector $\underline{a}^{\mathrm{T}}$ comprising p absorbance values) and on the calibration matrix, the concentrations of the m components can now be predicted (vector $\underline{c}^{\mathrm{T}}$ comprising m concentration values):

$$\underline{c}^{\mathrm{T}} = \underline{a}^{\mathrm{T}} \times (\underline{A}^{\mathrm{T}}\underline{A})^{-1}\underline{A}^{\mathrm{T}}\underline{C} \tag{53.38}$$

Advantages and disadvantages of inverse LSR are summarized in Table 53.6.

53.3.3.2.3 **PCR (Principal Component Regression)**

- Step 1: Choosing a model.
  The main problem in the above-described ILS is caused by possible multicollinearities between regressed spectra. This problem can be overcome by using a PCA (cf. Section 53.3.2.4) not only for data reduction but to combine the data reduction with elimination of multicollinearities as well. The PC scores computed this way are afterwards used as regressors in the ILS scheme.
- Step 2: Choosing a training set.
  - Full spectra or only spectral ranges showing contributions by the components of interest may be selected.
  - Concentrations of the components of interest have to be known.
  - Estimation of the number of PCs with respect to the chemical components to be calibrated (chemical knowledge!). This estimation based on chemical ground ensures the closest relation between the variance represented in the PCs and the change in concentration of the chemical components of interest.

Table 53.6 Advantages and disadvantages of inverse least squares regression.

	Inverse least squares
Advantages	**Disadvantages**
Relatively fast calculation	Difficulties in choosing the right spectral areas
The calibration model may only be based on knowledge about the interesting components, impurities are not important	Often, a larger number of calibration samples necessary ($n > p$ required for mathematical reasons)
Only one matrix inversion during calibration	Multicollinearity may cause problems
Complex mixtures may be analyzed	Time-consuming calibration

- Step 3: Estimation of model parameters.
  At first we introduce into the PCA (Eq. (53.18)) the equation $\underline{F}^{-1} = \underline{F}^{\mathrm{T}}$, which is based on the orthogonality of $\underline{F}$:

  $$\underline{S} = \underline{A}_{\mathrm{Z}}\underline{F} \tag{53.39}$$

  The second step yields in analogy to ILS ($\underline{B}$ corresponds to $\underline{P}$)

  $$\begin{array}{lcccccc} & \underline{C} = & \underline{S} \cdot & \underline{B} = & \underline{A}_{\mathrm{Z}} \cdot & \underline{F} \cdot & \underline{B} \\ \text{dimensions} & n,m & n,w & w,m & n,p & p,w & w,m \end{array} \tag{53.40}$$

  $\underline{B}$ represents the matrix of coefficients of the regression of the PCA scores (regressors) versus the concentrations of the chemical components (regressands). All other symbols are identical to those already described earlier or in Section 53.3.2.4.
  The estimation of the calibration matrix $\hat{\underline{B}}$ yields

  $$\hat{\underline{B}} = (\underline{S}^{\mathrm{T}}\underline{S})^{-1}\underline{S}^{\mathrm{T}}\underline{C} \tag{53.41}$$

- Step 4: Validation of the model by statistical means.
  The selection of the number of PCs was already described for PCA (Section 53.3.2.4). The validation of the model is effected in analogy to CLS.
- Step 5: Application of the model for prediction.
  The concentrations of all m components of interest (vector $\underline{c}^{\mathrm{T}}$ containing m concentration values) can be predicted on the basis of the measured spectrum of an unknown mixture (vector $\underline{a}^{\mathrm{T}}$ containing p absorbance values), the PC matrix $\underline{F}$, and the calibration matrix $\hat{\underline{B}}$:

  $$\underline{c}^{\mathrm{T}} = \underline{a}^{\mathrm{T}} \cdot \underline{F}\ \hat{\underline{B}} \tag{53.42}$$

  Advantages and disadvantages of PCR are summarized in Table 53.7. During the first step of a PCR, the absorbance matrix $\underline{A}$ is separated into its PCs. The regression of the resulting score matrix $\underline{S}$ on the actual target, the concentration matrix $\underline{C}$, is performed subsequently. The first step may involve a data reduction, which could cause a truncation of information. Truncated information cannot be included anymore in regression on the target. The PLS method described in Section 53.3.3.2.4 avoids this restriction during regression.

53.3.3.2.4 **PLS (Partial Least Squares)**

Step 1: Choosing a model.

The starting point is a model analogous to inverse calibration (ILS)

$$\begin{array}{lccc} & \underline{C} = & \underline{A} \cdot & \underline{B} \\ \text{dimensions} & n,m & n,p & p,m \end{array} \tag{53.43}$$

In real applications, the PLS algorithm may result in a better regression of the absorbance matrix $\underline{A}$ on the concentration matrix $\underline{C}$ because of the approach in Eq. (53.43) and the simultaneous separation of the matrices $\underline{C}$

Table 53.7 Advantages and disadvantages of principal component regression.

	Principal component regression
Advantages	**Disadvantages**
Full spectrum or larger parts of a spectrum may be used	PCA demands much chemical knowledge and sure instinct
Large number of spectral data points leads to noise reduction	Large number of calibration samples necessary
Only information about the components of interest necessary	Large calibration effort necessary
Rather complex mixtures may be analyzed	Selection of nonsignificant principal components or neglect of important principal component possible
Data reduction by PCA	

and $\underline{A}$ (while the criterion of maximal covariance is applied). As in PCA, both the concentration matrix $\underline{C}$ and the absorbance matrix $\underline{A}$ are decomposed into score and loading matrices $\underline{S}_\mathrm{C}$ and $\underline{F}_\mathrm{C}$ or $\underline{S}_\mathrm{A}$ and $\underline{F}_\mathrm{A}$, respectively:

$$\underline{C} = \underline{S}_\mathrm{C} \cdot \underline{F}_\mathrm{C}^\mathrm{T}; \underline{A} = \underline{S}_\mathrm{A} \cdot \underline{F}_\mathrm{A}^\mathrm{T} \tag{53.44}$$

The matrices $\underline{C}$ and $\underline{A}$ are decomposed interdependently with regard to their score matrices $\underline{S}_\mathrm{C}$ and $\underline{S}_\mathrm{A}$, which maintains the close coherence between spectral information ($\underline{A}$) and the component concentration ($\underline{C}$) in the best possible manner.

Step 2: Choosing a training set.

Measurement of a large number n of training spectra, covering as much of the concentration range as possible. The concentrations of the different components have to be varied independently.

Step 3: Estimation of model parameters.

The estimation of the calibration matrix $\hat{\underline{B}}$ yields

$$\hat{\underline{B}} = \hat{\underline{W}}(\underline{F}_\mathrm{A}^\mathrm{T} \hat{\underline{W}})^{-1} \underline{F}_\mathrm{C}^\mathrm{T} \tag{53.45}$$

where $\underline{W}$ represents the weight matrix, which is valued during the decomposition.

Step 4: Validation of the model by statistical means.

The selection of an optimal number of factors (loadings) is a central point in PCR and PLS. In both methods, the so-called prediction residual error sum of squares (PRESS) is calculated.

$$\mathrm{PRESS} = \sum_{i=1}^{n} \sum_{j=1}^{m} (C_{ij} - \hat{C}_{ij})^2 \tag{53.46}$$

where n is the number of training spectra, m the number of components in the mixture, C_{ij} are the prepared and $\hat{C}_{ij}$ the predicted concentrations. After a cross-validation is performed, the prediction error (PRESS) can be depicted versus the number of employed factor in order to select an optimized number of factors.

In Figure 53.12, the minimum for the prediction error is found at six factors by cross-validation. The following factors render the most noise, and their retention would deteriorate the quality of the model. Other validations are performed analogous to CLS.

Step 5: Application of the model for prediction.

The concentrations of all m components of interest (vector $\underline{c}^{\mathrm{T}}$ containing m concentration values) can be predicted on the basis of the measured spectrum of an unknown mixture (vector $\underline{a}^{\mathrm{T}}$ containing p absorbance values) and the calibration matrix $\underline{\hat{B}}$:

$$\underline{c}^{\mathrm{T}} = \underline{a}^{\mathrm{T}}\underline{\hat{B}} \tag{53.47}$$

Advantages and disadvantages of PLS regression are summarized in Table 53.8. A survey of presently available software products for data analysis is given in Table 53.9.

53.3.4
Spectral Imaging

Spectral images are constructed from 3D data sets (x and y are spatial dimensions, z the spectral intensities). These data sets are processed using the same algorithms as described in Section 53.3.2 for qualitative evaluation of spectra and in Section 53.3.3 for quantitative evaluation.

The subsequent discussion of data analysis in spectral imaging will be based on Figure 53.2 as the mathematical algorithms are the same for a small number or for a large number of spectra in the evaluation set. For this reason, the same software products as mentioned in Table 53.9 can be applied to calculate spectral images. This section will focus on qualitative analysis of spectral images. A crucial step

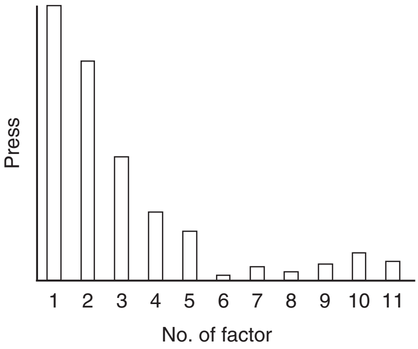

Figure 53.12 Estimation of the number of significant factors by means of the prediction residual error sum of squares (PRESS).

Table 53.8 Advantages and disadvantages of partial least squares regression.

Partial least squares	
Advantages	**Disadvantages**
Full spectra may be used	Abstract model
Most robust calibration	Large number of training spectra necessary
Only information about components of interest necessary	Extended computing time
Very complex mixtures may be analyzed	Determination of the optimal number of factors difficult
Computation of factors and regression in a single step, projection of the features of interest (concentrations) onto the factors superior to PCR	

Table 53.9 Software products for data analysis.

Product	**Manufacturer**	**Methods covered**
GRAMS	Thermo Fisher Scientific Inc.	LSR, PCA, PCR, PLS
PLSplus/IQ Add-on		
MATLAB	MathWorks Inc.	CLS, ILS, PCA, PCR, PLS
Chemometrics Toolbox	Applied Chemometrics Inc.	
PLS_Toolbox	Eigenvector Research Inc.	
Statgraphics	StatPoint Technologies Inc.	Cluster analysis, discriminant analysis, PCA, linear, and nonlinear regression
Statistica	Stat Soft	Cluster analysis, discriminant analysis, PCA, linear, and nonlinear regression
Unscrambler	Camo Software AS	PCA, PCR, PLS

in multivariate data analysis is the preprocessing of the raw spectra. It includes exclusion of nonlinearities of the detector (dead pixels, nonlinear response), elimination of outliers, noise reduction, baseline, and background correction, even a reduction of the data volume without significant loss of information. Details are discussed in Section 5.6.1.

53.3.4.1 Graphical Techniques

Graphical techniques may be regarded as simplest techniques of unsupervised learning. Figure 53.13 shows a false color image of a mixture of polystyrene and polyethene. A thin section of the mixture was measured in transmission. The lateral distribution of polystyrene was evaluated by plotting the height of the characteristic band of the aromatic stretching vibration of polystyrene at 1600 cm^{-1}. The color coding clearly reveals the lateral distribution of polystyrene across the sample. Blue areas indicate low proportions of polystyrene (here, 0.2 absorbance units), red areas high proportions of polystyrene (here, 1.2 absorbance units). The evaluation permits qualitative conclusions – presence or absence of a component, or even semiquantitative conclusions according to the color code. It has to be emphasized that the color code is usually assigned by the software, and the scale mostly differs between images even of the same sample. Cross-comparisons may lead to severe misinterpretations.

Intensity plots as in Figure 53.13 are constructed without much computational effort. Simple evaluation routines do not compensate for particular optical problems within the sample; sometimes they even highlight them. The main origin of these optical problems is the heterogeneity of all samples to be imaged; homogeneous samples need not be imaged. Heterogeneous samples usually exhibit different

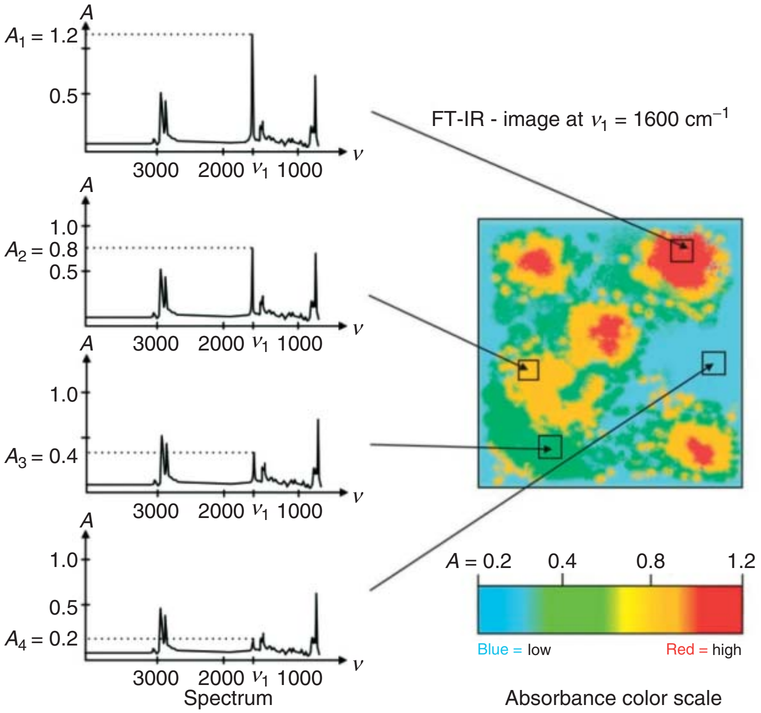

Figure 53.13 Color-coded FT-IR intensity image of a mixture of polystyrene and polyethene calculated from the height of the characteristic band at 1600 cm^{-1} wave numbers.

refractive indices according to the changes in their composition, or the sample thickness may change differently between regions of varying properties. The impact of varying sample thickness may be reduced by calculating intensity ratios instead of simple band heights as in Figure 53.13. Different refractive indices across the sample area require much more elaborated techniques to be dealt with.

53.3.4.2 Chemometric Techniques

In the past, the segmentation of spectroscopic images into regions of different properties was restricted both by the limited availability of dedicated chemometric software packages and by the amount of RAM installed in computer clusters. Both restrictions were significantly lifted during the past decade. Nowadays, large RAMs permit the joint evaluation of huge data sets. New algorithms become available or are adopted from other areas of science. This chapter can only refer to the most important of the algorithms listed in Table 53.2. More details are found in [21]. Application areas for qualitative data analysis for spectral imaging are summarized in Table 53.10 for the techniques of unsupervised learning, and in Table 53.11 for the techniques of supervised learning.

Table 53.10 Application areas for techniques of unsupervised learning.

Technique	Application area
Graphical techniques	Simple and clear Always applicable for structuring and reduction of data sets Particularly suited for explorative data analysis
Cluster analysis	Clusters within the images well visualized Hierarchical cluster analysis Well suited for explorative data analysis Nonhierarchical cluster analyze (e.g., k-means clustering) Distribution of spectral features between independent clusters Problem: distinction between local and global optima
Principal component analysis (PCA)	One of the most powerful techniques for explorative data analysis Can be used for data preprocessing, in particular for reduction and structuring of the data set Can be used in case of complex data sets with correlated variables Provides information about the distribution of variance within spectral features Applied after preceding mean-centering or standardization of the spectra (Section 53.2) Various visualization tools available

Table 53.11 Application areas for techniques of supervised learning.

Technique	Application area
Discriminant analysis	Algorithms of linear discriminant analysis (LDA) used to describe classes Variance between objects in the same class is minimized while variance between class centers is maximized Classification in case of larger deviation from the required statistical equality of the covariance matrices between classes; for this reason not capable for complex data structures
SIMCA	Modeling of complex and heterogeneous data structures possible A separate PC model developed for every class of objects, hence optimal reduction of dimensionality Good adaptation to enlarged data sets
k-nearest neighbor (KNN technnique)	Simple classification technique Optimum number of neighbors k mostly detectable by estimation of the minimum total number of misclassifications using resubstitution and leave-one-out approaches Particularly fast for two-class systems

PCA (Section 53.3.2.4) is one of the most powerful techniques to analyze spectral imaging data. The subsequent example illustrates how the distribution of a minor inorganic component in a polypropylene matrix can be determined and, moreover, how the chemical nature of the minor component can be identified. The size of the scanned area is 270 μm × 270 μm. The diffraction limited lateral resolution depends partly on the quality of the optical system of the spectrometer. A resolution of about 10 μm is considered reasonable for investigations at 1000 cm^{-1} (wavelength 10 μm). Typical technical details for FT-IR imaging (pixel numbers, measurement times, computation) are given in Section 5.6. Seven PCs were calculated, they cover 97% of the total variance in the data set. The first two PCs can be assigned to the polymer matrix. The discussion here shall be focused on the minor inorganic component. Figure 53.14 shows the score map and the loadings for the third PC, which comprises 11% of the total variance. The loading map provides information about the chemical nature of this constituent, while the score map illustrates its local distribution. As PCs are based on variance considerations and not on chemical analysis, a constituent according to PCA may comprise more than one chemical compound. The loadings of the third PC in Figure 53.14a reveal a feature around 1000 cm^{-1}, which can clearly be assigned to the antisymmetric stretching of the silicate group. High-score values (red to yellow in Figure 53.14b) reveal the location of the silicate in the polymer matrix.

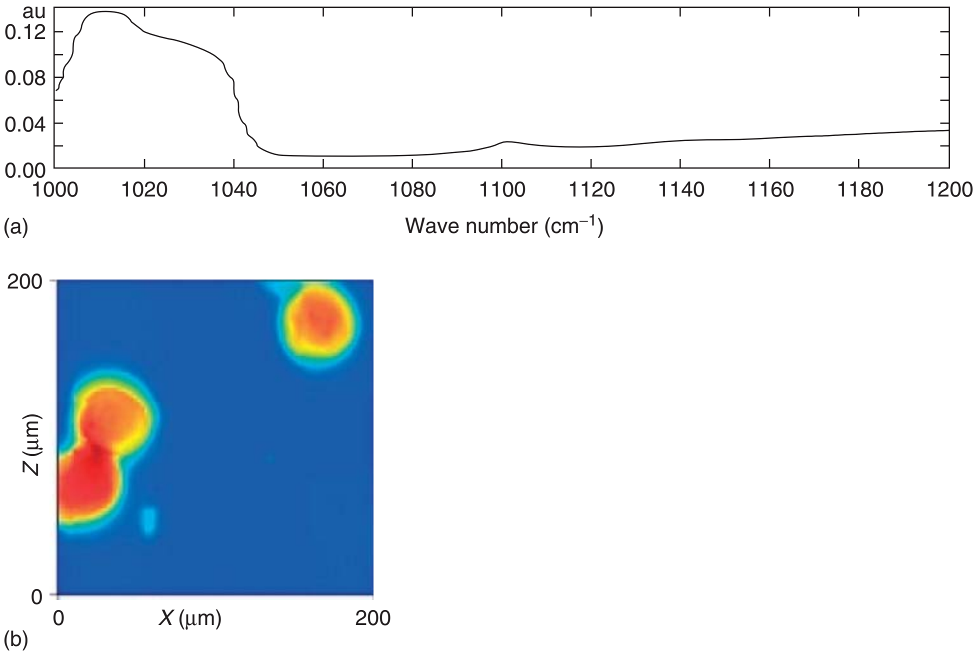

Figure 53.14 PCA of a polymer sample containing an inorganic powder. (a) The loadings of the third PC indicate silicate. (b) The score map reveals the location of the silicate in the matrix (red to yellow: high scores indicate silicate spots, blue: low scores indicate no silicate).

54
Nuclear Magnetic Resonance Spectroscopy

Wolfgang Robien

54.1
Introduction

Structure elucidation of organic compounds is mainly based on different types of spectroscopic techniques. Among the methods available, NMR spectroscopy contributes a large amount of information; in many cases, the obtained spectral data are often so rich in structural information content that the constitution, configuration, and the conformation of the unknown can be derived exclusively by the interpretation of such spectra. NMR spectroscopy is, in comparison to other techniques, an insensitive method, leading to a low signal-to-noise ratio of the obtained spectra. This disadvantage has been circumvented by the introduction of the principle of Fourier transformation, leading to much shorter data acquisition times and the possibility of observing more insensitive nuclei than protons and therefore getting more detailed information about the sample under investigation. During the past three decades, a great number of sophisticated pulse techniques have been developed, which allow – together with the use of high-field instrumentation – the investigation of extremely small amounts of samples and, in addition, to get more complete information about them. Especially the tremendous improvement based on two(three)-dimensional methods opened up a new horizon in structure elucidation [1]. For all these reasons, the earlier bottleneck of data acquisition as the most time-consuming step has been dramatically shifted to data interpretation – especially with the background of combinatorial chemistry and LC (liquid chromatography)-NMR coupling.

Structure elucidation of a complex molecule from its spectral data without software support is a challenging and time-consuming procedure, which can only be done by an expert in this field. In order to supply the expert with the necessary information during the spectrum interpretation and structure generation procedure, a large number of computer programs [2–4] and data collections have been developed. A good entry point, collecting links to many chemical shift tables, research groups, software vendors, and database producers in the field of NMR spectroscopy, is the web site spectroscopyNOW.com [5].

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

54.2
Comparison of NMR Spectroscopy with IR and MS

In order to understand the range of possibilities in computer-assisted structure elucidation methods, it is essential to compare the different spectroscopic techniques with respect to their information content and their suitability for computer-assisted handling of their data. High-resolution mass spectral data can lead to the molecular formula, which is a necessary parameter for most interpretation and isomer generation programs. MS is also well suited to detect certain functional groups, which is also true for IR. The main disadvantage of MS is the extremely high dependence of the spectral pattern on the ionization technique applied; this effect can be used to get more specific information about the unknown sample. Another reason that MS gives usually only supporting information during the structure elucidation process is the complex, and yet only partially understandable, correlation between spectral data and structural properties resulting in the absence of reliable methods to predict MS spectra for a given structure. Some work about this topic has been published [6], but the techniques developed were never routinely applied. From IR spectra, a large variety of functional groups and substitution patterns can be derived, but the correlation between spectral behavior and structural property is not as well defined as in NMR spectroscopy. For all these reasons, MS and IR are not well suited to rank a few hundreds of structural proposals as created by an isomer generation program, which is the usual case during computer-assisted structure elucidation, especially when dealing with molecules having a few noncarbon atoms that are only indirectly visible via the chemical shift values of the attached carbons.

NMR spectroscopy is an insensitive method compared to IR and MS, but it has been dramatically improved since its beginning. In organic chemistry, usually ^{1}H- and ^{13}C-NMR spectroscopy is routinely applied for the purpose of structure elucidation. The total shift range for protons spans roughly 12 ppm in typical organic compounds compared to 250 ppm for carbon. Solvent effects on protons are usually more pronounced, an effect (ASIS – aromatic solvent-induced shift) which is also systematically used in structure elucidation, leading to the disadvantage that spectrum prediction by computer programs becomes more complicated. The comparison of a query spectrum against spectra in a reference library is also a more complex task for ^{1}H-NMR spectra than for ^{13}C-NMR spectra because of the field dependence of the spectral patterns. In carbon NMR spectroscopy, the couplings between carbons at natural abundance are usually invisible and the couplings to protons are artificially suppressed by decoupling techniques, leading to simplified spectral patterns. Furthermore, carbon NMR spectroscopy allows direct insight into the skeleton of an organic sample. From all these above-discussed reasons, it can be concluded that ^{13}C-NMR spectroscopy is the method of choice for computer-assisted structure elucidation having the disadvantage of dealing with an insensitive nucleus, which is by a factor 5760 less sensitive than protons are.

54.3
Methods in NMR Spectroscopy

The advantage of NMR spectroscopy is the large number of experimental techniques that allow one to derive a very specific piece of information about the unknown chemical structure. The parameters usually extracted from an NMR spectrum are as follows:

- Chemical shift values
- Signal intensities
- Coupling constants.

The chemical shift value reflects the electron density and therefore gives information about hybridization and the environment of the corresponding nucleus. The signal intensity is proportional to the number of nuclei and therefore gives information about symmetry. The coupling constants give information about spin systems and, therefore, insight into the relationship between different nuclei. Application of additional techniques allows determination of the signal multiplicities in ^{13}C-NMR spectra (e.g., APT = attached proton test; DEPT = distortionless enhancement by polarization transfer) and getting more insight into the coupling network. The most prominent two-dimensional techniques used are as follows:

- *H–H correlation*: COSY (correlated spectroscopy)
- *C–H correlation over one bond*: HMQC (heteronuclear multiple quantum coherence), HSQC (heteronuclear single quantum coherence)
- *C–H correlation over multiple bonds*: HMBC (heteronuclear multiple bond correlation), COLOCs (correlation by long-range couplings)
- *C–C correlation*: INADEQUATE (incredible natural abundance double quantum transfer experiment).

Chemical shift values are the main information source for spectral similarity searches, whereas the correlation between spectral lines and the corresponding structural environment is the basis for spectrum prediction programs. The information derived from the correlation techniques is used by interpretation programs to prove the presence of certain structural fragments from a given set of correlation signals. These correlation signals are also used as distance constraints – in terms of the number of bonds between two coupled nuclei – in the case of ambiguity, which occurs in HMBC-type spectra frequently, and later on during the structure generation process.

54.4
Spectral Similarity Search Techniques

One well-established method used in computer-assisted structure elucidation is the comparison of the spectrum of the unknown against a reference data collection. The largest databases available hold, at the moment, some 500 000 spectra of the same method corresponding to roughly 1% of the known chemical structures. The consequence for the design of the algorithms is that the procedure used for comparison must be able not only to detect the identical spectral pattern in any case but it must also be able to retrieve similar patterns, which usually gives a lot of information about partial structures and typical skeletons contained in the unknown.

The basic algorithms for spectral comparison use the Euclidian distance between corresponding data points when comparing curves or a given deviation when comparing peak lists in order to select compounds having similar resonances. The procedure for comparing peak lists can only be applied sequentially in some computer programs, leading to the unwanted effect that similar structures can be excluded when starting with an uncommon chemical shift value. The better approach handles the complete peak list of the unknown at the same time and allows afterwards the selection of lines that must be present in the reference spectrum. Different implementations of this basic algorithm allow the user to control the number of lines present in the reference spectrum compared to the number of lines available in the query spectrum, allowing to analyze the reference structure with respect to structural fragments present in the unknown or to derive components within a mixture.

The disadvantage of such a type of similarity search based on the comparison of a peak list against the reference data collection on a line-by-line basis is that regions without any lines are completely neglected. Another approach is the SAHO (spectral appearance in hierarchical order) search method, which also takes into account regions without lines [7]. The typical range of the chemical shift values is divided into smaller ranges (typically 10–15 ppm for carbon) and the number of signals within such a region is counted. In order to achieve a higher selectivity, different multiplicities (either odd/even or singlet, doublet, triplet, and quartet) can be counted separately, leading to an array of numbers describing the spectral pattern very well. The same procedure is applied to the reference data collection and the resulting arrays are stored. The comparison of the pattern of the unknown against the reference patterns is extremely fast because only a small amount of data must be handled (typically 8 bytes per spectrum), leading to a speed of 10^6–10^7 comparisons per second. This algorithm is an ideal tool to deduce at least the compound class of the unknown under the assumption that the reference data collection contains examples of similar structures. In any case, it should be mentioned that the results from the similarity search based on line-by-line comparison and the SAHO method are usually complementary and the user is strongly advised to apply both methods when available. These spectral similarity search techniques are extremely fast and should therefore be applied first during the structure elucidation process in order to avoid more time-consuming techniques for solving trivial problems. Such a system based on the predicted ^{13}C-NMR spectra for the approximately 16 million structures available from PUBCHEM has been built recently [8, 9].

54.5
Spectrum Estimation Techniques

From the reasons given in the introduction, ^{13}C-NMR spectrum prediction is more popular than ^{1}H-NMR spectrum prediction; besides, some programs are known to perform at a reasonable level of precision [10–12]. The early work of collecting chemical shift values was severely influenced by the idea of predicting spectra for a given structure. The first very simple, but still useful approach of increment rules has been implemented into a large variety of computer programs. The central concept of this method is to use a parent structure (e.g., benzene [13]) and to start with this chemical shift value in the calculation. Increments are derived from the difference between the chemical shift value of the parent compound and the corresponding chemical shift value of the monosubstituted derivatives. Polysubstituted compounds are treated as ‘‘overlapping’’ monosubstituted derivatives and the tabulated increments are simply added to the base value of the parent compound, neglecting therefore any substituent interaction. More sophisticated systems allow for additional correction parameters, leading to improved results [14, 15]. The advantages of this method are the simple principle behind and the good results for certain compound classes, where other methods tend to fail (e.g., polysubstituted benzenes). One main disadvantage is that only a limited number of increment tables for a limited range of parent compounds are available in the literature.

A more elegant method has been developed to make use of all compounds in a large reference data collection. The increment table for a certain query structure is generated on the fly and therefore all reference spectra contribute to the solution of a particular problem. This method automatically includes substituent interactions if this information is available within the reference data. Furthermore, a polysubstituted compound can be generated by formally overlapping only monosubstituted derivatives (as with the basic increment method), but also by selecting, for example, di- or trisubstituted derivatives allowing different calculation pathways, leading to an expectation range for the signals of the query structure. The disadvantage of this method is the long computing time and the complex algorithms behind using partial structure search technologies [16].

A different approach is called HOSE code [17] (hierarchically ordered spherical description of environments) and is based on the extremely well-pronounced correlation between a ^{13}C chemical shift value and the corresponding carbon-centered substructural unit. The HOSE-code starts at a carbon atom (focus atom) and describes its hybridization and multiplicity. The neighbored atoms are described in the same manner, taking into account their atom type, hybridizations, number of directly bound hydrogens, and the type of bonds between them. This scheme is applied to the first neighbors of the focus atom, then to the second neighbors, and so on, leading to a spherical description of the structural environment. The atoms within each sphere of this carbon-centered fragment are sorted in a canonical way, giving a structure descriptor that is correlated to the known chemical shift value of its focus atom. This procedure is repeated for any carbon of any reference structure available and stored on a file during database creation. The query structure is analyzed in the same way and the fragments generated are compared against the corresponding file of the database. Chemical shift values of coincident structure descriptors are taken for the calculation of the mean value, the total shift range, and the standard deviation. The number of coincident spheres between the reference structures and the query structure determines the precision of the obtained result. For sp^3-carbons, at least three spheres (γ-effects) are necessary; in the case of conjugated systems, four spheres usually give reliable results (effects of para-substituents). This basic principle has been implemented in a very similar way into several computer programs. In addition, solvent-induced effects can be added, leading to an improved spectrum prediction capability. The HOSE-code was designed to handle a two-dimensional structure representation; therefore, stereochemical effects were ignored. Consequently, it was necessary to introduce a further extension that is able to describe steric interactions, leading to an extreme improvement of the precision of the spectral prediction [18, 19]. A further approach for introducing stereochemical information is the CAST-code [20]; in commercially available prediction programs, stereochemical information can be handled by NMRPredict [19] and in a newer release by ACD-CNMR-Predictor [21].

A totally different approach is the utilization of neural network technologies as proposed by several authors [22–24]. The intellectual challenge of designing a neural network is the selection of the structure descriptors in order to reflect the correlation between structural and spectral properties in an optimal manner. Network optimization is a time-consuming task that must be done only once. The application of the trained network to a given structure is extremely fast and the prediction of the chemical shift values to be expected is performed within milliseconds, thereby having an excellent tool for spectrum simulation and subsequent ranking of a large list of candidate structures.

54.6
Spectrum Prediction – Quality Consideration

There is a strong relationship between the quality of the database, the level of sophistication of the algorithms used, and the results obtained. General databases are usually built from literature data; despite most of the assignments given in the public domain literature being correct, a large number of either wrong structures and/or misassignments are known [25]. Even some very common functional groups (e.g., tosylate) are known to be systematically assigned in two different ways. The assignment simply depends on the literature used for reference purpose, thus propagating the wrong assignment when using the wrong reference without checking. These data may appear later in some databases and will be used for further prediction, leading to unreliable results. This type of error can be easily detected by analyzing a large reference collection by means of statistical methods and should be frequently applied by a database administrator. A detailed analysis of the quality of the reference data within the NMRShiftDB collection has been published [26], leading to an intense effort to correct these errors, which has been described shortly afterwards [27].

As stated, spectrum prediction is based on the correlation between structural environments and their corresponding chemical shift values. In order to simulate spectra by the methods described, adequate reference material is necessary, which is not given in some journals – in frequent cases, instead of assignments only peak lists (even without multiplicity information) as given by the spectrometer software have been published, diluting the basis for spectrum prediction of new classes of compounds. During the ongoing efforts of correcting data within the CSEARCH and SPECINFO collections, a list of literature references that needed massive reassignments and/or correction of chemical structures has been published [28].

In order to cover the enormous structural diversity, it is necessary to have the most diverse database available. On the other hand, it is necessary to fill gaps within the area of interest with own data. Usually a very small, but specifically dedicated database is much more powerful for solving a limited range of problems than a general database.

It is absolutely essential to have access to all parameters influencing the spectral simulation process; furthermore, the typical parameters obtained as results (mean value, range, deviation) are not sufficient to evaluate the results, because in many cases a visual inspection of the distribution might be necessary in order to detect outliers or to understand stereochemical effects. The access to the original data contributing to a specific result must be possible in order to clarify any ambiguity.

Spectrum prediction is a frequently used technique during the structure elucidation process, but a detailed inspection of the results is necessary. Some programs offer the possibility of using different algorithms for spectrum prediction (usually HOSE-code technology and neural networks) – in such a situation, both methods should be applied and the obtained results should be carefully compared [18]. At least in the case of different predictions, a further critical evaluation of the result should be an obligation.

54.7
Spectrum Prediction and Quality Control – Examples

Spectrum prediction is an extremely decisive tool for verification of structural proposals and therefore the implementation of the algorithms and the quality of the reference database used cannot be discussed independently, because the obtained results are strongly connected to both parameters. The most severe limitation of the HOSE-code is the availability of sufficient and correct reference material within the database, because a description of the query structure at a lower number of spheres dramatically influences the predicted chemical shift values. In Figure 54.1, an assignment error on carbons 11 and 12 has been *artificially introduced* into the correct assignment as given in the literature in order to demonstrate the effect of accessing wrong entries within the reference database. The predicted spectrum, as given in Figure 54.2 using HOSE-code technology with five coincident spheres (= all neighbors up to five bonds), estimates 93.7 and 94.3 ppm, respectively, for

carbons 11 and 12 together with an expectation range of some 60 ppm, which is totally useless for the spectroscopist. Estimation with two coincident spheres gives, in this case, the better mean values for carbon 11 and 12, again with extremely large expectation ranges as shown in Figure 54.3. A comparison of the estimated values at 1–5 coincident spheres, as given in Figure 54.4, demonstrates that there is only a small change in the mean values when increasing the number of coincident spheres, except for carbons 11 and 12 for which wrong reference material contributes heavily to the mean values. From this example, it can be concluded that the HOSE-code method is very sensitive to wrong assignments, leading to low-quality spectrum predictions in case of wrong reference material. Neural network technology is far less sensitive to assignment errors – despite the fact that the wrong data set was used during training – reasonable chemical shift values are predicted, as given in Figure 54.5.

Another important feature of spectrum prediction is the utilization of stereochemical information. Stereochemical effects may induce effects of up to about 30 ppm in typical organic compounds. The four isomeric tricyclo-octane derivatives, as given in Figure 54.6, demonstrate this clearly, especially at C_8 with a chemical shift range starting at 23 ppm in the exo, exo-derivative and going up to 53 ppm in the endo,endo-configurated isomer. The comparison of the corresponding carbon NMR spectra in Figure 54.7 shows these large increments were caused by steric interaction.

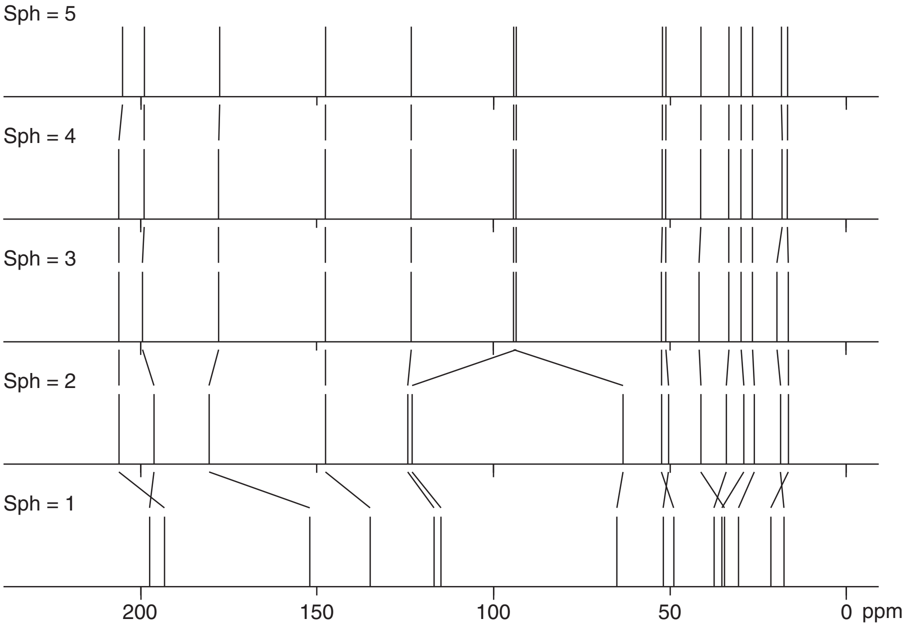

Figure 54.4 Dependence of the predicted chemical shift values from the number of coincident spheres given on the left-hand side. The large change when increasing the number of coincident spheres from two to three is worth a more detailed investigation of the reference material used.

Figure 54.8 Spectrum prediction of podocarpane using HOSE-code technology with stereochemical information [18]. The chemical shift values of the methyl groups located at position 4 are predicted in good agreement with the literature data.

Implementation of steric interactions into the HOSE-code and into neural networks improves spectrum prediction dramatically, as can be seen from the podocarpane example in Figure 54.8. The diastereotopic methyl groups located at C_4 can be well predicted – 21.7 ppm for the axial and 33.4 ppm for the equatorial methyl group – which is in excellent agreement with the values found in the literature. The separation can be easily understood when inspecting the distribution of the entries contributing to the predicted values as given in Figure 54.9. A total number of 34

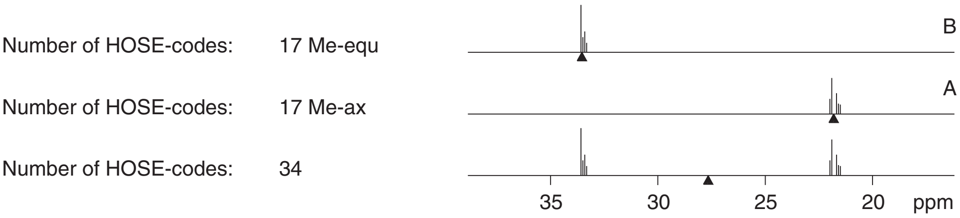

Figure 54.9 Distribution analysis of the entries contributing to the estimation of the methyl groups at position 4 of podocarpane. Bottom trace: stereochemical effects are ignored leading to a useless mean value around 28 ppm (small triangle); a total number of 34 reference data contribute to this mean value. Trace A and B: utilization of stereochemical interactions separates the 34 reference data into two distinct sets of chemical shift values leading to a correct prediction for the axial and equatorial methyl group.

entries selected from the reference database predict a useless mean value at 28 ppm for *both methyl groups* when using the structural descriptors from the original HOSE-code disregarding the stereochemical effects. The introduction of the number of 1,3-diaxial interactions divides these 34 reference data into two groups of shift values, estimating a chemical shift value of 21.7 ppm for the axial methyl group and 33.4 ppm for the equatorial one, which is shown in traces A and B of Figure 54.9.

54.8
Spectrum Interpretation and Isomer Generation

Isomer generation is the well-defined task to generate, exhaustively, and without redundancy, all possible chemical structures that are consistent with a given set of constraints [30–32]. This combinatorial problem itself is optimally suited for computer application and this definition seems to be ready for easy implementation into a piece of computer software. A more detailed look into the background of isomer generation shows immediately the problems associated with this task. The enormous number of possible candidate structures when starting from only the molecular formula can be seen in Table 54.1.

Table 54.1 Number of possible isomers (without stereochemistry) depending on the molecular formula and constraints derived from NMR experiments.

Molecular formula	Additional information	Number of possible isomers [33]
$C_{10}H_{22}$	—	75
$C_{15}H_{32}$	—	4 347
$C_{20}H_{42}$	—	366 319
$C_{10}H_{22}$	—	75
$C_{10}H_{20}$	—	852
$C_{10}H_{18}$	—	5 568
$C_{10}H_{16}$	—	24 938
$C_{10}H_{14}$	—	81 909
$C_{10}H_{12}$	—	201 578
$C_{10}H_{10}$	—	369 067
$C_{10}H_{10}$	—	369 067
$C_{10}H_{10}O$	—	7 288 733
$C_{10}H_{10}O_2$	—	79 402 190
$C_{10}H_{10}O_2$	—	79 402 190
$C_{10}H_{10}O_2$	Signal multiplicity (4S, 3D, 2T, 1Q)	10 370 392
$C_{10}H_{10}O_2$	Carbon hybridization ($3sp^3$, $5sp^2$, 2sp)	240 751
$C_{10}H_{10}O_2$	Signal multiplicity and hybridization as stated	38 353

Even a small molecular formula around C_{10} produces a large number of possible chemical structures. The introduction of one heteroatom and/or a degree of unsaturation increases the size of the problem dramatically. The molecular formulae chosen in Table 54.1 represent comparably small compounds, far away from typical applications in modern organic chemistry. The main problem in making structure generation programs a common routine tool is the necessity to implement all available pieces of information from the most important spectroscopic techniques at the earliest possible step in order to avoid the ''combinatorial explosion'' and therefore long computing times during the structure generation process itself and during the necessary postprocessing of the list of candidate structures. From Table 54.1 it can be seen that a powerful spectrum interpretation step is necessary even for a small molecular formula. The example $C_{10}H_{10}$ gives 369 067 isomers when using only the molecular formula without further constraints. The introduction of one oxygen increases the size of the problem by a factor of 20, a further oxygen leads to roughly 80 millions of possible isomers. The utilization of multiplicity information, which can be easily derived from DEPT spectra, reduces the size of this particular problem by nearly one order of magnitude. In addition, the use of hybridization information, as selected in Table 54.1 [34], reduces the number of possible isomers to 38 353 candidate structures. The determination of the multiplicity can be done by experimental techniques (usually DEPT) and is therefore a piece of information that is very secure. On the other hand, the determination of the hybridization is based on the interpretation of chemical shift value together with further supporting information (e.g., $^1J_{CH}$ couplings); therefore, some ambiguity might remain, especially in the region around 100 ppm where sp^3, sp^2, and sp-carbon atoms have resonance lines.

The process of structure generation is a well-defined task based on graph theory, whereas spectrum interpretation – the translation from the spectral information into structural constraints – is based on heuristics. Even the selection of the hybridization state of a carbon atom cannot be performed with absolute security from its chemical shift value and some further information. A much more complex situation is encountered when deriving substructural fragments from spectral data – the interpretation of the data leads to a large amount of alternative possibilities for substructural units. This feature must be taken into account during the isomer generation process, making the programs more complex and their speed slower.

There are two possible extreme situations that should be analyzed in further detail: the first approach uses a very detailed interpretation process based on a library of larger fragments as done, for example, by SPECSOLV [35], which makes structure generation working fast with the disadvantage that only a part of the possible candidate structure compatible with the given constraints will be obtained – a situation that is less useful for natural product chemistry dealing with new classes of compounds. The other extreme approach is to take into account only absolutely safe pieces of information, for example, signal multiplicities which can be determined experimentally. This situation uses only a very limited set of constraints for the structure generation process, leading to an incredible number of candidates for further processing. In any case, ambiguity (e.g., with valencies and hybridizations) must be handled by the isomer generator, which makes this tool much more complex. Usually, there is a tight connection between the interpretation and the isomer generation part of such systems.

54.8.1
Utilization of 2D-NMR Data

A new horizon was introduced with the popularity of two-dimensional NMR methods giving information about coupled-spin systems, and, therefore, distance information (in terms of intervening bonds between coupled nuclei). The most useful experiments for organic structure elucidation are the methods for H–H-, C–H-, and C–C-correlation, the detailed experimental conditions (e.g., gradient-enhanced, normal-reverse detection) do not change the basic principle of these methods for computer application. The general information is always that correlation signals are translated into distance information between two atoms, which will be used either by the interpretation process directly leading to substructural units or in case of ambiguity (distance over 2 to n bonds) as a constraint during the structure generation process in order to exclude certain combinations of the substructural fragments. The COSY-type spectra give information about H–H correlations over two (geminal), three (vicinal), and four (allylic, W-coupling) bonds, but in many systems long-range couplings over more than four bonds are known, leading again to some ambiguity. The case of a $^2J_{HH}$ coupling can be easily excluded by a heteronuclear correlation experiment. C–H-correlation experiments over one bond (HMQC, HSQC) are able to detect exclusively this type of connections because $^1J_{CH}$-couplings are much larger than any $^nJ_{CH}$-coupling. Long-range correlation techniques have to deal with two problems. The first one is the detection of artifacts from $^1J_{CH}$-correlations, which can be easily excluded from HMQC-type spectra. The second problem is a much more severe one based on the fact that long-range J_{CH} couplings are of similar size, especially $^2J_{CH}$ and $^3J_{CH}$ cannot be distinguished in many cases, prohibiting the differentiation between these two distances and leading to an increased computing time during the structure generation process and in many cases to a larger set of candidate structures produced. Frequently, signals corresponding to correlations over four to six bonds have also been observed, adding a further order of magnitude to the complexity of structure generation, whereas ignoring this possibility leads to wrong structure proposals. In addition, severe signal overlap may also increase the difficulties during the spectrum interpretation process [36]. C–C correlation techniques are well suited for computer-assisted structure elucidation but they have the disadvantage of low sensitivity. Another well-known concept to restrict the number of generated candidate structures is to use a list of forbidden substructures within the candidates. This option should also be used with extreme care, because exotic structures – such as highly strained or unexpected heterocyclic systems – will always be excluded [37].

54.8.2
Examples of Isomer Generator Programs

From the scope of the problem of structure generation it can be seen that there is a demand for spectrum interpretation programs that work in a very carefully designed way, allowing the user access to all constraints and therefore selecting the correct set of constraints from the given experimental data. The basic idea of spectrum interpretation of NMR data is to correlate a certain chemical shift value with a set of functional groups used as building blocks for subsequent structure generation. In order to improve this basic idea of using a single line, a complete subspectrum can be correlated with a set of larger substructural fragments, leading to higher selectivity during the interpretation process and therefore faster post-processing. The approaches known are working either with rule-based correlation tables (e.g., CHEMICS [38], DENDRAL [39], DARC [40]), or HOSE-code technology (SPECSOLV [35]); ACFs (atom-centered fragments) are used in SESAMI [41, 42] and EPIOS [43], three-atom fragments are selected in CSEARCH [44, 45]. The basic principle behind these technologies remains always the efficient correlation between spectral and structural property; in any case, these methods become slower when using smaller fragments or they generate only partial solutions when starting from a too specific set of fragments. The latter effect depends also extremely on the database used for the generation of the subspectra–substructure correlation tables. In any case, a high structural diversity within the reference database is obligatory.

54.9
Ranking of Candidate Structures

The usual case when applying an interpretation/isomer generation program to a real-world structure elucidation problem is not to obtain a single structural proposal to a specific set of constraints. Frequently, a list of possible candidate structures will be generated consisting either of only a few proposals or maybe a few thousands of proposals depending on the number of constraints given. Therefore, a ranking process based on spectrum prediction [45] is necessary to select proposals of higher probability. For ^{1}H- and ^{13}C-NMR spectra, well-established methods are available, which allow to select a set of most probable candidate structures. It is strongly recommended not only to use a single best solution but also useful alternatives should be included for further investigation. Isomer generator programs produce also very uncommon structures, which are not well represented by databases used for spectrum prediction purposes, leading to a biased evaluation of the hit list and to the effect that more common structures might be ranked better than uncommon ones. Spectrum prediction based on a database having a high degree of structural diversity is a fast and reliable method that can be applied to a hit list of a few thousands of chemical structures within a reasonable time. In the case that more structures have been generated, the set of constraints should be refined and/or additional experimental data should be collected.

54.10
NMR Data Collections on the Internet

The incredible development of Web-applications during the past decade has led to an enormous amount of spectroscopic information available on the Internet. A few examples are mentioned here – knowing that every list of such applications might be outdated soon. One of the first examples was the SDBS system [46] holding approximately 108 000 spectra coming from approximately 33 000 compounds, with the advantage of summarizing data for different methods (NMR, MS, IR, Raman, ESR) but having the disadvantage that spectrum prediction is not possible. Another approach based on the ''Open Source – Open Data'' idea was ''NMRShiftDB'' [47], where the community was invited to contribute to the system or, in other words, ''to build their own system.'' At the moment, approximately 25 000 CNMR spectra are available, the greatest part coming from the DKFZ collection and from the in-house database of the University of Mainz; the contribution of the community consists only of a few thousands of spectra. A similar approach has been started on CHEMSPIDER [48], leading to a few hundreds of spectra. The advantage of the aforementioned systems is clearly their availability free-of-charge. Commercial systems such as KnowItAll U [49] and NMRPredict [50, 51] hold up to approximately half a million of NMR data, which leads to an improved structural diversity.

54.11
Conclusions

For the synthetic organic chemist, spectrum simulation in order to verify a structural proposal is the most decisive task; in natural product chemistry, the starting point is usually a spectral similarity search using the experimental spectrum of the unknown. Both methods are extremely fast and can be done automatically immediately after the measurement of the one-dimensional routine spectra. When these basic methods give no solution, usually further spectroscopic experiments are performed giving more detailed information about the unknown sample. Spectrum interpretation and the subsequent isomer generation are mainly successful when a large amount of additional information is available. The most important pieces of information are the presence/absence of certain functional groups and the efficient use of distance constraints as derived from two-dimensional correlation spectroscopy. This information usually allows one to deduce the constitution of an organic compound; in order to determine the configuration and conformation, a more specialized set of tools is available. Many of these techniques – either experimental or computational methods – have been developed to deal with specific classes of compounds, especially with biopolymers [52]. The typical application field of the computer techniques described in this chapter is structure elucidation of organic compounds up to C_{50}. Many steps during the structure elucidation process can be done – or at least simplified and accelerated – by appropriate computational technologies, but the results must be critically evaluated by the expert. A large variety of algorithms and more or less integrated systems have been described in the literature and the field of computer-assisted structure elucidation is dynamically evolving. Also, numerous tools are commercially available and can support the chemist during the structure elucidation process – a critical evaluation of these tools with specific examples from the own field of application is strongly advised.

Mass Spectrometry

Wolfgang Werther

55.1
Introduction

Computational data treatment plays an essential role in the world of mass spectrometry (MS). Mass spectrometers have been connected to computers very early, enabling an efficient data acquisition and instrument control. The complex data conversion of measured ion currents behind the user-friendly representations of mass spectra is not fully known to the current users of MS.

However, the main focus of this contribution is the software and database assistance in the interpretation of mass spectra, especially the search for chemical structure information in mass spectral data. Because of the high amounts of measured data, interpretation is often the bottleneck in present day analytical processes.

Complexity of tasks and the requirements for algorithms and computing power have increased since the time of measuring only singly charged nominal mass spectra created by electron impact (EI) ionization in a mass range up to 1000 Da. Electrospray ionization (ESI) produces ions with multiple charges, especially for biomolecules such as proteins and nucleic acids. The mass range has been extremely extended to about a million Dalton. High-resolution MS and tandem MS require for all applications (e.g., databases, library searches, or isotope pattern calculations) new or at least adapted conceptions.

The aim of this chapter is to describe the most important fields of data treatment in MS, where computer-assisted approaches are applied. Principles, strategies, and outcomes of these approaches will be briefly explained.

Some interesting topics cannot be covered, for example, the computer treatment of multiple charged peaks from electrospray mass spectra. Furthermore, the wide field of computer applications for mass spectral data in bio-science is not fully addressed, but the description of the methods used in protein MS should be a first entry.

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

55.2
Databases

Three different types of databases used for evaluation of mass spectral data are discussed:

- *Mass spectral databases*: containing mass spectra of compounds.
- *Fragmentation databases*: containing mass spectral fragmentation reactions described in literature.
- *Structure databases*: containing chemical structure descriptions of compounds (e.g., protein sequence databases) – the mass spectral information is derived mathematically from the structures.

The beginning of mass spectra collection of organic compounds in computerized databases was in the early 1960s [1]. In this period EI ionization of gas-phase molecules was dominating in MS and powerful ionization methods for liquid and solid phases were far from being realized. Therefore, the first large mass spectral databases contained only EI mass spectra. Up to now, collections of EI mass spectra dominate the field of large and commercially available databases; the reasons are discussed later.

The typical data structure of a mass spectral database entry is as follows: of course, a database entry must contain the mass spectrum, which is a list of pairs of numbers: mass/charge (m/z) and peak intensity. In EI databases, m/z information is mostly stored as an integer value. For compounds with a molecular weight above 400 Da real numbers for the m/z values would be desirable, for storage of accurate masses this is a necessity. Molecular weights above 400 Da are important in liquid- or solid-phase MS, especially of biological and pharmaceutical molecules.

For chemical identification, a database entry must contain the name of the molecule, for example, the systematic name supplied by the International Union of Pure and Applied Chemistry (IUPAC). Some databases offer access to an additional list of further common names (especially ‘‘trivial names’’ and ‘‘trade names’’). Chemical Abstracts Service (CAS) numbers as unique identifiers are available in many, but not all mass spectral databases. Molecular formula and molecular weight complement this block of information.

As chemists are familiar with the images of chemical structure drawings, this kind of structure representation is very informative and more intuitive than chemical names alone. The number of mass spectra entries containing structural information has strongly increased during the past years. Chemical structures are stored either only as drawings or as the so-called connection tables. The latter are graph theoretical descriptions of all atoms and bonds and enable computer treatment of the structural information. Thus, substructure retrieval of database entries, structure similarity searches, and the evaluation of spectra structure correlations become possible.

Some databases contain chromatographic retention data (mostly GC retention indices), which are important as a second dimension for compound identification. Information about sources of mass spectra, instrument type, and measurement conditions may be valuable particularly for soft-ionization mass spectra as later discussed.

55.2.1
Databases of Electron Impact (EI) Mass Spectra

An important issue for the storage of mass spectra in databases is the need, that the measurement of the spectra must be reproducible enough to enable comparison for identification purposes. EI mass spectra fulfill this requirement to a high degree. Almost all EI ionization sources use an electron energy of 70 eV. At this energy level, the fragmentation patterns of molecular ions are very stable against small energy fluctuations and highly independent of the instrument.

Even different types of mass spectral analyzers produce very similar EI mass spectra from the same compound. Mass spectra from magnetic sector-field instruments – the dominating analyzer type in the beginning – are comparable to present day quadrupole mass spectra – only the peak intensities in the upper mass range can be higher in sector-field instruments than in quadrupole instruments.

The very first ion trap mass analyzers showed different mass spectra for some chemical compound types (e.g., nitrogen compounds) because of ''self-chemical-ionization.'' These problems have been solved by controlling the sample load of the ion trap. Time-of-flight (TOF) analyzer mass spectra do not show significant differences from mass spectra measured by a quadrupole or a sector-field instrument.

Only labile structures can sometimes give different mass spectra with different instruments or measuring conditions. Labile compounds can be decomposed at active spots before ionization, thus producing partly or totally the mass spectrum of the decomposition product.

Existing databases can be classified in two groups:

- *General collections* of EI mass spectra containing compounds with a widespread chemical diversity. These databases are mostly large or middle sized.
- *Specialized collections* containing only a group of chemical compounds such as drugs, pesticides, essential oils, and so on. These libraries are mostly smaller than the general ones.

Most databases are commercially available as in-house versions and often offered by mass spectrometer suppliers. Some (mostly smaller) libraries are freely available. There exist also Internet databases free of charge or with costs.

55.2.1.1 Wiley Registry and NIST/EPA/NIH Mass Spectral Databases

Two large general collections dominate the field: (i) the ''Wiley Registry of Mass Spectral Data'' [2] – its ninth edition (2009) contains mass spectra of 590 000 chemical compounds. (ii) The NIST/EPA/NIH Mass Spectral Library [3] from 2011 (''NIST 11'') contains mass spectra of 213 000 chemical structures. In addition, there exist 100 000 duplicate spectra within the Wiley registry and 31 000 duplicates within the NIST library.

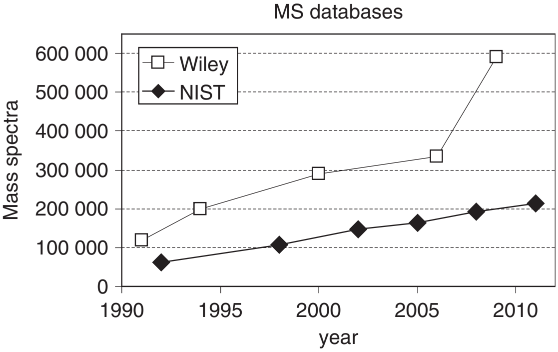

Figure 55.1 Growth of the NIST and Wiley mass spectral databases in the past two decades (total number of unique compounds).

The Wiley database had its origin in the Mass Spectrometry Registry by Stenhagen and Abrahamsson and its enormous growth is connected with the work of McLafferty and his group.

The roots of the NIST/EPA/NIH Mass Spectral Library – now under the auspices of the US National Institute of Standards and Technology (NIST) – go back to the Atomic Weapons Research Establishment (AWRE) in Aldermaston, UK. This database was extended by incorporating collections of the US agencies NBS (National Bureau of Standards), EPA (Environmental Protection Agency), and NIH (National Institutes of Health).

Figure 55.1 shows the growth of the NIST and Wiley libraries during the past years. In spite of all efforts in collecting mass spectra, the enormous numerical gap to total number of documented chemical compounds remains high: CAS registry contains 67 mio. compounds in 2012 [4]. About 10–20% of these compounds are volatile enough for measurement by EI-MS.

Moreover, the theoretically possible number of chemical structures generated by exhaustive structure generation is unimaginable higher. To get an impression about this fact, Table 55.1 shows a comparison of these numbers for three selected molecular formulae.

Nevertheless, both databases supply a considerable benefit, as many "unknowns" of daily routine work are contained. The costs for these databases (~2 cent/spectrum) are low in comparison to infrared or NMR spectra or to some "specialized" mass spectral collections.

55.2.1.2 **Quality of Mass Spectra in Databases**

In the first decades of building mass spectral data collections, the number of entries was the most important criterion for a good database. Scarcely checked, mass spectra were seldom discarded because of measurement deficiencies such as incorrect mass calibration, limited mass range (starting mass too high), electron multiplier saturation (several peaks show 100% base intensity), poor dynamic range, peaks from contaminations, and lacking isotope peaks. Even mass spectra

Table 55.1 Comparison of the number of isomers for three molecular formulae (not considering cis/trans and optical stereoisomers).

Brutto formula	Molecular weight	MS library	Commercially available	CAS registry	Isomer generation
$C_4H_8O_1$	72	17	20	25	26
$C_9H_{18}O_1$	142	78	96	1 682	4 745
$C_{14}H_{18}O_1$	212	25	37	779	839 823

The numbers are given for a mass spectral database (NIST 05), commercially available compounds, registered compounds in the Chemical Abstracts Service (CAS), and exhaustive isomer generation by software MOLGEN [5].

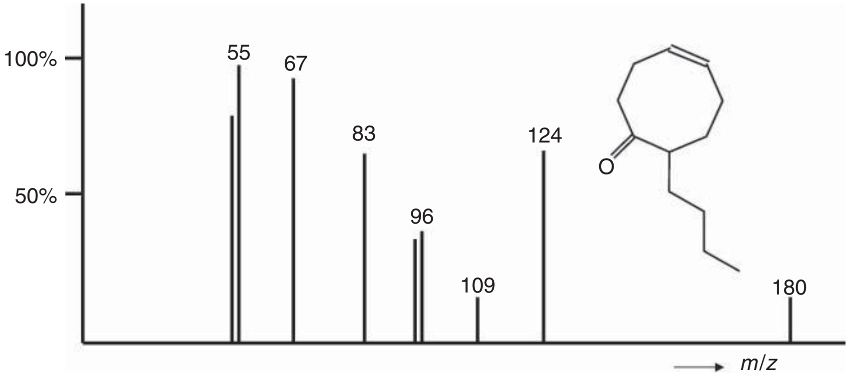

Figure 55.2 Example of a low-quality database mass spectrum: only a few peaks, usually extracted from literature.

reduced to only 8–10 peaks were extracted from scientific literature and have been included in databases (Figure 55.2).

In the meantime, the need for high-quality spectra has been recognized and some attempts were made to evaluate the quality of the existing databases and to eliminate the incorrect and low-quality mass spectra. Quality indices for mass spectra were created [6] and computer algorithms assisted to check automatically for typical errors, quality deficiencies, and inconsistence between structure and mass spectrum.

All these efforts have improved the quality of mass spectral databases. In particular, NIST library editions since 1998 show a high-quality standard, as all mass spectra have been visually evaluated and selected by mass spectroscopic experts [7]. The strategy of the Wiley registry seems to be different: collecting a high number of mass spectra to remain the world's largest database seems to be to still the major driving force. A typical example may illustrate the situation: 29% of the mass spectra of compounds with a molecular weight of 400 Da in the Wiley registry (seventh edition) contain less than 10 peaks – often a hint for lower quality mass spectra. For the NIST'05 database, this value is only 1.4%.

Both strategies have their merits. Sometimes a reduced mass spectrum is better than no mass spectrum and supplies ideas for the identity of an unknown. However, for reliable identifications, good quality library spectra are mandatory.

55.2.1.3 **Other General EI Databases**

The organic compound mass spectra collection of Yarkov [8] (37 000 mass spectra) is a middle-sized database originating partly from combinatorial synthesis.

Two databases can be accessed free of charge via the Internet: the NIST Chemical Webbook [9] presents a selected part of the NIST mass spectra (more than 15 000) and other physical and spectroscopic data. The integrated spectral database system (SDBS) for organic compounds [10] is a Japanese initiative containing 24 700 mass spectra together with NMR and IR spectra.

A huge multispectral organic spectroscopy Internet database (NMR, IR, MS) with user fees is SpecInfo [11]. It is accessible by the web client SpecSurf [12].

55.2.1.4 **Specialized Mass Spectral Databases**

Some analytical areas have a particular need for reliable identification of analytes based on GC–MS data. Typical areas are medicine and toxicology (drugs), regulated compounds (e.g., pesticides), aroma analysis, and metabolomics.

Special requirements are a maximum coverage of the relevant area including possible metabolites, high quality of the mass spectra, and often the availability of GC retention indices. Mass spectra and retention data of silylated, acylated, and otherwise derivatized compounds are of specific interest, as polar analytes are often derivatized to increase their volatility for the gas chromatographic analysis.

Table 55.2 shows a selection of specialized databases. Prices for these databases are higher, usually about $1 per mass spectrum must be assumed.

In a few cases, user initiatives collect mass spectra to make them available to the public or to the contributors, for instance, in forensics [25], in metabolomics [26], and by museum analysts [27].

55.2.1.5 **GC Retention Indices in Mass Spectral Databases**

Retention indices normalize gas chromatographic retention times to *n*-alkane GC peak series [28]. Most GC retention indices in mass spectral databases originate from unpolar stationary phases such as DB-1 (polydimethylsiloxane) and DB-5 (polydimethylsiloxane with 5% phenyl instead of methyl). However, retention index data from GC phases of middle or strong polarity such as OV-1701 (cyanopropyl modified polysiloxane) and WAX (polyethylene glycol) are important too and are contained in some databases, for example, for flavor chemicals [29].

Retention indices are influenced to a certain degree by other GC parameters such as flow rate, phase ratio, and the temperature program, which have all to be standardized for high-quality identifications. Therefore, retention indices extracted from literature can be used only as a rough ‘‘filter.’’

Table 55.2 A selection of specialized collections of EI mass spectra.

Compound classes	No. of compounds	Authors	References

55.2.2
Databases for Mass Spectra from LC–MS

55.2.2.1 Soft Ionization versus Electron Impact

Since the late 1980s, powerful “atmospheric pressure” ionization methods exist to measure mass spectra from molecules in the effluent of liquid chromatographs: APCI (atmospheric pressure chemical ionization) and ESI have become established since in routine analysis.

APCI and ESI mass spectra are different from EI mass spectra. Therefore, the existing large EI-MS databases cannot be used for comparison and library searches.

APCI and ESI are both “soft-ionization” methods. As less energy is transferred to the ions than by EI ionization, less or no fragment ions are produced and the mass spectrum is dominated by “quasi-molecular” ions. For a higher information content of the mass spectra, additional fragmentation has to be induced, for example, by “collision-induced dissociation” (CID).

In a single-stage mass spectrometer, fragmentation can be obtained or enhanced by applying appropriate voltages to the orifice of the ion source (“source-CID”).

In true tandem mass spectrometers (“MS/MS”), a “precursor ion” – mostly the quasi-molecular ion – is selected and collides with gas atoms in a collision cell. The produced fragments (“product ions”) are mass analyzed in a second step. These

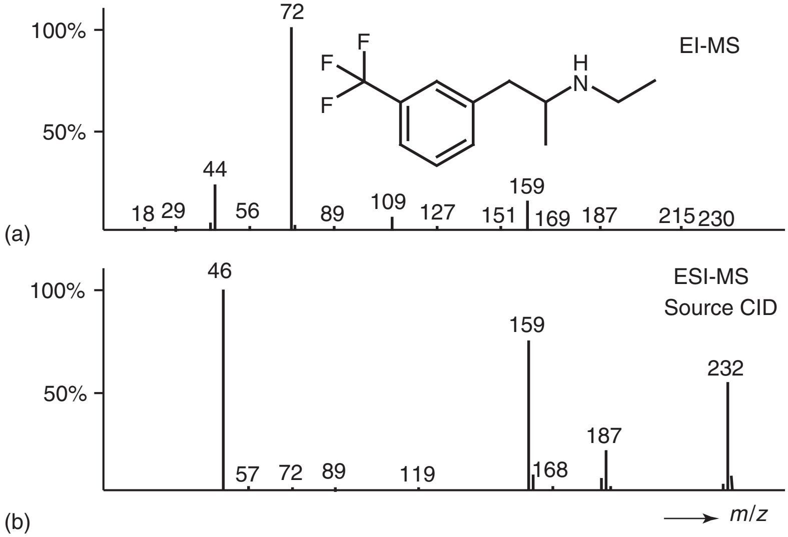

Figure 55.3 Comparison of (a) the EI mass spectrum (70 eV) and (b) the ESI "source-CID" mass spectrum (cone voltage 40 V) of fenfluramine (molecular weight 231).

processes occur either in a separate collision cell and in a second mass analyzer (MS/MS in space, e.g., by triple quadrupoles) or completely in the same mass analyzer (MS/MS in time, e.g., in quadrupolar ion traps).

EI molecular ions are radical cations and have an odd number of electrons. Quasi-molecular adduct ions common in soft ionization as $[M + H]^+$, $[M + NH_4]^+$, $[M + Na]^+$, $[M - H]^-$, and so on, have an even number of electrons. Fragmentation reactions of "even-electron" ions are completely different from those of "odd-electron" ions (Figure 55.3).

55.2.2.2 **Reproducibility of CID Mass Spectra**

Contrary to EI and unfortunately for data collection and comparison issues, CID mass spectra of the same compound are not similar in any case. Large differences in mass spectral appearance stem (i) from different instrument types and (ii) from sensitivity to measurement parameters.

A large diversity of mass spectrometers for ESI-MS and APCI-MS exists: single-stage instruments with source-CID, different collision cell types for low-energy CID (eV range), and high-energy CID (keV range). The energy regime in the collision cell is responsible for the product ions appearing.

Source-CID mass spectra are instrument dependent because ion source geometries play an important role [30].

Low-energy CID in triple quadrupoles and quadrupole/time-of-flight hybrid instruments (QqTOF): consecutive fragmentations are possible

Low-energy CID in quadrupolar ion traps: only unimolecular decays take place, rearrangements can be enhanced because of longer residence time.

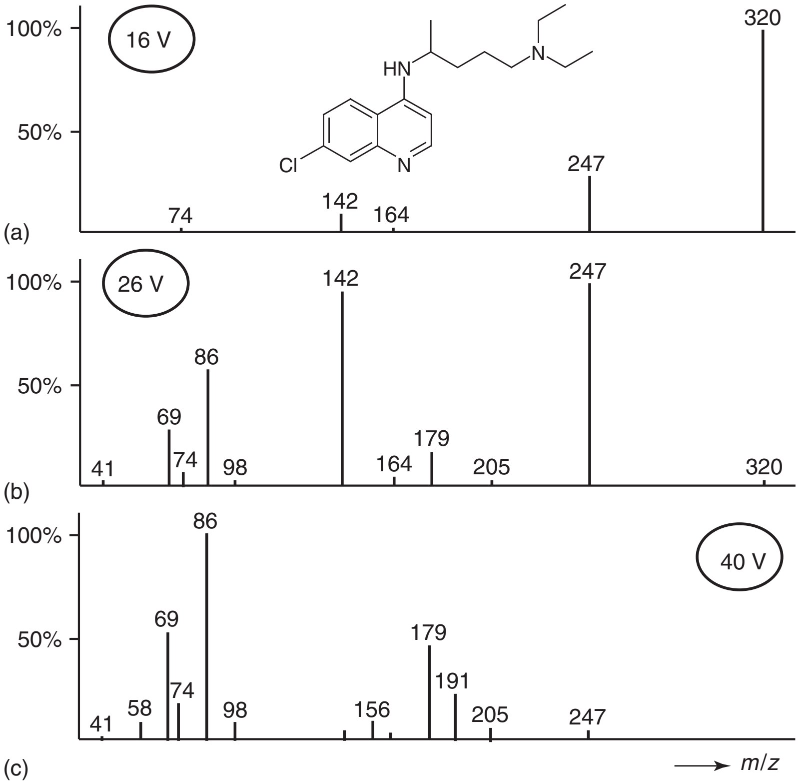

Figure 55.4 Comparison of ESI triplequad CID mass spectra of chloroquine: precursor ion m/z 320 ($[M+H]^+$), collision energies (a) 16 V, (b) 26 V, and (c) 40 V.

High-energy CID in sector-field and TOF–TOF instruments generates considerably more fragments than low-energy CID. As these instruments are not so widespread, we focus on low-energy CID spectra.

Source-CID mass spectra and true tandem MS/MS spectra are both very sensitive to slight changes in instrumental properties and parameters (applied voltages, collision gas pressure, etc.) and therefore of little reproducibility (Figure 55.4). Unlike in EI ionization with its standardized 70 eV electron energy regime, there exist no robust instrumental parameters. Particularly, instrumental parameters for an informative fragmentation with many peaks depend on the measured compound.

55.2.2.3 **Databases of CID Mass Spectra**

For reasons discussed, no large databases of source-CID or MS/MS spectra (comparable in size to Wiley or NIST EI databases) have been collected up to now. Only smaller collections exist for compounds of special interest such as drugs and pesticides (Table 55.3).

Table 55.3 Examples of source-CID and true MS/MS libraries.

Compound classes	No. of unique compounds	CID type	Author	References
Drugs/toxicants	1100	Source-CID	Marquet *et al.*	[31]
Miscellaneous	559	Source-CID	Little	[32]
β-Blocking drugs	400	Triplequad	Gergov *et al.*	[33]
Drugs/toxicants	800	Triplequad	Dresen *et al.*	[34]
Miscellaneous	1200	Ion trap	Baumann *et al.*	[35]
Human/veterinary drugs, natural compounds	1041 pos. 524 neg.	Ion trap (MS^n "trees")	HighChem	[36]
Drugs/toxicants	1200	QqTOF	Oberacher	[37]
Drugs/toxicants	2500	QqTOF	Broecker *et al.*	[38]
Drugs/toxicants	780	Ion trap	Liu *et al.*	[39]
Drugs/toxicants	1253	QqLIT	Dresen *et al.*	[40]
Drugs/toxicants	1000 pos. 250 neg.	QqLIT	Sauvage *et al.*	[41]

QqLIT, quadrupole linear ion trap.

Different strategies have been attempted to overcome the problem of instrument and parameter dependence of CID mass spectra:

1) Collecting 3–10 CID mass spectra varying the relevant instrumental parameter (cone voltage for source-CID, collision energy for tandem MS) [34]. The mass spectra can be stored separately or merged to one composite mass spectrum per compound. Alternatively, one "information-rich" mass spectrum per compound can also be obtained by voltage ramping during measurement [39].
2) Observing a result-oriented measurement protocol in CID analysis, for example, increasing the collision energy until the precursor ion intensity is reduced to 10%: ion trap MS^2 and MS^3 spectra of pharmaceuticals and pesticides have been acquired with this protocol to build a quality spectra database. CID mass spectra from ion traps of different suppliers looked very similar, even independent from ionization mode (ESI, matrix-assisted laser desorption ionization (MALDI)) [42];
3) Collecting as many mass spectra as possible from all available sources. This strategy tries to copy the success story of EI databases. NIST seems to make first attempts in this direction. Their MS/MS library [43] now contains collision-cell CID spectra (triplequad, QqTOF) of 9232 different precursor ions and ion trap CID spectra of 12 047 different precursor ions from overall 6999 compounds (metabolites, drugs, phospholipids, surfactants, sugars, peptides, etc.). Approximately 90% of the spectra have been analyzed in the positive ion mode.

As there is an urgent need for applicable MS/MS databases and powerful search options, there are many different ongoing efforts and it will be highly interesting to see how the situation will consolidate. It will be a laborious way to establish a general MS/MS database comparable to the standard in EI-MS. It must contain a multiple of entries: mass spectra from different instruments, varying voltages, positive and negative ionization.

Standardizations in acquisition techniques will be necessary and some types of mass spectrometers will become specialized ''identification machines'' in the future – the ion trap or the QqTOF seem to have good chances for this task. In ''closed'' areas such as pesticide regulations or toxicological analyses, instrument-specific high-quality databases will further play their role. In each case, it is advisable for users to build their own MS/MS libraries containing the spectra of their research area measured with their own instruments.

A special emphasis has to be spent on MS^n, as ion trap CID spectra can be measured not only from the quasi-molecular ion but also from the resulting product ions. The complete data structure is a tree of mass spectra [44]. All relations should be conserved in the database.

Two MS/MS databases can be accessed free of charge via the Internet: MassBank is a distributed public repository for sharing mass spectral data for life sciences [45]. The MS/MS spectra of 2337 metabolites and 679 synthetic drugs stem from different research groups using various types of mass spectrometers. The METLIN metabolite database is a repository of metabolite information [46] containing also high-resolution MS/MS data for 10 125 of its chemical structures, analyzed with a QqTOF mass spectrometer.

55.2.3
Fragmentation Databases

Mass spectral fragmentation is the result of gas-phase reactions of ions in high vacuum. These reactions have been investigated intensely since the beginning of organic MS. Generalized fragmentation rules are condensed in many textbooks and used nowadays in fragmentation prediction software. However, a limited set of common rules usually cannot explain all fragment ions appearing in a mass spectrum of a chemical structure.

On the other hand, many detailed fragmentation pathways for single compounds or compound groups are documented in the scientific literature. One part of these pathways is thoroughly verified by mass spectrometric means such as isotopic labeling, metastable ion experiments, and high-resolution techniques, supported by theoretical considerations and calculations. Other published pathways rely only on the comparison of mass spectra of differently substituted compounds.

Only one large database with fragmentation reactions from MS is currently available. Nineteen thousand individual fragmentation reactions have been extracted from literature [47] and serve as a knowledge base for the prediction of fragmentation pathways in the software ''Mass Frontier.''

All fragmentation reactions have been manually evaluated for accuracy, plausibility, and consistency of fragment masses with mass spectral peaks. Automatic evaluation algorithms have checked for charge and radical consistency and other electron-related issues.

55.2.4
Protein Databases

Most databases for the interpretation of protein mass spectral analysis contain protein sequences and no measured mass spectra. Mass information is calculated from the amino acid sequences. Protein databases are very large. The sequence information is often derived by translating the protein coding genes from DNA databases, because sequencing techniques for nucleic acids have a higher throughput.

Real proteins show some differences from the sequence information coded in nucleotide databases: after translation of the genetic code, proteins are often modified, for example, starting peptides are cut off, disulfide links are created, and posttranslational modifications such as glycosylation, phosphorylation, and sulfatization can take place. These modifications are annotated only for a part of the protein sequences in the databases.

Protein database entries are characterized by the biological species and the protein name and contain additional information, for example, about biological functions, secondary structures, and bibliographic references.

A number of huge protein sequence databases exist, often freely accessible via the Internet (Table 55.4). The number of entries was growing very fast during the past years.

As information about the same protein sequence can be found in different databases, an urgent need for cross-referencing was given. ‘‘UniParc’’ [55] is the most comprehensive, nonredundant protein sequence archive containing only

Table 55.4 A selection of sequence databases (database sizes from July 2012).

Database	Sequences	Description	References
PIR-PSD	—	The world’s first database of classified and functionally annotated protein sequences, 2004 incorporated in UniProtKB	[48]
UniProtKB/Swiss-Prot	536 789	Manually annotated protein sequences	[49]
UniProtKB/TrEMBL	23 165 610	Protein sequences automatically translated from nucleotide sequences	[49]
EMBL/DDBJ/ GenBank	247 335 689	Nucleotide sequences	[50]
NCBI RefSeq	16 393 342	Explicitly linked protein and nucleotide sequences	[51]
PRF/SEQDB (Osaka)	1 365 912	Peptide and protein sequences from literature and from nucleotide databases	[52]
MSDB	3 239 079	Collection of nonredundant protein sequences from different databases	[53]
NCBI Entrez protein	—	Collection of protein sequences from a variety of sources (SwissProt, PIR, PRF, PDB, GenBank, RefSeq)	[54]

the protein sequences and their cross-references to the source databases. The sequences are stored with a unique protein identifier (''UPI'' and 10 hexadecimal numbers, e.g., UPI000014B174 for horse myoglobin).

55.3
Library Search/Database Retrieval

In a library search, mass spectra of unknowns are compared with all mass spectra of a database. If a mass spectrum of the unknown is present in the database, it should be found and thus the unknown is identified. Library search is the most successful and broadly used method among all computer-based mass spectral interpretation and identification attempts.

Library search is looking for the most similar mass spectrum in a database. That seems to be a simple task, but a library search algorithm has to deal with some obstacles: measurement uncertainties, differences between instruments, low-quality spectra (measured or database spectra), background (air, column bleeding), overlapping chromatographic peaks, and skewing effects on peak intensities within chromatographic peaks.

Typically, the result of a library search is not a single reference compound. The most similar mass spectra are sorted by a similarity measure and form a ''hitlist'' of candidates.

55.3.1
Search Algorithms for EI Mass Spectra

A typical algorithm for library search in large mass spectral databases can be described in four steps:

1) *Transformation of mass spectra*: different types of intensity transformations are applied to change the influence of the peaks, for example, higher weight for significant mass values or transformation to binary (yes/no) values. Examples of more complex transformations are modulo-14 features (''ion series'') or neutral loss spectra.
2) *Data reduction*: the number of variables (original mass values or derived features) is reduced by some heuristics (influenced either only by statistics or also by mass spectrometric ideas) to save computer time in the presearch and the main search.
3) *Presearch (''filter'')*: applying a computationally efficient simple method, the number of candidate mass spectra from the database is strongly reduced to about 100–500 reference spectra;
4) *Main search*: a more or less sophisticated similarity measure between two spectra is calculated for all reference mass spectra surviving the presearch. The most similar reference mass spectra are sorted by this criterion to produce the hitlist.

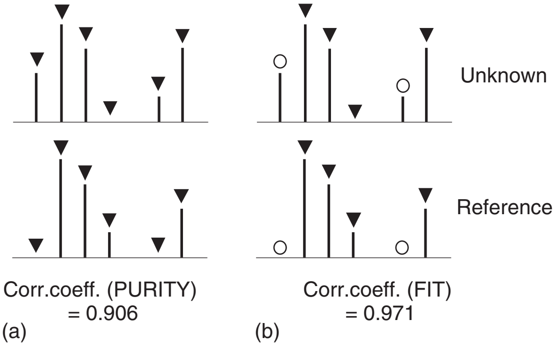

Figure 55.5 Two variants for calculating similarity measures: (a) PURITY (or "forward search") matches all peaks; (b) FIT (or "reverse search") considers only peaks present in the reference and is less affected by contaminations, background and coeluting compounds. Filled triangles designate peaks used in calculating the similarity measure, while unfilled cycles designate peaks that are not considered for calculation.

A widely used similarity measure for spectra comparison is the normalized scalar product (dot product) S_{UR} (Eq. (57.1)) of the two mass spectra (unknown and reference). More complex algorithms have been built by heuristics or by "trial and error."

$$S_{\mathrm{UR}} = \frac{\sum_m x_{\mathrm{U},m} x_{\mathrm{R},m}}{\sqrt{\sum_m x_{\mathrm{U},m}^2 \sum_m x_{\mathrm{R},m}^2}} \tag{55.1}$$

$x_{\mathrm{U},m} =$ Peak intensity at $m/z = m$ of the mass spectrum of the unknown
$x_{\mathrm{R},m} =$ Peak intensity at $m/z = m$ of the reference mass spectrum.

The similarity measures can be calculated in different variants (Figure 55.5) leading to hitlists differently sorted. For example, the "FIT" value ("reverse" or "mixture search") uses only peaks present in the reference spectrum and is less sensitive to contaminations of the unknown mass spectrum often present in real samples.

55.3.1.1 **Library Search Software**

Three widely used library search programs are briefly explained: INCOS (Integrated Control System) [56], PBM (Probability-Based Matching [57], and SISCOM (Search for Identical and Similar Compounds [58]. Some details about the algorithms are shown in Table 55.5.

The algorithm of the INCOS system is simple and robust. Weighting of high mass ions is an important feature emphasizing molecular ions and prominent neutral losses.

The idea behind PBM is that mass values and intensities of mass spectral peaks are not equally distributed. A combination of "uniqueness" (reflecting the different

Table 55.5 INCOS, PBM, and SISCOM algorithms (simplified).

	INCOS	PBM	SISCOM
1. Spectra transformation	Intensity weighting with $\sqrt{m/z}$	A (“abundances”): values corresponding to logarithmic intensity ranges U (“uniqueness”): $^2\log p\ (m/z)$, p = probability of a peak at m/z	1. Original intensities (no transformation) 2. Binary m/z values (yes/no)
2. Data reduction	Iterative selection of most intense peaks in mass windows with decreasing window sizes: approximately 40% of the peaks are selected	Selection of 15–26 peaks with highest significance $(U + A)$ = “condensed” spectrum (base peak, molecular ion, and some neutral losses included!)	Selection of characteristics (char.) = peaks that “exceed” their neighbors in CH_2-homologous modulo-14-series: $I_m > (I_{m-14} + I_{m+14})/2$
3. Presearch (filter)	Match the 16 highest peaks in UNK with the 8 highest in every REF: minimum number of peaks present in both spectra (no intensity match!) About 150 reference spectra survive	Match all significant peaks in the condensed unknown spectrum with the “most significant peak” in every REF (no intensity match!) About 5% of reference spectra survive	1. Only database section of the most dominant modulo-14-ion series in UNK. 2. Preselection by N_C, N_R, and N_U (see below) About 150 reference spectra survive
4. Similarity measure	Normalized *scalar product* (Eq. (57.1))	“Confidence value” K: $K = \Sigma\ (U_i + A_i + W_i)$ for all matching reference peaks i (present within an abundance window in UNK), with “window factor” W (measure matching peak abundances)	“Similarity index” SI combining: N_C: number of matching char. N_R: number of char. only in REF N_U: number of char. only in UNK I_R: intensity of char. only in REF I_U: intensity of char. only in UNK P_C: pattern correlation of char.

UNK, unknown mass spectrum; REF, reference mass spectrum.

frequency of each mass value in the whole library) and ‘‘abundance’’ (categorization to logarithmic peak intensity classes) is the driving force for the selectivity of a fast spectra comparison using only few selected peaks.

INCOS and PBM are implemented in various modifications in the instrument software of mass spectrometers or in standalone library search systems.

The SISCOM algorithm is part of the standalone software MassLib [59]. An interesting feature is the selection of peaks (‘‘characteristics’’) that are locally prominent within their CH_2 homolog peak series. This feature incorporates a kind of ‘‘mass spectral knowledge’’ and is one reason for good ‘‘structural similarity search’’ properties of SISCOM as later explained.

55.3.1.2 **Identity of the First Candidate**

Is the first candidate of the hitlist really the unknown? The best method is visual inspection of the candidates in comparison with the mass spectrum of the ‘‘unknown’’: if significant peaks in the library spectrum are lacking in the unknown mass spectrum, then the library spectrum corresponds certainly not to the ‘‘unknown.’’

To get an unambiguous evidence of the identity of a candidate with the unknown, however, is almost impossible. The absolute value of the similarity measure alone is not a good criterion; therefore, attempts are made to calculate real probabilities for the ‘‘identity’’ of a candidate in a hitlist, for example, by the NIST MS-Search program [60].

Retention indices – if available – can help in the identification in ambiguous situations, especially in cases of very similar mass spectra (e.g., cis/trans isomers or 1-alkenes/1-alkanols). Some library search systems use this ‘‘orthogonal’’ information to filter the hitlist [61].

55.3.1.3 **Structural Similarity Search**

INCOS and PBM search algorithms are optimized to retrieve even database spectra of low quality. The most important requirement for such ‘‘**identity search**’’ programs is that the target compound is in the hitlist and in the best case in rank one. The search criteria look only for significant ‘‘spectral similarity.’’

What is to be done if the unknown is not contained in the library and therefore cannot appear in the hitlist? In this case, a hitlist that contains a multitude of chemical structures similar to the unknown would be helpful. This would supply a first information and a starting point for the interpretation of the unknown’s mass spectrum by comparing it with the mass spectra of obviously related structures. Such a library search is called a ‘‘(**structural**) **similarity search**’’. The algorithm must look for structural similarity features in the mass spectral data.

The SISCOM algorithm is optimized for this purpose: contrary to INCOS and PBM, variable selection in the data reduction step is not only related to intensity and statistics but also respects implicitly mass spectrometric rules. The modulo-14 categories of the presearch and the selection mode for the ‘‘characteristics’’ have a clear correlation to structural properties.

The intensity of mass fragments can be strongly influenced by small structural changes. Thus, in a structural similarity context, the presence of peaks is more important than their intensity. Therefore, SISCOM emphasizes binary variables in addition to the intensity criteria within its similarity measure. The weighting parameters of the algorithm have been heuristically optimized to yield hitlists with a large number of chemical structures similar to the unknown.

It has been shown that using spectral features rather than peak intensities within library search algorithms optimizes structural similarity between the hitlist and the target [62].

Neutral loss searches have "structural similarity search" properties for some classes of compounds. An obstacle to the automatic use of this technique is the necessity to know the molecular ion of the unknown.

The frequency of a distinct substructure in a hitlist of a structural similarity search can be used to predict the presence or absence of this substructure in the unknown. This feature is implemented, for example, in SISCOM search, in the NIST MS Search and in the STIRS (Self-Training Interpretive and Retrieval System) [63].

55.3.2
Search Algorithms for MS/MS Spectra

Up to now, the same algorithms as in EI-MS (especially INCOS derivates such as NIST MS Search) are used for library search in MS/MS databases. Some slight modifications consider increasing mass increments at higher molecular weights by using real m/z values and tolerances instead of nominal masses.

However, there are many differences between MS/MS data and EI mass spectra: MS/MS spectra often show only few peaks and their intensities and intensity pattern can vary to a much higher degree than in EI-MS. Fragment ions can be present or absent dependant on instrument type and collision parameters. While the molecular ion in EI mass spectra may be absent or very small, the precursor ion is always known in MS/MS and can be used as a filter for molecular weight of compounds.

Some new algorithmic developments try to reflect these facts. For instance, a newly presented "matching probability" (mp) uses a high weight for the presence and absence of peaks (raised to the fourth power!) and a low weight for the intensity differences [64]:

$$\mathrm{mp} = \frac{f_{\mathrm{M}}^{4}}{\left(f_{\mathrm{U}} f_{\mathrm{R}} \sum_{m} \left| i_{\mathrm{U},m} - i_{\mathrm{R},m} \right| \right)^{0.25}} \tag{55.2}$$

f_{M} = number of matching peaks
$f_{\mathrm{U}}, f_{\mathrm{R}}$ = number of peaks in the unknown and in the reference, respectively
$i_{\mathrm{U,m}}$ = intensities (%) of matching peaks m in the unknown
$i_{\mathrm{R,m}}$ = intensities (%) of matching peaks m in the reference.

Another algorithm, X-Rank [65], ranks the peaks of the mass spectra by intensity and matches the rank pattern of the reference spectrum with the rank pattern of the unknown. The probability of a correct identification is computed for this match using parameters that have been trained before.

Interpretation of hitlists from searches in MS/MS databases requires a modification: if in EI the first candidate spectrum of a library search does not look like the unknown spectrum, then this candidate is rather sure not identical to the unknown. This conclusion is not valid for MS/MS hitlist candidates, as library spectra can originate from different instruments or measurement conditions producing different spectra with lacking or additional peaks and larger variability in peak intensities.

As accurate mass measurements with high-resolution mass spectrometers play an increasing role, especially in LC–MS/(MS), algorithms should be able to utilize this information by adjusting mass matching limits to instrumental performance.

Special comparison algorithms are needed for library search in databases containing complete tree-structured sets of MS^n experiments [66]. All possible spectral matches should be done and contribute to an overall similarity parameter. The search, however, should also give reasonable results if parts of the MS^n tree have not been measured for the unknown.

A more sophisticated search strategy handles the MS^n tree as a graph with nodes (fragment peaks) and edges (fragmentation reactions) [67]. Thus, concepts from similarity searching for chemical structures can be applied, for example, calculating the Tanimoto coefficient of binary subgraph fingerprints.

55.3.3
Search Strategies for Proteins

Proteolytic digestion of a protein sample and ESI or MALDI MS of the cleavage peptides is the most frequently used strategy for mass spectrometric identification of proteins. The mass spectral data are then compared to large protein sequence databases, available on the Internet or purchased as in-house versions and enlarged by own data.

Digestion of a protein by endopeptidases yields peptides with defined sequences as each enzyme cleaves at distinct amino acids (e.g., trypsin cleaves at arginine or lysine).

Different identification strategies are briefly described here. More detailed overviews can be found, for example, in [68].

55.3.3.1 Peptide Mass Fingerprint (PMF)

The peaks in a MALDI or ESI mass spectrum of the cleavage peptides are matched with the calculated masses from theoretical cleavage of the proteins in a database (Table 55.6). A hitlist of the best matching proteins is generated. Search algorithms have to be robust against missed peptides (some have a low sensitivity in MS), ‘‘missed cleavages’’ (not all theoretically possible cleavages occur), and posttranslational modifications.

Table 55.6 Tryptic peptides of monoisotopic $[M + H]^+$ ions are calculated *in silico* from the database sequence (one-letter amino acid code) of horse myoglobin, the cleavage positions (**K** = lysine, **R** = arginine) are printed in bold.

The leading methionine is cleaved off at protein synthesis.

Peptide mass fingerprint (PMF) does not need tandem MS. However, high mass accuracy improves the search results.

55.3.3.2 **Peptide Fragment Fingerprint (PFF)**

Low-energy CID fragmentation of peptides results in clearly defined ion series a, b, c, x, y, z (Figure 55.6) [69]. In ESI-MS/MS, mainly b- and y-ions are present, thus simplifying the spectrum interpretation.

Peptide fragment fingerprint (PFF) computes theoretical MS/MS spectra (mostly b- and y-ions) from peptide sequences in the protein databases and compares them with the measured peptide MS/MS spectrum. Currently, PFF is the most

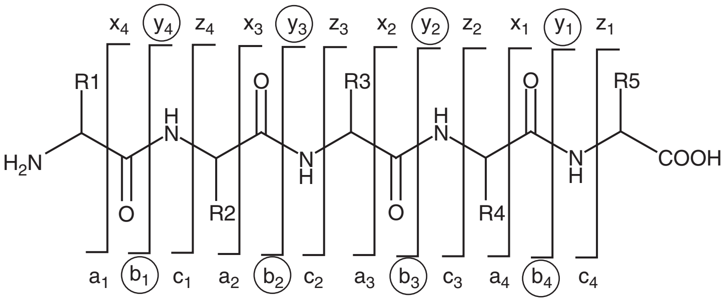

Figure 55.6 CID fragmentation scheme for peptides (nomenclature of Roepstorff and Fohlmann) [69]. In ESI, low-energy CID spectra mainly b- and y-ions are present.

important identification technique for proteins from mass spectral data. A number of commercial and free PFF programs exist; SEQUEST (commercial) and MASCOT (a commercial and a free Internet version) are popular packages. The MASCOT [70] algorithm is probabilistically based, whereas SEQUEST [71] utilizes a cross-correlation approach.

As the size of protein databases is very large, efficient discrimination between correct protein hits and random ‘‘false-positive’’ identifications is a burning issue. According to the importance of MS in proteomics, much effort is undertaken to improve the reliability of protein identification as well as the speed of the searches to enable high-throughput applications.

55.3.3.3 **Sequence Tag**

An alternative strategy for protein identifications by MS/MS spectra matches sequences and not mass spectra. Often, a short part of an amino acid sequence of the peptide can be read directly – either visually or by software – from succeeding peaks of an ion series in the MS/MS spectrum. This information can be used to derive a ‘‘peptide sequence tag’’ [72] with high selectivity (Figure 55.7). Fortunately, this sequence tag can be translated from the amino acid code into the nucleotide

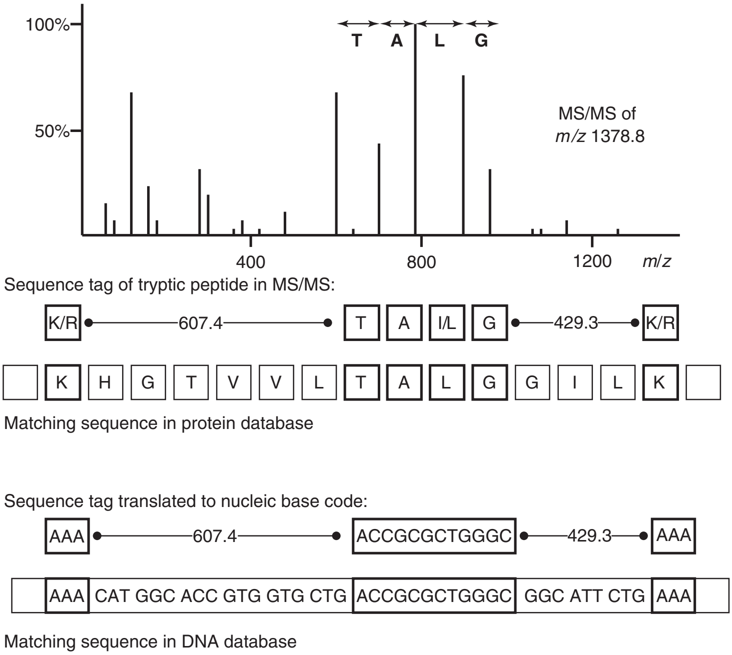

Figure 55.7 A sequence tag is a partial amino acid sequence observed in a peptide MS/MS spectrum (e.g., of b-ions). Its high information content originates from the N-terminal cleavage specificity, the short ‘‘tag’’ of amino acid sequence, the C-terminal cleavage specificity, and the sizes of the two regions between tag and cleavage positions. Amino acid sequence tags can be translated back to the nucleotide base code, enabling searches in the large cDNA databases.

base code. Thus, the search can be performed also on the level of the genome using large nucleotide databases.

55.3.3.4 **Peptide-MS-Search**

Recently, attempts were made to build large databases of measured and reliably identified peptide MS/MS spectra [73]. Searches in those databases yield a higher reliability of identification. Intensities of real database spectra are more similar to the MS/MS spectrum of the unknown peptide than intensities predicted from amino acid sequences by algorithms such as ‘‘SEQUEST.’’ Efforts of spectra collection concentrate to well-characterized proteomes such as the human and yeast proteome.

55.3.3.5 **De novo Sequencing**

The most challenging task in protein identification is the determination of the amino acid sequences from MS/MS spectra of peptides not contained in databases. Excellent mass spectral data are necessary to have a real chance for de novo sequencing, for example, accurate mass measurements from FT-ICR-MS or Orbitrap MS and/or complementary fragmentation methods including high-energy CID (e.g., with a MALDI-TOF/TOF). Several computer programs try to solve this puzzle; however, at best, correct amino acid sequences are derived for only about one-third of the investigated peptide MS/MS spectra [74].

55.4
Fragmentation Pathway Prediction

The knowledge of the chemical structure of fragment ions present in a mass spectrum is often helpful in the interpretation and identification of an unknown. This information can be used to solve problems of different complexity:

- C*orrelate mass spectrum and structure*: explain mass spectral peaks for a known chemical structure.
- *Evaluate structure candidates*: determine ‘‘unexplained peaks’’ in the mass spectrum of the unknown to check the plausibility of the candidates.
- Predict the mass spectrum for a given chemical structure.

Two different approaches have been tried: (i) *Rule-based* methods rely on fragmentation rules (either formulated from experts in textbooks or implicitly contained in fragmentation databases). (ii) *Combinatorial* approaches are based on the connectivities between the atoms and search for all possible fragments or fragmentation paths with a ranking of the results.

For both approaches, the availability of accurate mass measurements of the fragment ions leads to better results and is therefore very valuable.

55.4.1
Rule-Based Approaches

Much scientific efforts have been done in the past to find rules for the fragmentation reactions in EI-MS and later on also for MS/MS fragmentation from soft-ionization precursor ions; the results are condensed in comprehensive textbooks, for example, [75].

These reactions range from simple cleavages and dedicated rearrangements to almost statistically scattering of parts of the molecule and include unexpected wide-range sterical rearrangements. The full complexity of fragmentation rules has reserved this field to the MS experts.

Fragmentation reactions can be implemented in a computer program with benefit for the user: it provides expert knowledge and saves much time by handling logical and calculational issues.

Two prominent commercial software products are (i) Mass Frontier [76] from HighChem and (ii) MS Fragmenter [77] from Advanced Chemistry Development (ACD).

Ionization modes implemented in *Mass Frontier* are EI (nonbonded electron, π bond, σ bond), $[M+H]^+$, and $[M-H]^-$. Fragmentation rules contain alpha cleavage, inductive cleavage, and hydrogen rearrangements. Bond creation (except hydrogen bonds), ring contractions, cyclizations, and non-H-rearrangements are not included. All reactions consider charge localization and the even-electron rule. Only unimolecular reactions are allowed. The number of fragmentation steps can be selected.

The created fragmentations are only formally possible solutions; no checks for stability of ions, thermodynamics or kinetics are performed. The resulting fragmentation paths are presented in a style as chemists and mass spectrometrists are accustomed to seeing them in journals and books (Figure 55.8).

Mass Frontier assists chemists in the explanation of mass spectral peaks for a known structure or at the plausibility evaluation of structural candidates for a

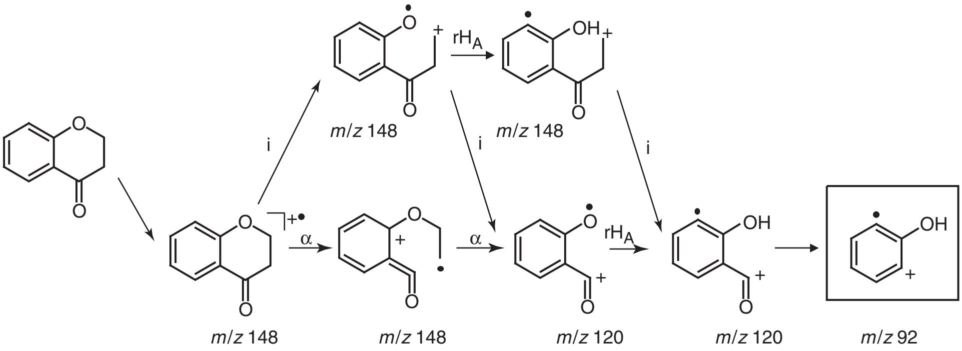

Figure 55.8 Possible fragmentation pathways for the formation of the ion *m*/*z* 92 from 4-chromanone, as evaluated by the software Mass Frontier.

mass spectrum of an unknown. Furthermore, a ''bar code'' mass spectrum without intensities can be predicted from a chemical structure.

Besides the above-introduced set of ''general fragmentation and rearrangement rules'' from textbooks, a database with 19 000 fragmentation reactions extracted from mass spectrometric literature can be used. As no restrictions exist for database fragmentations contrary to the ''general fragmentation and rearrangement rules,'' skeletal and individual rearrangements, ring closures and expansions, and other compound specific mechanisms can also be found in the results.

The *ACD/MS Fragmenter* offers possibilities similar to Mass Frontier, enabling fragmentations of molecules ionized by EI or by APCI or ESI protonation techniques. The number of consecutive fragmentation steps can be selected too. The set of fragmentation rules is partly different from Mass Frontier, for example, ring formations are possible. Other differences concern the logical structure of possible fragmentations and their nomenclature.

The fragmentation reactions predicted for a given chemical structure are represented by a fragmentation tree of ion masses. The corresponding ion structures can be displayed. For comparing mass spectra with structure candidates, an ''assignment quality index'' (AQI) can be calculated.

An important experience has to be noted for all rule-based systems: a small set of rules leads to less ambiguity of the explanations, however, to a not negligible number of unexplained peaks. For structure candidate evaluation, this results in a higher rejection rate of correct structures. Including more rules covering more fragmentations effectuates a higher explanation rate of peaks, but unfortunately also more false-positive candidates.

55.4.2
Combinatorial Approaches

Combinatorial search systems look for all substructures within a given molecule that match the fragment masses in a mass spectrum. The output of the substructures is ranked by varying criteria.

As these algorithms rely only on the connectivity of atoms in a molecule, the description of rearrangements is very limited. Mostly, only rearrangements of one hydrogen are enabled by varying the fragment mass by ±1 Da. Skeletal or steric long-range rearrangements can be hardly realized. Parts of the molecule that are not connected would have to be combined, which would cause a combinatorial explosion of solutions.

Combinatorial approaches have eminent advantages, if the rule base is deficient or does not exist in certain fields of structures and mass spectrometric methods. For the combinatorial explosion of possible fragments, a filtering by accurate mass data is very helpful and more necessary than for methods based on fragmentation rules.

Combinatorial search systems differ in the definition of the substructures, the bonds allowed to break, and the ranking criterion. A very early product was *MASSPEC* [78] working with nonbreakable ''superatoms'' (e.g., benzene ring) and minimizing the number of broken bonds as ranking criterion. New attempts are *EPIC* (differently penalizing broken bonds) [79], *FiD* (ranking by dissociation energies of broken bonds) [80], and the computationally fast *MetFrag* (combining dissociation energies and mass-weighted peak intensities as ranking criterion) [81]. *MassFragment* [82] is a mass spectrometer company's product based on systematic bond disconnection of the precursor structure, earning its power for CID mass spectra evaluation from high accurate mass measurements with switching collision energies.

A less sophisticated tool is *Mass Spec Calculator Pro* [83]. Possible fragment masses for a given molecule can be produced either by manual bond cleavage or by an automatic fragmentation routine. *MS Interpreter* is a software tool of NIST [84] that evaluates bond cleavages by estimating dissociation rates of the precursor ions.

55.5
Determination of the Element Composition

The molecular mass of a compound is determined by the molecular formula. Deriving the molecular formula from a molecular mass, however, is in general not unique because many possible elemental compositions exist for one given nominal mass.

Nevertheless, additional information about the elemental composition is available from (i) the ''accurate'' mass, (ii) the isotope peak pattern, (iii) fragment ions, and (iv) connectivity requirements.

55.5.1
Elemental Composition from Accurate Mass

The monoisotopic masses of elements (relative to carbon-12) show a small and nuclide-dependant difference to the corresponding integer value (Table 55.7). Therefore, the accurate mass of the monoisotopic ion of a molecule also differs from the nominal value by a characteristic increment or decrement.

This information of accurate mass measurements obtained by high-resolution mass spectrometers has been utilized for a very long time. Computer programs

Table 55.7 Accurate relative atom masses of selected nuclides.

Element	Mass	Element	Mass
^{1}H	1.007 825	^{28}Si	27.976 927
^{11}B	11.009 306	^{31}P	30.973 762
^{12}C	12.000 000	^{32}S	31.972 071
^{14}N	14.003 074	^{35}Cl	34.968 853
^{16}O	15.994 915	^{79}Br	78.918 338
^{19}F	18.998 403	—	—

have assisted the generation of possible candidates almost since the beginning, but this strategy was not applied in routine analysis because expensive double-focusing sector-field instruments (or the almost unaffordable FT-ICR mass spectrometers) were necessary to fulfill the accuracy and resolution requirements.

Nowadays, a variety of different high-resolution mass spectrometers is available: TOF instruments, Orbitraps, and FT-ICR in different configuration (with and without MS/MS or MS^n possibility). These instruments produce high to very high resolution data of excellent mass accuracy of both precursor and product ions. These mass spectrometers are still very expensive. However, analytical needs make them a routine instrumentation in some areas of profitable research such as proteomics, metabolite detection, and combinatorial synthesis, but also for regulatory and diagnostic issues in environmental, clinical, and food analysis.

For a given mass accuracy, the number of formula candidates increases with increasing molecular mass and with increasing number of elements allowed to be present. To reduce this ‘‘exploding’’ number, further constraints are helpful: valence considerations, heuristic experiences about element ratios, and the isotope pattern.

Valence constraints for possible molecular formula can be implemented in the form of the *LEWIS* rule (each compound has an even number of electrons and all atoms obey the octet rule) and the *SENIOR* theorem [(i) the sum of valences is an even number; (ii) the sum of valences is greater than or equal to twice the maximum valence; and (iii) the sum of valences is greater than or equal to twice the number of atoms minus 1] [85]. Only a few really existing compounds are undesirably discarded by these rules, for example, radical *N*-pyridinyloxy compounds, because they have an odd number of electrons.

LEWIS and SENIOR checks are preferred because RDBEs (ring and double bond equivalents) rules are too uncomfortable to handle formulae containing atoms of elements with different possible valence states (e.g., nitrogen, phosphorous, and sulfur). Further limits for naturally existing formulae (e.g., for element ratios) can be derived from structure databases of known compounds. This filter can be adapted to the area of research.

55.5.2
Mass Defect Plots and Mass Defect Filtering

Usual mass spectral bar plot representation would be very long and confusing for ultrahigh-resolution mass spectra from complex mixtures. A more appropriate arrangement is a ‘‘mass defect plot’’ of mass defects (to nearest integer mass value) versus mass. Within these plots, compound group membership can be visually detected, as molecular ions of similar compounds are arranged on lines (Figure 55.9). A special kind of this technique is the use of so-called Kendrick masses, which simplifies the peak pattern of hydrocarbon systems [86].

$$\text{Kendrick mass} = \text{IUPAC mass} \times \frac{14.00000}{14.01565} \tag{55.3}$$

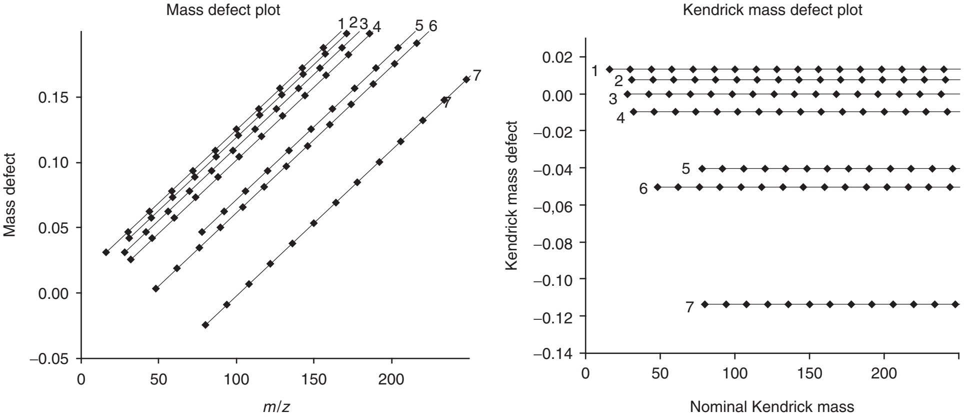

Figure 55.9 CH_2 homolog series are situated on lines in mass defect plots. The Kendrick mass defects for all members of a CH_2 homolog series is constant (1. alkanes, 2. amines, 3. alkenes, 4. aromatic compounds (with one benzene ring), 5. alcohols and ethers, 6. thiols and sulfides, and 7. disulfides).

14.015 65 is the accurate mass of CH_2 group, and IUPAC mass is the measured mass corresponding to $^{12}C = 12.000\,00$.

Mass defect filters can be used for metabolite screening, as the typical metabolizing reactions are connected each to a definite accurate mass shift [87].

55.5.3
Elemental Composition from Isotope Peak Pattern

Chemical elements may be either monoisotopic (e.g., fluorine and phosphorous) or polyisotopic (e.g., Table 55.8). Every mass spectral peak containing polyisotopic elements is accompanied by isotope signals with their natural occurring abundances.

If the formula shows more than one atom from one or from different polyisotopic element species, the observed isotope pattern obeys combinatorial rules. For

Table 55.8 Isotope pattern of selected polyisotopic elements.

A	%	A+1	%	A+2	%
^{12}C	100	^{13}C	1.1	—	—
^{14}N	100	^{15}N	0.37	—	—
^{16}O	100	^{17}O	0.04	^{18}O	0.20
^{28}Si	100	^{29}Si	5.1	^{30}Si	3.35
^{32}S	100	^{33}S	0.8	^{34}S	4.44
^{10}B	24.53	^{11}B	100	—	—
^{35}Cl	100	—	—	^{37}Cl	32.4
^{79}Br	100	—	—	^{81}Br	97.86

Table 55.9 The molecular isotope pattern of Cl_3Br is calculated by expansion of "$(a_0 + a_2)^3 \times (b_0 + b_2)$" derived from Eq. (57.4) and summation of all isobaric contributions using $a_0 = 1$ (^{35}Cl), $a_2 = 0.324$ (^{37}Cl), $b_0 = 1$ (^{79}Br), and $b_2 = 0.979$ (^{81}Br). The resulting isotope pattern is normalized to the most abundant peak.

m/z	Molecular species	Terms of isobaric contributions		Normalized pattern
184	$^{35}Cl_3{}^{79}Br$	$a_0{}^3b_0$	1.000	0.513
186	$^{35}Cl_2{}^{37}Cl^{79}Br$, $^{35}Cl_3{}^{81}Br$	$3a_0{}^2a_2b_0 + a_0{}^3b_2$	0.972 + 0.979	1.000
188	$^{35}Cl^{37}Cl_2{}^{79}Br$, $^{35}Cl_2{}^{37}Cl^{81}Br$	$3a_0a_2{}^2b_0 + 3a_0{}^2a_2b_2$	0.315 + 0.951	0.649
190	$^{37}Cl_3{}^{79}Br$, $^{35}Cl^{37}Cl_2{}^{81}Br$	$a_2{}^3b_0 + 3a_0a_2{}^2b_0$	0.034 + 0.308	0.175
192	$^{37}Cl_3{}^{81}Br$	$a_2{}^3b_2$	0.033	0.017

nominal mass resolution, calculation of the isotope pattern of a small compound with a molecular formula A_mB_n is mostly based on the expansion of the following product of polynomial expressions [88]:

$$(a_0 + a_1 + a_2 + \ldots)^m \cdot (b_0 + b_1 + b_2 + \ldots)^n \tag{55.4}$$

where $a_0, a_1, a_2, \ldots$ and $b_0, b_1, b_2, \ldots$ are the isotopic abundances of the elements A and B. The molecular isotope pattern of A_mB_n then results from adding all terms belonging to isobaric species, as shown for the simple molecule Cl_3Br (bromine trichloride) in Table 55.9.

It is more difficult to build a fast and accurate algorithm for very large compounds such as proteins [89].

The isotope pattern is a kind of information about elemental composition, which is available also on low-cost quadrupole benchtop mass spectrometers with unit mass resolution. This information is utilized in the visual interpretation of mass spectra to recognize elements with remarkable isotope pattern such as chlorine, bromine, or sulfur. There exist numerous software tools (many of them freely available for download or as web calculators), which calculate theoretic isotope patterns for comparison issues [90].

Computer programs have been developed for automatic recognition of specific isotopic patterns, often using variants of correlation coefficients as similarity measures [91]. "Chemometric" detectors (CMDs) have been created applying such algorithms to every mass spectrum of a GC-MS run. The results are selective signal traces for compounds containing selected elements, for example, chlorine or selenium [92].

55.5.4
Combined Algorithms for Element Composition

The discriminative power of algorithms calculating molecular formulae increases if mass accuracy and isotope pattern are concertedly applied. It has been shown

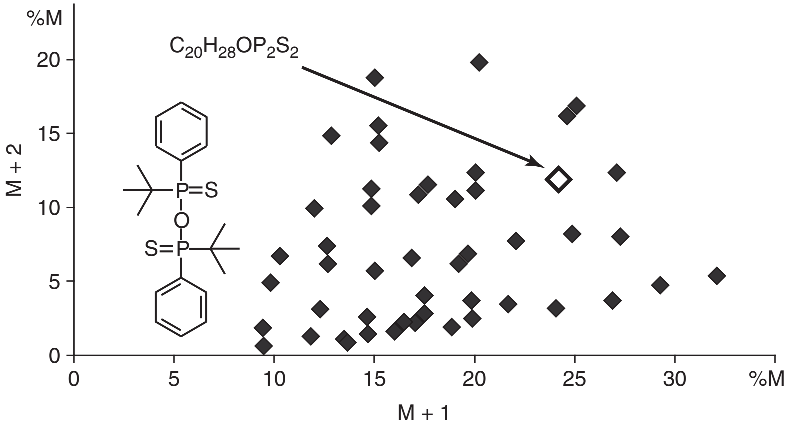

Figure 55.10 The relative isotopic abundances of the M + 1 and M + 2 ions (specified in percentage of the abundance of the monoisotopic molecular ion M) can be used to filter molecular formula candidates. Phenyl-t-butyl-thiophosphinic acid anhydride ($C_{20}H_{28}OP_2S_2$) has an accurate molecular mass of 410.10 568 Da. Forty-nine molecular formulae (C, H, O, N, S, P allowed) are possible within a ±5 ppm range. The correct formula can be found unambiguously by using isotopic abundances of M + 1 and M + 2.

that even 1 ppm mass accuracy (e.g., by Orbitrap or FT-ICR mass spectrometers) is not enough for achieving a moderate number of candidate formulae for molecular masses above 400 Da [93]. Better results are attainable by combining mass accuracy and isotope abundance (Figure 55.10).

For utilizing the full discriminating power of combined accurate mass and isotope pattern information, accurate masses of the M + 1 and M + 2 isotope peaks and their complete mass peak profile should be evaluated, as these peaks are composed of different ion species [94].

Additional information for further narrowing the solution space originates from MS/MS and MS^n experiments. A general rule is that all fragments must have elemental compositions that “fit” into a valid molecular formula. It depends strongly on the instrumental abilities (availability and mass accuracy of MS^1, MS^2, and MS^3 spectra, accuracy of isotope pattern of MS^1, resolution of precursor selection, etc.), which variant of the combined algorithms can be applied.

55.6
Deconvolution and Detection of Components

An important strength of MS is the possibility of being connected to a chromatographic instrument, especially a gas chromatograph or a liquid chromatograph. The resulting data of such hyphenated techniques are time series of mass spectra. Other types of time-resolved MS data are produced by pyrolysis MS and fractionated evaporation MS.

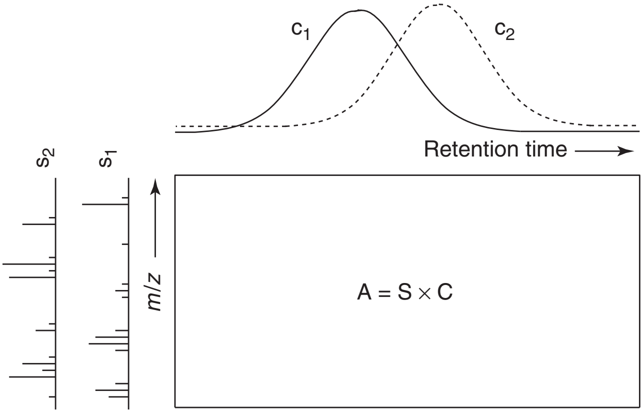

Figure 55.11 Time series of mass spectra form a data matrix A (time axis ×mass axis), which is mathematically a matrix product of the pure compound chromatogram traces (C) times the pure compound mass spectra (S).

Although resolution of chromatography is sometimes extremely high, overlap of chromatographic peaks cannot be excluded. In addition, noisy background from air and column bleeding in GC or from solvents and buffers in LC can hide small peaks from visual detection.

Therefore, computational methods that detect components of a mixture in a chromatogram, also at a high level of background noise and in cases of chromatographic peak overlap, are very valuable.

Time series of mass spectra form a data matrix (time axis × mass axis), which is a matrix product of the pure compound chromatogram traces times the pure compound mass spectra (Figure 55.11). The inverse procedure to this matrix multiplication is called *deconvolution* and should result in the component chromatograms and component mass spectra. Unfortunately, this inverse procedure has mathematically no unique result. Additional information is needed for a solution.

Additional knowledge or assumptions helpful to solve the problem can be ''pure regions'' in the chromatograms, ''unique ions'' representing only one component, knowledge of the typical chromatographic peak shape, number of components in the mixture, or common ''maximizing masses.'' Mass spectrometric time series of different origin need different deconvolution methods for optimal results; for example, components in chromatographic data usually show defined narrow peaks contrary to pyrolysis MS and direct evaporation MS.

55.6.1
GC–MS Deconvolution

The early introduced Biller and Biemann [95] procedure extracts all mass chromatograms that maximize simultaneously. This idea was later improved by considering the time shift between the measurement of high and low masses by scanning mass spectrometers [96].

The ''model peak method'' is a more sophisticated algorithm using also maxima of ion chromatograms to detect components [97]. One maximizing ion forming a ''sharp'' singlet peak is selected as model for the peak shape and those ion profiles that have similar shapes are extracted. Mass spectral intensities of the component are estimated from the extracted mass chromatograms after a local background correction. Components with peak maxima differing only 1.5–2 scan times can be detected and separated.

This very efficient and reliable method was selected for the widely used spectra extraction within the *AMDIS* (Automated Mass Spectral Deconvolution and Identification System) software [98]. Some improvements were made to also extract weak signals. The result of analyzing GC-MS data with AMDIS is a chromatogram with markers for detected mixture components (Figure 55.12). The extracted mass spectrum for each component can be displayed and subjected to library search – either with a built-in algorithm or with an external software.

AMDIS has been developed as a verification tool in the context of the chemical weapons convention. AMDIS is freely available from NIST and has proved to be a widely used and successful software, which can be considered as the present day standard in GC–MS component detection and extraction.

Fast MS of TOF instruments facilitates the deconvolution twofold: no time shift between masses occurs and the peak shape is almost perfectly represented because of the high acquisition rate of up to 500 mass spectra per second. Therefore, deconvolution of *GC-TOF-MS* data exhibits excellent results. Components can be

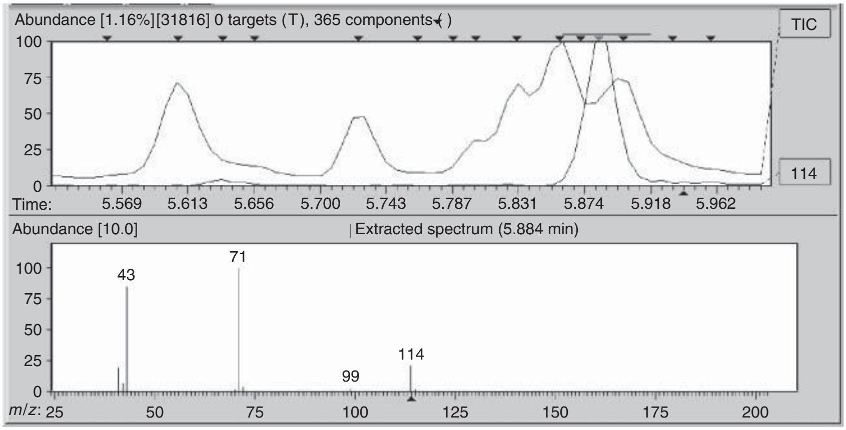

Figure 55.12 All components detected by AMDIS are marked in the GC–MS display as triangles above the chromatogram. Also, minor components can be detected within an overlap of several GC peaks. The extracted spectrum is displayed beneath and can be subjected to library search. The displayed chromatogram section stems from a headspace measurement of a hazelnut paste. The extracted mixture component was identified as one of two isomers: 4-heptanone or 2-methyl-3-hexanone.

detected for very small differences in retention time and small spectral differences of, for example, isomers.

55.6.2
LC–MS Deconvolution

Since LC–MS chromatograms are often dominated by a high level of background and noise, mixture component peaks are often hidden and cannot be visually detected in the total ion current chromatogram. ESI and APCI mass spectra show only one or a very small number of quasi-molecular ion species per component. Therefore, using common maximizing masses is less reasonable.

Two different strategies have been implemented in computer programs for LC–MS deconvolution: (i) considerations about distinguishing noise and meaningful data and (ii) mass spectrometric knowledge about related ion species.

An approach of the first type is *CODA* (component detection algorithm) [99] – the program code is freely available but is also implemented in commercial software. CODA calculates a ‘‘similarity index’’ between each mass chromatogram and its smoothed and mean-subtracted version. Thus, spikes and chemical noise from solvents are removed. Only mass chromatograms with low noise and low background are selected and combined to form a reduced total ion chromatogram.

The software *IntelliXtract* [100] is a more sophisticated LCMS component detector of the second type. After running a modified version of CODA, all ions of a distinct retention time are further analyzed, if they are logical contributors to a chemical component: isotope ions, adduct ions, and usual neutral losses. The real molecular mass is determined within this logical ion cluster and all identified adduct ions are annotated. Comparable strategies of grouping adduct masses, isotopic peaks, and sometimes also different charge states are part of metabolite identification software both of mass spectrometer suppliers and academic research teams.

55.6.3
Factor Analysis Methods

Matrix-based factor analysis approaches making no assumptions about maximizing masses and peak shapes are mainly used in pyrolysis MS and fractionated evaporation MS.

Finding correlations of ions with principal component analysis (PCA) or similar methods is often the first step, but this does not lead to pure component mass spectra [101]. ‘‘Rotation’’ of the factors is necessary – visually or automated. Target factor analysis, VARDIA (‘‘variance diagram’’), SIMPLISMA (‘‘simple-to-use interactive self-modeling mixture analysis’’) [102], and EFA (‘‘evolving factor analysis’’) [103] are examples of algorithmic efforts to solve this task.

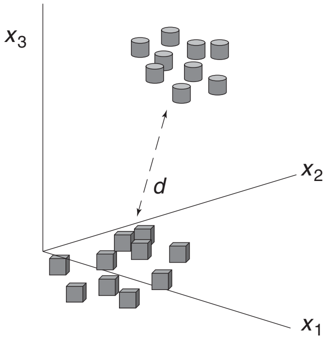

Figure 55.13 Each variable of a multivariate data sample represents a coordinate axis in a data space. Similar objects (samples) are situated close together. This is schematically demonstrated for two categories of samples using three variables.

55.7
Multivariate Data Analysis (MVDA) of Mass Spectra

Mass spectra are multivariate data samples, which means that there exist more than one measured variable for one sample. A multivariate data sample can be seen as a distinct point in a multidimensional data space, each variable representing a coordinate axis of this data space. This can be easily imagined and demonstrated for up to three variables (Figure 55.13). For higher dimensionality, imagination is difficult or impossible, but mathematical algorithms for treatment of such data are analogous to the three-dimensional world. A comprehensive treatment of multivariate data analysis (MVDA) methods in chemistry can be found in a newly published textbook [104].

55.7.1
Distance and Similarity

A basic assumption of MVDA is that similar objects (samples) are situated close together in multivariate data space. Therefore, distances between the samples can be seen as measures of ''dissimilarity.'' Different distance measures (with different properties) can be used, such as Euclidean distance, city-block distance, and Mahalonobis distance. The latter considers the covariance structure of the dataset thus scaling the influence of the different variables.

This distance–similarity concept is also the basis of library search algorithms already discussed in this contribution.

55.7.2
Dimensionality Reduction

There are different reasons for a dimensionality reduction of a high-dimensional data space: (i) Multivariate data often have a lower ''intrinsic'' dimensionality owing to correlations between the variables. (ii) Not all parts of multivariate data may be relevant for the intended data analysis. (iii) High-dimensional data space cannot be imagined well by the human mind.

Linear methods produce new ‘‘latent’’ variables that are linear combinations of the original ones. All significant latent variables can be used as a model for the original dataset or only one- to three-dimensional representative subspaces (lines, planes, 3D spaces) are extracted. In the latter case, two latent variables span a projection plane or a single variable serves for classification of samples.

Nonlinear methods distort the multivariate data space to get lower dimensional representations. Besides different nonlinear ‘‘classical’’ optimization methods, artificial neural networks are often used to deal with nonlinearities. Another new way to import nonlinearities are support-vector-machines (SVMs).

Advantages of linear methods are an easier judgment of the stability of the results and the possibility of estimating the influences of the original variables.

55.7.3
Mass Spectral Features

In principle, mass spectral peak intensities can be used directly as variables in multivariate data. However, structural similarity information is often not directly connected to intensities at distinct m/z values. Mass shifts of characteristic peaks can complicate the relationships between mass spectra and chemical structures.

Therefore, new variables (‘‘spectral features’’) are calculated by mathematical transformations of the original peak list data [105]. Spectral features are often normalized (e.g., to a constant sum) and calculation can be restricted to limited mass ranges. Selected examples of spectral feature calculations from peak intensities I_m are as follows:

- *Modulo-14 features* collect peak intensities of CH_2 homolog series and reflect compound classes ($k = 1$–14 and $n = 0, 1, 2, 3, \ldots$).

$$x_k = \sum_n I_{k+14n} \tag{55.5}$$

- *Autocorrelation features* emphasize periodicities, intense neutral losses, and mass differences (d = mass differences and $m = m/z$).

$$x_d = \sum_m I_m I_{m+d} \tag{55.6}$$

- *Logarithmic intensity ratios* reflect the fact that intensity ratios (especially of neighboring peaks) are more reproducible than absolute mass spectral peak intensities (d = mass differences and $m = m/z$).

$$x_{m,d} = \log\left(\frac{I_m}{I_{m+d}}\right) \tag{55.7}$$

55.7.4
Exploratory Data Analysis

If the used variables contain appropriate chemical (=structural) information, similar chemical compounds should lie close together and form "clusters." Exploratory data analysis tries to find such clusters.

Important methods for exploratory data analysis of mass spectra are mapping methods that extract relevant data to a two-dimensional plane enabling "visual cluster analysis." Linear exploratory methods are the PCA and partial least-squares ("PLS") substructure mapping.

55.7.4.1 Principal Component Analysis (PCA)

PCA produces orthogonal and uncorrelated "latent variables" exhibiting maximum variance [104]. Therefore, it is assumed that interesting information about data structure and similarities between "objects" (samples, spectra) is contained in the first principal components.

Two principal components span a projection plane, allowing visual cluster analysis. As the principal components are linear combinations of the original variables, the coefficients of these linear combinations (called *loadings*) characterize the importance of the original variables for the data structure. Figure 55.14 shows the PCA mapping of an ambiguous library search hitlist containing alkenes and cyclopropane compounds.

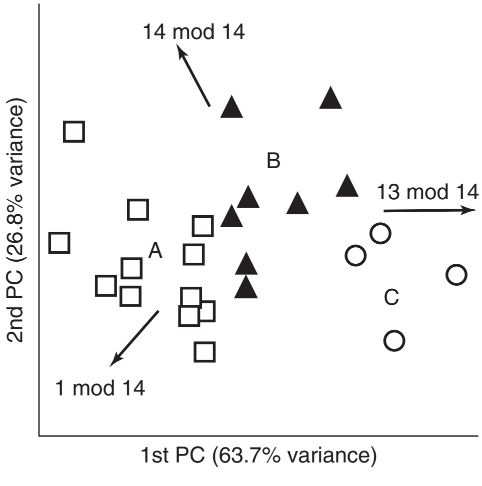

Figure 55.14 PCA mapping of alkenes and cyclopropane compounds using modulo-14 spectral features. Three groups of similar chemical structures ("structural similarity clusters") are observed: (A) 1- and 2-alkenes (squares) (B) cyclopropane compounds (black triangles), and (C) 4- and 5-alkenes (circles). Spectrum-structure relationships can be found by evaluating prominent "loadings" (shown by arrows). An intense peak m/z 43 (→1 mod 14) is characteristic for 1- and 2-alkenes, m/z 56 (→14 mod 14) for cyclopropane compounds, and m/z 55 and 41 (→13 mod 14) for 4- and 5-alkenes.

55.7.4.2 **PLS Substructure Mapping**

Contrary to PCA, the PLS substructure mapping looks not only at mass spectral variables but simultaneously at a set of binary variables describing the presence or absence of substructures in the compounds [106]. The projection plane is spanned by new variables maximizing the covariance between the mass spectral features and the binary structural descriptors. With this method, ''structural similarity clusters'' that are hidden by dominant mass spectral data can be found.

55.7.5
Mass Spectral Classifiers

A mass spectral classifier is a mathematical or logical rule for an assignment of a mass spectrum to a class of chemical compounds. The output of a classifier is a discriminant variable. If the value is above a defined limit, then the answer for class membership is ''yes.'' If the discriminant variable is less than this limit, then the answer is ''no.'' If the complete distribution of the discriminant variable has been estimated, then a probability of class membership can be given (Figure 55.15).

The performance of classifiers can be characterized by two parameters: reliability and recall. The reliability is the probability that the answer to the classifier is correct. It is usually calculated separately for ''yes'' and ''no.'' The recall for a compound class is the probability that a compound belonging to a compound class is actually detected by the classifier. For mass spectral screening procedures, a high recall may be important – all potential candidates for a class membership should be detected. On the other hand, substructure constraints for structure elucidation (e.g., for automatic isomer generation) need a very high reliability – one incorrect substructure constraint makes it impossible to generate the correct chemical

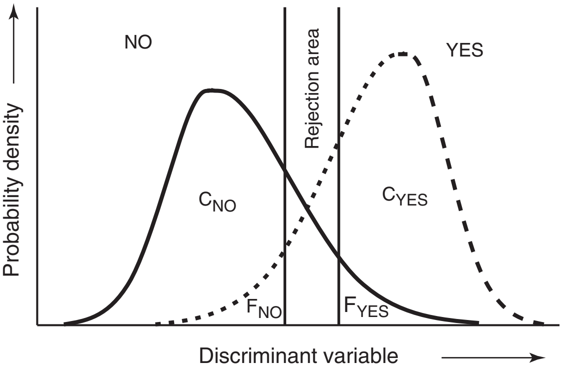

Figure 55.15 Probability densities for answers ''YES'' and ''NO'' (class membership). Selection of the classification limits (vertical lines) and the width of an optional ''rejection area'' influences (i) the probabilities, that a compound of a certain class is classified correctly (''recall'' C_{YES} and C_{NO}) or incorrectly (F_{YES} and F_{NO}), and (ii) the reliabilities $R_{YES} = C_{YES}/(C_{YES} + F_{YES})$ and $R_{NO} = C_{NO}/(C_{NO} + F_{NO})$.

structure. A rejection range can improve the reliability of classifiers, but decreases the recall.

Such classifiers can be built by different methods from multivariate statistics (linear discriminant analysis, PLS discriminant analysis), artificial neural networks, SVMs, and rule-based methods [104].

Chemical classes are often defined by substructures; therefore, classification of the presence or absence of substructures is of great interest for structure elucidation. For example, different types of substructure classifiers have been developed in the past [107]. Application of such classifiers to unknowns does not require a mass spectral database. Database spectra are, however, necessary for the ''training'' of the classifiers.

55.7.5.1 Chemometric Detectors for GC–MS

Mass spectral classifiers can be applied to each mass spectrum of a GC-MS analysis, resulting in selective traces for compound classes. Such CMDs have been developed for different substance categories, for example, for alkanes, PAHs, PCBs, and chlorinated phenols, allowing the fast screening of a complex chromatogram for the target compound class [108]. Figure 55.16 shows the results from a CMD for chloro- and nitrophenols.

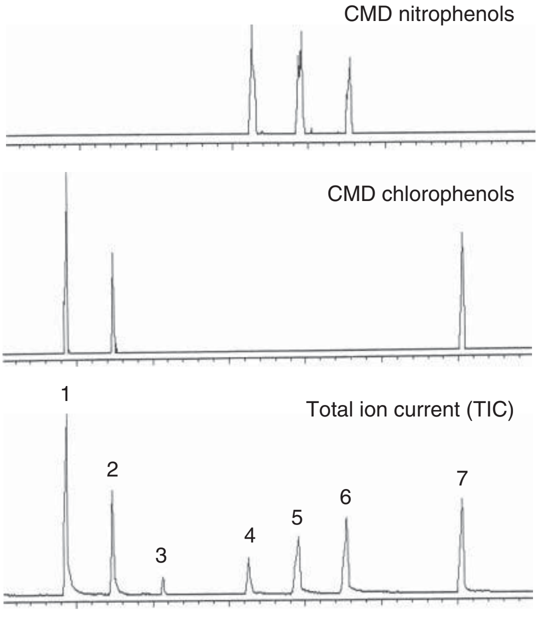

Figure 55.16 A chemometric detector (CMD) produces selective traces for compound categories by classifying every mass spectrum of a GC-MS analysis, as seen in this example of CMDs for nitrophenols and chlorophenols (1. 4-chloro-3-methylphenol, 2. 2,4,6-trichlorophenol, 3. *n*-tetradecane, 4. 2,4-dinitrophenol, 5. 4-nitrophenol, 6. 2-methyl-4,6-dinitrophenol, 7. pentachlorophenol).

55.7.5.2 **Hitlist Substructure Classifiers**

A special type of substructure classifiers is implemented in some library search systems (e.g., NIST, MassLib): the hitlist frequency of a substructure is a measure of the probability of this substructure to appear actually in the target. The relationships between hitlist frequency and probability have been estimated before by extensive ''training searches'' of a high number of known compounds used as unknowns.

A similar approach in the past has been realized in STIRS [63]. Different library search hitlists were produced by using different search criteria (''data classes''), reflecting different aspects of mass spectra – structure – relationships. The result is a list of substructures occurring in the hitlist and showing a high reliability.

55.7.5.3 **Mass Spectral Classifiers Supporting Automatic Structure Elucidation**

A new mass spectrometric approach based on the DENDRAL strategy for systematic structure elucidation [109] has been developed within the software MOLGEN-MS [110]:

1) A molecular formula hitlist is calculated from the combined isotope patterns of the molecular ion and all fragment ions.
2) The presence and absence of substructures (''goodlist'' and ''badlist'') are predicted by mass spectral classifiers.
3) An exhaustive set of isomeric molecular candidate structures obeying these constraints is generated by the mathematical isomer generator MOLGEN.
4) The candidate structures are then evaluated by prediction of the mass spectra and comparison with the measured mass spectrum.

56
Raman Spectroscopy Fundamentals

David Moore

This chapter presents the state of the art in Raman fundamentals including theory, laser sources, spectrometers, detectors, Raman microscopy (confocal and micro-Raman), Raman imaging, fiber optic probes, and methods to obtain depth profile information.

Next, the chapter discusses data treatment. Raman spectra should be calibrated both along the abscissa and the ordinate to be universally utilizable. The calibration of the abscissa (Raman shift) is presented using the ASTM-E-1840 (American Society for Testing and Materials) guide. Several methods to calibrate the ordinate (Raman intensity) are discussed. The issue of fluorescence interference will be considered from the perspectives of excitation wavelength selection and post-acquisition data reduction.

Finally, the chapter deals with the concept of Raman spectral databases. There are at present several such databases, including common data format libraries and proprietary libraries. However, such databases and libraries should ultimately satisfy stringent criteria for long-term data archiving, including readability for long times into the future, robustness to changes in computer hardware and operating systems, and use of public domain data formats. The latter criterion implies that the data format should be platform independent and the tools to create the data format should be easily and publicly obtainable or developable. Several examples of attempts at spectral libraries exist, such as the ASTM ANDI format (analytical data interchange), and the joint committee on atomic and molecular physical data exchange (JCAMP-DX) format. On the other hand, proprietary library spectra can be exchanged and manipulated using proprietary tools. As the above-mentioned examples have deficiencies according to the three long-term data archiving criteria, Extensible Markup Language (XML; a product of the World Wide Web Consortium (W3C), an independent standards body) as a new data interchange tool is being investigated and implemented. This chapter presents today's status of this effort.

Handbook of Spectroscopy, Second Edition. Edited by Günter Gauglitz and David S. Moore.

56.1
Theory

Raman scattering is one of a family of scattering processes involving interaction of a primary light quantum with atoms, molecules, or crystals by which a secondary light quantum is produced. Raman involves inelastic scattering, producing secondary light quanta of different energy from the primary light quanta. The energy difference is equal to the vibrational energy of a molecule or crystal and/or the rotational energy of a molecule, and thereby Raman scattering provides a means of measuring vibrational spectra, alternatively to infrared (IR) absorption spectroscopy. These two types of spectroscopy are illustrated schematically in Figure 56.1. If monochromatic radiation is used for the primary light quanta, recording the secondary quanta produces a Raman spectrum. Scattering from molecules or crystals in their ground rotational and/or vibrational states produces a Stokes, or redshifted, Raman spectrum. Scattering from excited vibrational and/or rotational states produces an anti-Stokes, or blueshifted, Raman spectrum. The relative intensity of the Raman lines in the Stokes and anti-Stokes Raman spectra may be used, via the Boltzmann equation, for the determination of the vibrational (or rotational) temperature [1–4].

An electric field incident on a molecule forces the electrons and nuclei to move in opposite directions. A dipole moment is induced, which is proportional to the electric field strength and the molecular polarizability. A molecular vibration described by the normal coordinate q_k can be observed in the Raman spectrum only if it modulates to first order the molecular polarizability. Molecular symmetries that fulfill this condition are allowed, or Raman active; otherwise forbidden, or Raman inactive.

IR absorption, on the other hand, involves direct resonance between the frequency of the IR radiation and the vibrational frequency of a particular mode of vibration, with the absorption strength proportional to the change in dipole moment with

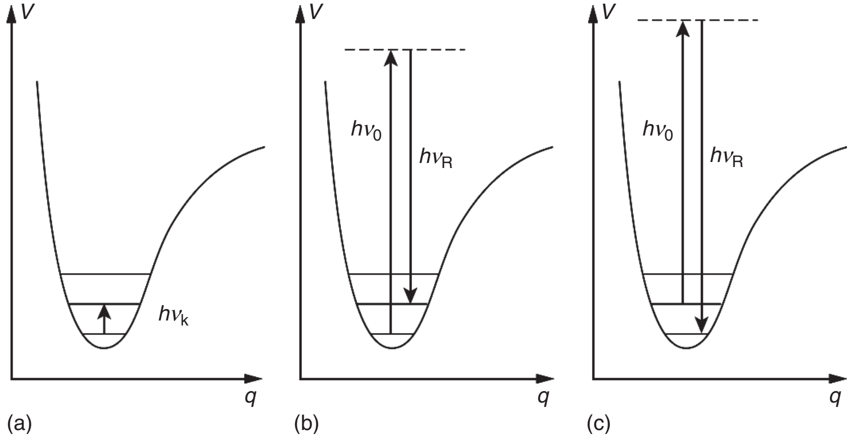

Figure 56.1 (a) Infrared absorption, (b) Stokes Raman scattering, and (c) anti-Stokes Raman scattering.

respect to the particular vibrational motion. The photon incident on the molecule, if it is absorbed, disappears, and leaves the molecule in an excited vibrational state. The molecular symmetries that modulate the dipole moment are IR active. Often, there are symmetries in a given molecule that are Raman active, but IR inactive and vice versa, making IR and Raman complementary vibrational spectroscopic methods. This attribute is illustrated in Figure 56.2 [5]. Figure 56.2 also illustrates the recommended spectrum presentation, that is, linear abscissa scale with increasing wavenumber from right to left for better comparison to standard IR spectra representation; linear ordinate scale increasing from bottom to top (whereas IR spectra are usually represented as percent transmission, increasing from bottom to top) [1].

A normal vibration is described by the normal coordinate q_k and the normal frequency ν_k

$$q_k = q_k^0 \cos(2\pi \nu_k t) \tag{56.1}$$

If a molecule is put into an alternating electric field of frequency ν_0, a dipole moment p with alternating polarity at the frequency ν_0 is induced. The components of the vector of the electric field according to a molecular fixed Cartesian coordinate system are described by E_x, E_y, and E_z. The *induced dipole moment* p_i can be described by its components:

$$\begin{aligned} p_x &= \alpha_{xx} E_x + \alpha_{xy} E_y + \alpha_{xz} E_z \\ p_y &= \alpha_{yx} E_x + \alpha_{yy} E_y + \alpha_{yz} E_z \\ p_z &= \alpha_{zx} E_x + \alpha_{zy} E_y + \alpha_{zz} E_z \end{aligned} \tag{56.2}$$

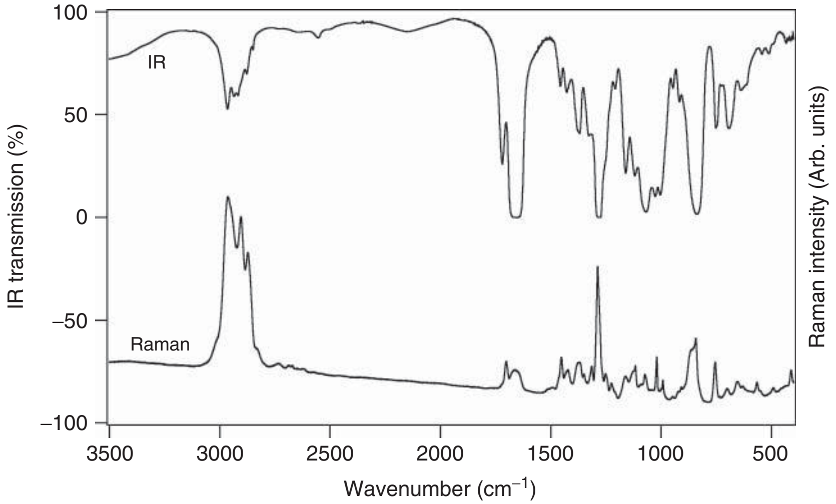

Figure 56.2 Raman and IR transmission spectra of nitrocellulose, illustrating their complementary nature. (From Ref. [5], used with permission.)

where α_{ij} are components of the *polarizability tensor* α:

$$\alpha = \begin{bmatrix} \alpha_{xx} & \alpha_{xy} & \alpha_{xz} \\ \alpha_{yx} & \alpha_{yy} & \alpha_{yz} \\ \alpha_{zx} & \alpha_{zy} & \alpha_{zz} \end{bmatrix}$$

which projects the electric field vector to produce the induced dipole moment vector. This can be written in matrix notation as

$$\mathbf{p} = \alpha \mathbf{E}$$

$$\alpha_k = \alpha_0 + \left[\frac{\partial \alpha}{\partial q_k}\right]_0 q_k^0 \cos 2\pi \upsilon_k t + \cdots \tag{56.3}$$

Equations (56.2) and (56.3) can be combined to give

$$p_k = \alpha_0 E_0 \cos(2\pi\nu_0 t) + \frac{1}{2}\left(\frac{\partial \alpha}{\partial q_k}\right)_0 q_k^0 E_0 \left\{\cos\left[2\pi\left(\nu_0 - \nu_k\right) t\right] + \cos[2\pi(\nu_0 + \nu_k)t]\right\} \tag{56.4}$$

This oscillating *Hertzian dipole* $|\mathbf{p}_k|$ produces electromagnetic radiation. The first term in Eq. (56.4) describes Rayleigh scattering, the second term *Stokes Raman scattering*, and the third *anti-Stokes Raman scattering*. This classical equation, however, does not show the individual intensities of *Stokes* and *anti-Stokes Raman lines*.

Placzek's theory (1934) describes the Raman effect quantitatively on the condition that the exciting frequency differs considerably from the frequencies of electronic as well as of vibrational transitions.

In order to describe the intensity of the Raman lines of liquids or gases, the parameters α'_k and γ'_k are used. They stand for the isotropic and the anisotropic parts of the polarizability change during a normal vibration ν_k, respectively, and are given by (in order to simplify these equations, the subscript k has been omitted):

$$\alpha' = \frac{1}{3}[\alpha'_{xx} + \alpha'_{yy} + \alpha'_{zz}] \tag{56.5}$$

$$\gamma'^2 = \frac{1}{2}\left[\left(\alpha'_{xx} - \alpha'_{yy}\right)^2 + \left(\alpha'_{yy} - \alpha'_{zz}\right)^2 + \left(\alpha'_{zz} - \alpha'_{xx}\right)^2 + 6\left(\alpha'^2_{xy} + \alpha'^2_{xz} + \alpha'^2_{zy}\right)^2\right] \tag{56.6}$$

The terms $\alpha'_{ij} = \left[\frac{\partial \alpha_{ij}}{\partial q}\right]_0$ are the components of the *tensor of the polarizability change* resulting from a normal vibration q.

The polarizability has the dimension $\mathrm{J^{-1}\,C^2\,m^2}$. In older literature, the polarizability has been described as a volume, in analogy with the molecular volume ($1\,\text{Å}^3 = 10{-}24\,\mathrm{cm}^3$). The *polarizability volume* results when the polarizability given in SI units is divided by $4\pi\varepsilon_0$ (in $\mathrm{J^{-1}\,C^2\,m^{-1}}$). The normal coordinates are mass weighted and have the dimension cm $\mathrm{g}^{1/2}$.

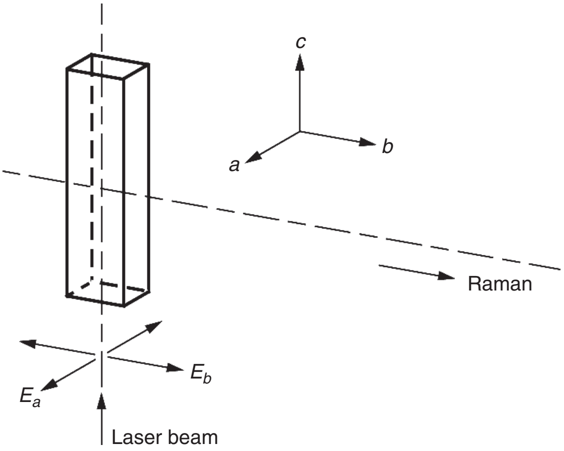

Figure 56.3 Orientation of the electric vector of the exciting laser beam to the Raman observation direction.

Referring to Figure 56.3, when the Raman spectrum of a liquid or a gas is measured by irradiating along the *c*-axis with linearly polarized radiation whose electric vector is oriented in the *a* direction and the Raman spectrum is observed along the *b* axis, then the *c* and *b* axes define the *plane of observation*.

The *integral Raman scattering coefficient* (the *absolute differential Raman scattering cross section* $(\mathrm{d}\sigma/\mathrm{d}\Omega)$ in $\mathrm{cm}^2\,\mathrm{sr}^{-1}$) of the Stokes line (shifted to lower energies) of the *k*th Raman-active vibration of wavenumber, $\tilde{\nu}$ (symbol defined in Ref. [6]), with the electric vector of the exciting radiation oriented perpendicular to the plane of observation, is given by

$$\left(\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega}\right)^{-}_{k\perp} = \frac{\pi^2}{45\varepsilon_0^2}\cdot\frac{b_k^2(\tilde{\nu}_0-\tilde{\nu}_k)^4}{1-\exp(-hc\tilde{\nu}_k/kT)}\cdot g_k(45\alpha_k'^2+7\gamma_k'^2) \tag{56.7}$$

where σ is the scattering cross section, Ω is the solid angle, and g_k is the *degeneracy* of this vibration and the superscript $^-$ indicates Stokes Raman scattering. The expression

$$g_k(45\alpha_k'^2+7\gamma_k'^2) \tag{56.8}$$

is known as the *scattering activity*, and

$$b_k^2 = h/8\pi^2 c\tilde{\nu}_k \tag{56.9}$$

is the square of the *zero point amplitude* of the vibration. Equation (56.7) may be simplified:

$$\left(\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega}\right)^{-}_{k\perp} = \frac{h}{2^3 c\varepsilon_0^2}\cdot\frac{(\tilde{\nu}_0-\tilde{\nu}_k)^4}{\tilde{\nu}_k[1-\exp(-hc\tilde{\nu}_k/kT)]}\cdot g_k\left(\alpha_k'^2+\frac{7}{45}\gamma_k'^2\right) \tag{56.10}$$

This equation is valid for observation without a polarization analyzer. Equations valid for the other polarization conditions and a discussion of depolarization ratio measurements can be found in Refs. [1–3].

The differential Raman scattering cross section is proportional to the fourth power of the emitted frequency, the ν^4 *factor*. Dividing Eq. (56.7) by $(\nu_{\text{ref}} - \nu_k)^4$, gives the *absolute normalized Raman scattering cross section* (Eq. (56.11)) of a Raman line with frequency shift ν_k [3].

$$\left(\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega}\right)^{-}_{k\perp} \cdot (\tilde{\nu}_{\text{ref}} - \tilde{\nu}_k)^{-4} = \frac{h}{2^3 c\nu\varepsilon_0^2} \cdot \frac{g_k}{\tilde{\nu}_k[1 - \exp(-hc\tilde{\nu}_k/kT)]} \cdot \left(\alpha_k'^2 + \frac{7}{45}\gamma_k'^2\right) \tag{56.11}$$

where ν_{ref} is the *reference excitation wavenumber* (Ref. [4]). The right-hand side of Eq. (56.11) represents the microscopic parameters of the sample and has been tabulated for a number of gases and liquids and for several ν_{ref} in Ref. [4]. According to Placzek's theory, this expression should be independent of the frequency of the exciting radiation in the absence of a resonance or a near-resonance Raman effect. The term on the left-hand side normalizes the observed Raman intensity by including the ν^4 factor.

The radiant power of the observed radiation is proportional to the absolute normalized Raman scattering cross section, that is, to the ν^4 factor and to the *number of molecules per unit volume N*. The *Raman scattering coefficient* s_{R} of this line is thus:

$$s_{\text{R}} = \left(\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega}\right)^{-}_{k\perp} \cdot (\tilde{\nu}_{\text{ref}} - \tilde{\nu}_k)^{-4}(\tilde{\nu}_0 - \tilde{\nu}_k)^4 N L_{\text{n}} \tag{56.12}$$

where L_{n} is the internal field factor:

$$L_{\text{n}} = \left(\frac{n_{\text{R}}}{n_0}\right)(n_{\text{R}}^2 + 2)^2 \frac{(n_0^2 + 2)^2}{3^4} \tag{56.13}$$

and n_0 and n_{R} are the refractive indices of the scattering medium at the wavelength of the exciting and the Raman radiation, respectively, which takes into account the increase of the incident and scattered electric field due to the dielectric nature of the scattering medium.

The *radiance of a Raman line* L_{R} (scattered power per unit solid angle per unit area of sample integrated over the Raman line in question) is proportional to the radiant power of the exciting radiation divided by the cross-sectional beam area r^2 π and multiplied by the Raman scattering coefficient:

$$L_{\text{R}} = \frac{\Phi_0}{r^2\pi} d s_{\text{R}} \tag{56.14}$$

where *d* is the *sample thickness* of the observed sample and *r* is the beam radius.

56.2
Qualitative Analysis

Schrader [3] has provided an excellent compilation of typical characteristic vibrational frequencies and Raman and IR intensities for organic compounds. The complete listing is found in his Table 4.1-1. A similar table is available as a PDF download from Horiba Jobin-Yvon [7]. A recent book by Socrates [8] provides an extensive collection of characteristic frequencies. These characteristic frequencies can be divided into typical regions as follows. The X–H stretching vibrations are located in the highest frequency region, between 3700 and 2500 cm^{-1}. The O–H vibrations are weak in the Raman spectrum, so that water is a weak Raman scatterer (making Raman an excellent probe of aqueous samples, in contrast to IR). Most C–H and S–H vibrations are strong (with the exception of acetylenic hydrogens), and N–H medium. The next region, between 2500 and 2000 cm^{-1}, contains stretching vibrations of groups with triple bonds as well as the antisymmetric stretching vibrations of groups with cumulated double bonds, X=Y=Z. The following region, between 2000 and 1500 cm^{-1}, exhibits stretching vibrations of double bonded X=Y groups. X–H deformation vibrations are observed between 1500 and 1000 cm^{-1}. The region between 1300 and 600 cm^{-1} shows stretching vibrations of single bonds of atoms of the second period. The next region contains bending vibrations of these groups and stretching vibrations of groups with heavier atoms. Finally, the region between 200 and 20 cm^{-1} is characterized by lattice vibrations of crystalline molecular materials. Some examples of often-utilized characteristic spectral features are the C=O stretching vibrations (usually strong in the Raman) between 1820 and 1680 cm^{-1} and the C–(NO_2) stretches, with the antisymmetric stretch between 1530 and 1590 cm^{-1} (medium to weak) and the symmetric stretch between 1340 and 1380 cm^{-1} (very strong).

56.3
Experimental Details

The most convenient monochromatic light source for excitation of Raman spectra is the laser. The currently preferred excitation sources are solid-state lasers and their harmonics, or specialty lasers for specific wavelength regions. The most common excitation laser is a 785 nm diode laser, with Si-based charge-coupled device (CCD) for detection. However, the long wavelength responsivity cutoff of Si-based detectors only allows collecting the Raman spectrum with any efficiency to $\sim$2500 cm^{-1}. Figure 56.4 shows efficiency curves of a typical Si-based CCD detector for three different excitation wavelengths, illustrating the restriction on how far into the near-infrared (NIR) the excitation laser can be pushed. Fourier transform Raman instruments using 1064 nm neodymium-doped yttrium aluminum garnet (Nd:YAG) lasers and cooled semiconductor detectors have allowed fluorescence reduction by moving further into the NIR [9]. Other harmonics of solid-state Nd:YAG (or variants) lasers allow excitation at 532, 355, 266, and 212.8 nm. A large number of compact portable Raman spectrometers have appeared recently from commercial suppliers, which allows taking Raman on the road [10]. Deep UV excitation has recently become easier using efficient transversely excited hollow cathode lasers [11].

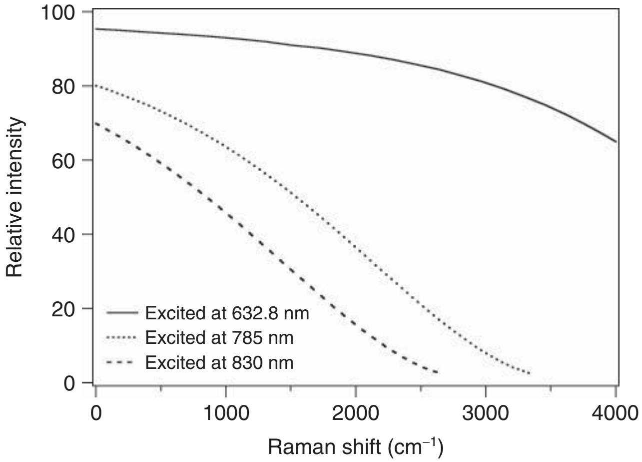

Figure 56.4 Relative Raman intensity of typical Si-based CCD detectors for three different excitation wavelengths, based on a quantum efficiency versus wavelength curve for a thinned, backside-illuminated, visible antireflection coated CCD. (From Ref. [10], used with permission.)

56.3.1
Fluorescence Interference

The principal detriment to Raman spectroscopy is fluorescence, either native to the analyte or from background, matrix, or interferent materials. Several methods have been developed to reduce the effects of fluorescence. Most utilize far-red or NIR excitation sources because of the assumption that there are fewer molecules with strong absorption and fluorescence when excited in the red or NIR. However, such a choice extracts a severe signal penalty because of the ν^4 factor, for example, the ratio of signal strength (all other things being equal) for 785 nm versus 514.5 nm excitation is 0.18. In addition, not all fluorescence is eliminated. Fourier transform Raman was developed to enable excitation with the Nd:YAG fundamental at 1064 nm, reducing fluorescence as well as decomposition issues for biological samples [9].

Another choice is to use UV excitation, with the aim of exciting at energies high enough that most of the vibrational Raman spectrum occurs at wavelengths shorter than fluorescence from the majority of organic molecular species (typically >250 nm). For example, for excitation at 224.3 nm (transversely excited hollow cathode laser) [11], the Stokes Raman spectrum from 0 to 4000 cm^{-1} ends at 246.4 nm, much before the onset of most fluorescence. Second, the ν^4 factor increases the scattering coefficient by a factor of ~25 over that at 532 nm. Finally, a large fraction of molecules have electronic potential energy surfaces near 5 eV above the ground state, resulting in large resonance enhancements of the Raman cross section (up to factors of 10^8). This combination makes deep UV Raman very attractive especially for detection of small amounts of material or micro-Raman imaging. On the other hand, a large fraction of molecules react photochemically when excited in the deep UV, so that the Raman process is no longer generally noninvasive.

Other fluorescence interference removal schemes have been developed, including correlation of spectra obtained using two or more alternating, closely spaced, excitation wavelengths (the two-wavelength version is commonly called *shift excitation Raman difference spectroscopy* or SERDS [12]), time gating methods, which take advantage of the near instantaneous response of Raman scattering and the longer lifetimes of fluorescence [13, 14], and various forms of filtering, such as Fourier-domain filtering and edge detection algorithms [15].

56.3.2
Imaging

Raman microscopy can be performed using point-by-point, linescan, or imaging methods. All methods inject the excitation laser into the microscope via reflection from a dichroic or notch filter and focusing of the excitation light onto the sample and gathering of the Raman scattering using the microscope objective. The Raman scattering then passes through the dichroic or notch filter to be dispersed and detected. For creation of Raman images, the point-by-point method utilizes a programmable sample stage synchronized with the detection electronics so that complete spectra are obtained at each sample voxel, giving at the end a hyperspectral image from which various display options can be explored via software (i.e., concentration maps, species maps, spectra at any spatial location, etc.). If high-axial spatial resolution is needed, a confocal microscope can be used.

Linescan images can be obtained by dithering the laser spot (using a vibrating mirror) and recording the Raman spectrum at each point along the line by image transfer onto the spectrometer slit. Then the complete image only requires coordinated sample stage movement in one (2D image) or two (3D image) orthogonal directions.

Another concept for obtaining Raman images is to illuminate the entire microscope field of view using a defocused laser source, then record CCD images through a tunable filter (acousto-optic or liquid crystal variations have been used), building up the data hypercube by consecutive spectral bands. A confocal version and coordinated z-axis sample movement allows building up a volume spectral hypercube layer by layer.

56.3.3
Fiber Optic Probes

Finally, remote applications of Raman have been accomplished using various optical fiber coupled probes. In most cases, the Raman signals produced through transit of the excitation laser through long distances of optical fiber are removed using a dichroic filter built into the probe housing, and the excitation laser elastically scattered (or reflected) from the sample is removed via a notch or dichroic filter

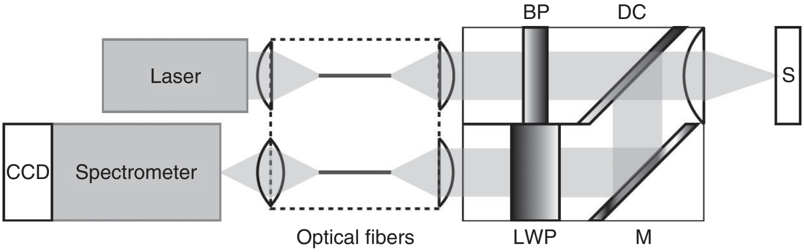

Figure 56.5 The essential elements of a portable Raman system, with optical fiber coupling shown in the dashed block: CCD charge-coupled device detector, BP, bandpass filter; DC, dichroic filter; LWP, long wavelength pass filter; M, mirror; and S, sample.

before the collected Raman light is focused into the return fiber (or fibers). This concept is illustrated schematically in Figure 56.5. The optical conductance trade-offs necessary for optical fiber couple probe Raman are discussed in Ref. [10]. More recently, stand-off Raman has been demonstrated for distances of many tens of meters using pulsed laser excitation and large aperture telescopes to collect the scattered light [16–18].

56.4
Raman Data Treatment and Calibration

Figure 56.6 illustrates schematically the present situation for Raman data calibration in the worldwide Raman spectroscopy community, and presents some of the terminology used.

Figure 56.7 shows three Raman spectra of polystyrene obtained using three different compact Raman systems. The spectra in Figure 56.7 and the concepts

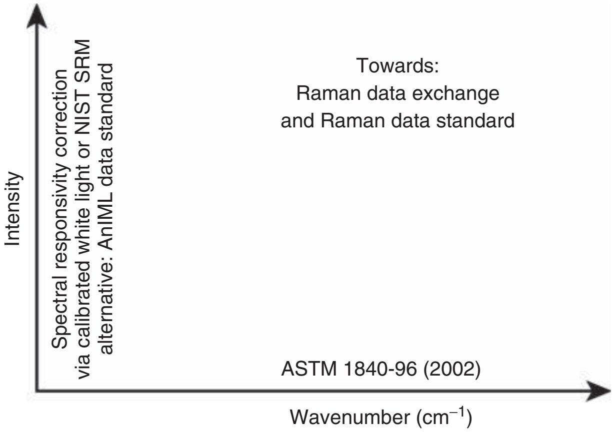

Figure 56.6 Present status of Raman data standard as well as abscissa and ordinate calibrations.

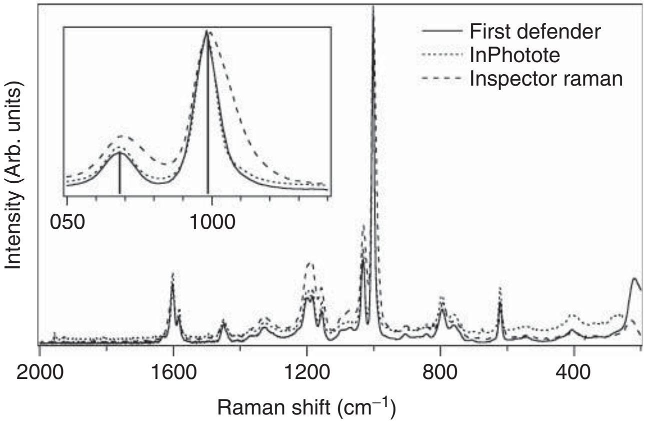

Figure 56.7 Raman spectra of polystyrene obtained using (solid line) First Defender (Ahura Scientific), (dotted line) InPhotote (Inphotonics, Inc.), and (dashed line) Inspector Raman (DeltaNu, LLC). The solid vertical lines in the inset are at the ASTM-E-1840 calibrated wavenumbers and relative intensities.

in Figure 56.6 will be used in the discussion in subsequent text to illustrate the various facets of Raman data calibration.

In order to enable the most accurate comparison of Raman spectra obtained from various instruments, abscissa (wavenumber axis) calibration must be performed, and some method of accounting for the system spectral responsivity should be used to correct the ordinate. For abscissa calibration, the ASTM-E-1840 guide recommends several means [19]. [Note: despite the ASTM guide usage of the term *Raman shift* for the abscissa, it is not a recognized physical quantity [6], and the term *wavenumber* (or *Raman wavenumber*) should instead be used with the unit cm^{-1} [6].] The ASTM utilized a round-robin methodology to determine the peak wavenumbers for eight different readily available materials having no known polymorphs, selected to cover a wide wavenumber range (85–3327 cm^{-1}) for both solids and liquids. The standard error for the peaks is usually <1.0 cm^{-1}. Often, Raman instruments have some kind of calibration routines built in, which involve measurement of the excitation laser wavelength and calibration of the detector pixel versus wavelength using an atomic line source. The results of this type of calibration should be verified using at least one of the approved ASTM-E-1840 guide materials before reporting abscissa wavenumbers for any Raman spectral features.

The spectra in Figure 56.7 were abscissa calibrated according to each instrument vendor's instructions or routines. The inset shows the recommended polystyrene wavenumber values as vertical lines. Two of the instruments produced spectra with calibrations better than 0.4 cm^{-1} compared to ASTM-E-1840, and one was right at $\sim$1 cm^{-1}, the standard error for the ASTM recommendations.

One abscissa parameter not considered by the ASTM-E-1840, which has less to do with wavenumber calibration than with the ultimate ability of library search algorithms to identify materials, is the instrumental spectral resolution. The spectra in Figure 56.7 show that two of the instruments have very similar resolution

($\sim$5 cm^{-1}) but one has much less ($\sim$8 cm^{-1}). The ASTM-E-1840 recommends peak wavenumbers, but some search routines are also influenced by line widths, so that library spectra obtained with instruments of different spectral resolution could result in identification errors.

Correction of ordinate data is more problematic. The ν^4 factor causes changes in Raman signal strength with excitation wavelength. In addition, electronic preresonance and resonance effects can cause changes in the relative intensities of various Raman features depending on their associated chromophore. For a given selected excitation wavelength, however, the ordinate correction process is straightforward. The detected Raman intensities should be multiplied by a relative spectral responsivity correction curve obtained for the entire optical train from sample to detector. Two methods are available to measure the spectral responsivity curve. One is using a calibrated white light irradiance source. More recently, NIST has developed three certified luminous optical glasses (for different excitation wavelengths, 785, 532, and 488/514.5 nm) that emit a broad luminescence spectrum when illuminated with the Raman excitation laser [20]. To perform the correction, either the white light irradiance or the glass luminescence is recorded using the Raman system. Then the spectral irradiance value curve or the relative spectral luminescence curve (I_{SRM}) is used to obtain the spectral intensity correction curve C_{SRM} by dividing I_{SRM} by the spectrum measured by the Raman instrument S_{SRM}. The relative-intensity-corrected Raman spectrum is then obtained by multiplying the measured Raman spectrum by C_{SRM}.

Note the ordinate differences shown in Figure 56.7 for the polystyrene Raman spectrum obtained using three different portable Raman systems, which is indicative of the kinds of ordinate calibration problems that can occur. At low wavenumbers, one of the spectra has too high a baseline compared to the other two. In the middle wavenumber region, another of the instruments produces peaks that are too large compared to the other two, relative to the largest peak at 1001.4 cm^{-1}. The inset shows the relative intensities of two features near 1000 cm^{-1}, for which spectra from two instruments match very well, but the spectrum from the third instrument (the same one that has lower spectral resolution) is quite different. These differences apparently occur because of inadequate (or lack of) ordinate spectral responsivity correction, and could affect library search outcomes (see subsequent text).

56.5
Raman Spectral Databases

There are a number of Raman spectral databases available [21]. For example, Raman spectra for a large number of minerals are available at the Caltech/University of Arizona RRUFF™ Project Web site (allows download of spectra in American Standard Code for Information Interchange (ASCII) text pairs) [22]. Raman spectra of natural and synthetic pigments are available at the University College London Web site [23]. The University of Siena has a Raman database (graphical spectra with listing of selected peaks) for minerals and inorganic materials [24]. A searchable database of molecular spectra (from NMR to IR and Raman) of organic compounds is available from the Advanced Industrial Science and Technology (AIST) in Japan [25]. Some commercial enterprises offer online Raman database searching, such as the Fourier transform infrared spectroscopy (FTIR)/Raman search.com from Thermo Fisher Scientific. It uses the GRAMS/AI methodology and Thermo Scientific spectral databases [26]. In addition, a number of instrument manufacturers offer extensive proprietary Raman spectral databases.

Nevertheless, these databases do not satisfy the stringent criteria for long-term data archiving, which include readability for long times into the future, robustness to changes in computer hardware and operating systems, and use of public domain data formats. The latter criterion implies that data formats should be platform independent and the tools to create the data forms should be easily and publicly obtainable or developable. In the United States, there is regulatory pressure to archive ‘‘accurate and complete’’ copies of electronic records provided to government agencies ((Food and Drug Administration) FDA 21 CFR 11 (Code of Federal Regulations): data formats).

To date, none of the available Raman spectral databases abide by all long-term data archiving criteria, yet there has been some progress. Some open source spectral library formats have been developed. The ASTM E01.25 Subcommittee on Laboratory Analytical Data Interchange Protocols and Information Management develops ANDI protocols to increase laboratory efficiency and productivity by facilitating the integration and use of data from multiple vendors’ instruments. The International Union of Pure and Applied Chemistry (IUPAC) developed the JCAMP-DX data format for spectroscopic data [27]. JCAMP is completely ASCII based for simple transport and readability, and utilizes a fixed dictionary of tags, but suffers from numerical accuracy (translation of binary to decimal). Galactic developed the SPC data format primarily for optical spectroscopy, and has made its structure available in the public domain [28]. The ANDI and SPC protocols suffer from not being human readable. None of the three are easily validated for formatting and content nor extensible for future changes in equipment and analysis methods.

56.6
Database Searching

For identification of unknowns, many Raman practitioners perform some sort of search of the spectrum obtained for the unknown against a library of spectra, with the hit quality index (HQI) being the measurement of the likelihood of identity. The searches utilize a variety of algorithms, from full spectrum methods such as simple Euclidean distance (essentially a normalized dot product of the unknown spectrum with a library spectrum, with HQI as given in one embodiment in Eq. (56.15):

$$\mathrm{HQI} = \sqrt{2}\left[1 - \frac{(\mathrm{Lib}\cdot\mathrm{Unkn})}{\sqrt{(\mathrm{Lib}\cdot\mathrm{Lib})}\sqrt{(\mathrm{Unkn}\cdot\mathrm{Unkn})}}\right] \qquad (56.15)$$

where Lib is the library entry being searched and Unkn is the unknown spectrum; best match gives HQI = 0; no match gives HQI = 1.414), correlation (similar to Euclidean distance, but with both library and unknown spectra centered about their respective means, which makes the HQI independent of the spectral normalization, as given in one embodiment in Eq. (56.16):

$$\mathrm{HQI} = 1 - \frac{(\mathrm{Lib_m} \cdot \mathrm{Unkn_m})^2}{(\mathrm{Lib_m} \cdot \mathrm{Lib_m})(\mathrm{Unkn_m} \cdot \mathrm{Unkn_m})} \tag{56.16}$$

where $\mathrm{Lib_m} = \mathrm{Lib} - \sum_{i=1}^{n} \mathrm{Lib}_i/n$ and similarly for $\mathrm{Unkn_m}$; best match gives HQI = 0; no match gives HQI = 1), to first derivative correlation (FDC, correlation of first derivatives of both unknown and library spectra, which helps remove nonlinear effects of baselines that cannot be removed by baseline preprocessing) [29]. Denton *et al.* [21] found that the first derivative absolute value algorithm produced the best HQI when searching an unknown spectrum against an arbitrary Raman spectral library obtained with a different Raman system. This algorithm has the advantage of removing most of the error from a slowly varying baseline in the unknown, especially when the baseline is not linear (similar to the FDC algorithm). It also appears to be relatively insensitive to spectral resolution effects. Other algorithms used include peak matching, absolute value, and least squares.

An example of the use of these library search routines is given in Figure 56.8, for an unknown spectrum taken from a small amount (1.5%) of TATB (triamino trinitrobenzene) in soil, and searching a spectral library of about 100 different explosives.

Using the correlation algorithm, automatic baseline correction, and involving the entire spectrum (rather than several distinct regions) in the search, the best HQI for the Figure 56.8 sample spectrum was obtained for TATB (0.738), followed by DAAZF (diaminoazofurazan, 0.818) and HNS (hexanitrostilbene, 0.825), and a number of other materials with HQI above 0.84. The library search identified the correct material, but an HQI of 0.738 does not instill a great deal of confidence. In fact, the "HQI" does not provide any absolute measure of the probability that the sample actually is the same as the library sample. The arbitrary scale of the HQI values does not provide a good statistical measure of the similarity of the spectra. This occurs because using only a single training spectrum to represent all possible samples in the future does not give any statistical assurance that the unknown and library spectra are truly the same or different. It only provides a relative measure for all the library samples. Nevertheless, useful criteria for confidence in the identification (for systems where the best HQI is 0 and the worst 1.0) are HQI between 0 and 0.2 indicates a close match, 0.2–0.5 a suggestive match, and above 0.5 one should "be careful" [30]. (For algorithms with other HQI ranges, the criteria are within 20% of the best HQI is a close match, 20–50% a suggestive match, and >50% one should be careful.)

Alternatively, Raman databases and unknown spectra can be analyzed using multivariate analysis or chemometrics methods. These are particularly valuable when a large number of very similar spectra from complex mixtures, such as from

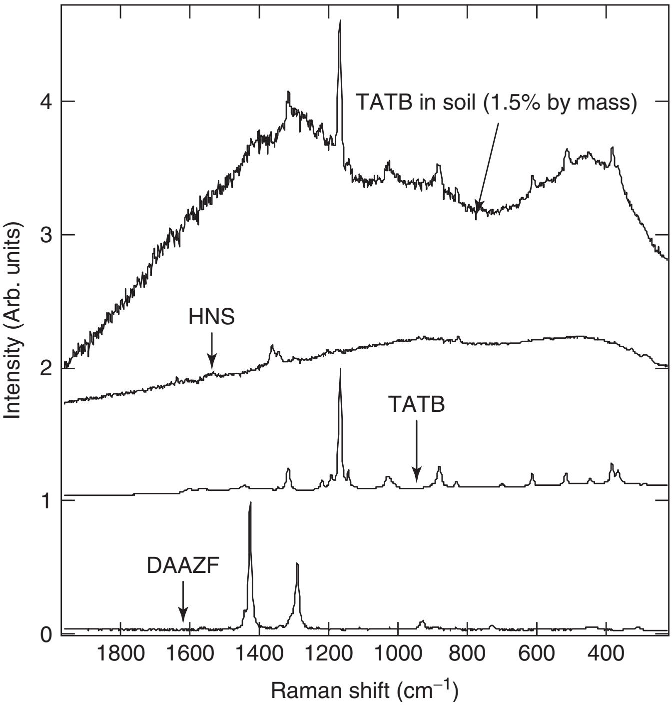

Figure 56.8 Raman spectrum of 1.5% TATB (triamino trinitrobenzene) in Bandelier Tuff soil, with library spectra of the three best matches (not plotted in order – see text) using the correlation algorithm and baseline correction.

biological samples, need to be categorized or the salient important characteristic features identified. This subject is handled in depth in Chapter 27: Principles of Vibrational Spectroscopic Methods and their Application to Bioanalysis.

56.7
Extensible Markup Language (XML) Data Model

XML is not a file format, but rather a universal markup language for exchanging structured documents and data on the Web with its own vocabulary and syntax, constrained by the recently adopted XML Schema Definition (XSD) language. It can be used to represent any data structure. The XML model provides the ability to link to other documents, called *XML Schema*, that describe exactly what each piece of data means and how it is related via XML language descriptions of a particular type of information and its storage. With the appropriate Schema, a software application can parse data from any XML data structure as well as determine that it is well formed. Therefore, XML documents can be externally validated for both content and syntax. XML data is human readable ASCII text, and the XML standard is public domain managed by the W3C.

The latest implemented version of this idea is embodied in the Analytical Information Markup Language, AnIML, *http://animl.sourceforge.net/* [31]. The project is a collaborative effort between many groups and individuals and is sanctioned by the ASTM under subcommittee E13.15. A variety of techniques have Definition Documents, which apply tight constraints to the flexible core and are in turn defined by the Technique Schema. The Open Source development is hosted on SourceForge. As of this writing, there is a Technique Definition Document for IR and UV–visible spectroscopic data, as well as sample parameters, but not yet for Raman spectroscopic data.
